An example of polarity determination and its application is the study of the growth mechanism of ZnO nanowires.[66] During ZnO growth, asymmetric side growth is often observed with one side showing finger-like structures and the other side tip-like structures. The difference was attributed to the surface termination; whether it is Zn- or O-terminated. To check this hypothesis, CBED electron diffraction was used to determine the wire polarity. The experimental diffraction pattern was first recorded from the wire (Figure 16). The orientation relationship between the wire direction and CBED was calibrated. The $\pm(0002)$ disks are asymmetric reflecting the lack of center of symmetry. To index the experimental diffraction, a Bloch simulation of the CBED pattern is performed for different thicknesses and compared with the experimental pattern. A best match is obtained (Figure 16). The determination was unique because of the complex intensity distribution in CBED and its sensitivity to the thickness.

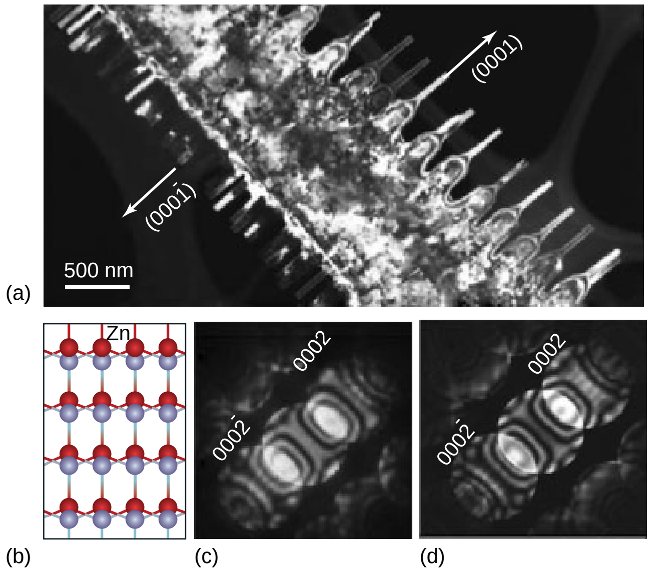

Figure 16 An example of polarity determination and application in the study of the growth mechanism of ZnO nanowires

3.8 Accurate Lattice Parameter Measurement and Strain Mapping

Measuring d-spacings from conventional spot diffraction patterns requires the calibration of the camera constant; the measurement accuracy is limited by errors in the calibration and the location of diffraction peak positions. An alternative is to measure lattice parameters from the HOLZ line positions. The advantages of using HOLZ lines are the high accuracy and high sensitivity to changes in lattice parameters. They have the advantage that (i) calibration is not required; the measurement relies on the relative positions of HOLZ lines, (ii) high order reflections are used in the measurement, which are sensitive to changes in lattice parameters, (iii) only the transmitted beam is used which is least affected by the lens distortion in the microscope. The strain is measured by fitting the position of HOLZ lines. There are two methods for fitting HOLZ lines; one is based on the kinematic approximation, in which HOLZ lines are approximated by straight lines.[67] The second is based on dynamic diffraction simulation. The fitting in this case is achieved by using pattern matching between the experimental and the simulated diffraction patterns.[68] Kinematic fitting is fast and involves several tasks, including measuring the experimental lines from the recorded CBED pattern, indexing the experimental lines and finally carrying out the fitting. These tasks are achieved through the following automated functions: (i) preprocessing of diffraction patterns for line detection; (ii) line detection using the Hough transformation; (iii) indexing the HOLZ lines; (iv) defining the fitting parameters; and (v) performing the fitting.

The most accurate measurement comes from dynamic fitting, which takes account of EMS effects. Using the Si crystal as a test, Kim *et al.* measured the Si lattice parameter at different orientations and sample positions. Their standard deviation is 0.0012 Å, which corresponds to 0.02% of the Si lattice parameter. The error bar of kinematic fitting includes a systematic error due to the neglect of the dynamic scattering. This error can be reduced by using the ‘‘so-called’’ kinematic orientations,[69,70] such as the [430] and [230] zone axes in Si.[71]

The spatial resolution depends on several factors: the electron probe size, the probe broadening in the sample due to diffraction, the beam direction relative to the strain axes. Theoretical consideration based on the column approximation suggests that the resolution in the zone-axis orientation can be as small as a few nanometers.[72] In the case of a thick sample, the resolution is limited by the probe broadening.[73]

3.9 Nanostructure Determination—the Case of Carbon Nanotubes

Nanostructure determination is a challenge in materials characterization. Many inorganic nanostructures lack the uniformity and symmetry of a single crystal or the monodispersity of some organic molecules. Their structure determination thus requires a high-resolution probe that can examine individual nanostructures. Electron diffraction has the resolution required; the nanoprobes used in CBED and NED are especially suited for studying nanomaterials. For structures like single-wall CNT, the structure can be determined directly from electron diffraction patterns.

A single-wall nanotube (SWNT) can be regarded as a single layer of graphite that has been rolled up into a cylindrical structure. In general, the tube is helical with the chiral vector (n, m) defined by $\vec{c} = n\vec{a} + m\vec{b}$, where $\vec{c}$ is the circumference of the tube, and $\vec{a}$ and $\vec{b}$ are the unit vectors of the graphite sheet. A striking feature is that tubes with $n - m = 3l$ (l is an integer) are metallic, while others are semiconductive. This unusual property, plus the apparent stability, has made CNTs an attractive material for constructing nanoscale electronic devices. As-grown SWNTs have a dispersion of chirality and diameters. Hence, a critical issue in CNT applications is the determination of the individual tube structure and its correlation to the properties of the tube. This requires a structural probe that can be applied to individual nanotubes.

Gao *et al.* have developed a quantitative structure determination technique of SWNT using NED.[74,75] This, coupled with improved electron diffraction pattern quality using NED, allows a determination of both the diameter and chiral angle, and thus the chiral vector (n, m), from individual SWNTs. The CNT they studied were grown by chemical vapor deposition (CVD). TEM observation was carried out in a JEOL2010F TEM with a high voltage of 200 keV.

Figure 17 shows the diffraction pattern from a SWNT. The main features of this pattern are as follows: (i) a relatively strong equatorial oscillation which is perpendicular to the tube direction; (ii) some very weak diffraction lines

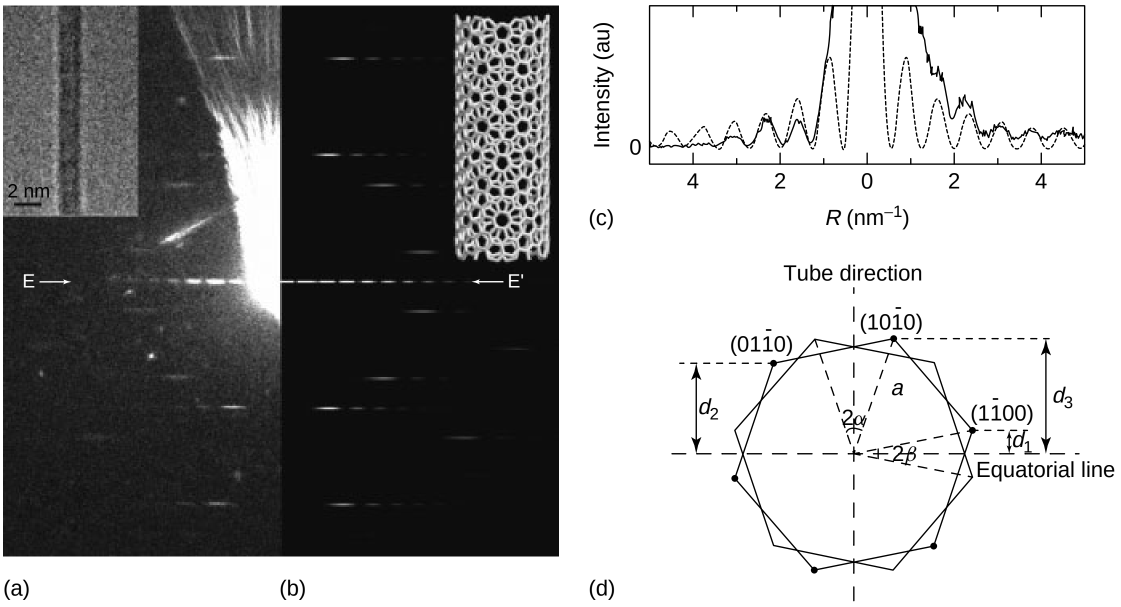

Figure 17 (a) A diffraction pattern from an individual SWNT of 1.4 nm in diameter. The inset is a TEM image. The radial scattering around the saturated (000) is an artifact from aperture scattering. (b) A simulated diffraction pattern of a (14,6) tube. The inset is the corresponding structure model. (c) Profiles of equatorial oscillation along EE′ from (a) and simulation for (14,6). d) A schematic diagram of electron diffraction from an individual SWNT. The two hexagons represent the first order graphite-like {100} diffraction spots from the top and bottom of the tube

from the graphite sheet, which are elongated in the direction normal to the tube direction.

The diameter of the tube is determined from the equatorial oscillation, while the chiral angle is determined by measuring the distances from the diffraction lines to the equatorial line. The details are as follows. The diffraction of SWNT is well described by kinematic diffraction theory (Section 3). The equatorial oscillation in the Fourier transformation of a helical structure like SWNT is a Bessel function with $n = 0$[76] which gives:

$$I_0(X) \propto J_0^2(X) \propto \left| \int_0^{2\pi} \cos^{X \cos \Omega} d\Omega \right|^2 \qquad (21)$$

Here $X = 2\pi R r_0 = \pi R D_0$, R is the reciprocal vector, which can be measured from the diffraction pattern, and D_0 is the diameter of the SWNT. We use the position of $J_0^2(X)$ maxima $(X_n, n = 0, 1, 2, \ldots)$ to determine the tube diameter. With the first several maxima saturated and unaccessible, X_n/X_{n-1} can be used to determine the number N for each maximum in the equatorial oscillation. Thus, by comparing the experimental equatorial oscillation with values of X_n, the tube diameter can be uniquely determined.

To measure chirality from the diffraction pattern, Figure 17 is considered, which shows the geometry of the SWNT diffraction pattern based on the diffraction of the top-bottom graphite sheets. The distances d_1, d_2, d_3 relate to the chiral angle α by[74]:

$$d_1 + d_2 = d_3,$$
$$\alpha = \operatorname{atan}\left(\frac{1}{\sqrt{3}} \cdot \frac{d_2 - d_1}{d_3}\right) = \operatorname{atan}\left(\frac{1}{\sqrt{3}} \cdot \frac{2d_2 - d_3}{d_3}\right) \qquad (22)$$

These relationships are not affected by the tilting angle of the tube (see below). Because d_2 and d_3 correspond to the diffraction lines having relatively strong intensities and are further from the equatorial line, they are used in our study instead of d_1 to reduce the error. The distances can be measured precisely from the digitized patterns. The errors are estimated to be $<1\%$ for the diameter determination and $<0.2°$ for the chiral angle.

Using the above methods, the SWNT giving the diffraction pattern shown in Figure 17 was determined to have a diameter of 1.40 nm (±0.02 nm) and a chiral angle of 16.9° (±0.2°). Among the possible chiral vectors, the best match is (20,6), which has a diameter and chiral angle of 1.39 nm and 17.0°, respectively. The closest alternative is (21,6), having a diameter of 1.46 nm and chiral angle of 16.1°, which is well beyond the experimental error. Figure 17(b) plots the simulated diffraction pattern of (20,6) SWNT from the structure model shown in the inset. Figure 17(c) compares the equatorial intensities of experiment and simulation. These results show excellent agreement.

The principles described are equally applicable for double-wall and multiwall nanotubes. For details, see Ref. 77 and 78.

3.10 Structure Factor Measurement and Charge Distribution

A major application of quantitative electron diffraction is the accurate determination of crystal charge density. The question here is how atoms bond to form crystals. This can be approached by accurate measurement of crystal structure factors (Fourier transform of charge density) and from these, electron distributions in crystals can be mapped. The full description is beyond the scope of this article. Here the results on the study of charge density in Cu_2O are summarized with an emphasis on the significance.

Cu_2O has a cubic structure with no free internal parameters (only Ag_2O is isostructural). The copper atoms are at the points of a face-centered cubic lattice with oxygen atoms in tetrahedral sites at (1/4,1/4,1/4) and (3/4,3/4,3/4) of the cubic cell. The resulting arrangement of Cu–O links is made up of two interpenetrating networks. The simplest description of Cu_2O using an ionic model with closed-shell Cu^+ and O^{2-} ions is known to be inadequate. It fails to explain the observed linear two-coordination of Cu.

Accurate measurements of the low-order structure factors were made with the quantitative CBED technique described in Section 4. Using the small electron probe, a region of perfect crystal was selected for study. The measurements are made by comparing experimental intensity profiles across CBED disks (rocking curves) with calculations, as illustrated in Figure 18. The intensity was calculated using the Bloch wave method, with structure factors, absorption coefficients, the beam direction, and thickness treated as refinable parameters. Structure factors for the (531) and higher-order reflections out to (14,4,2) were taken from X-ray measurements. Weak (ooe) (with o for odd and e for even) and very weak (eeo) reflections were also taken from X-ray work.[79]

There are two approaches to map crystal charge density from the measured structure factors; by inverse Fourier transform or by the multipole method.[80] Direct Fourier transformation of experimental structure factors was not useful due to the missing reflections in the collected data set, so a multipole refinement was used to map the charge density from the measured structure factors. In the multipole method, the crystal charge density is expanded as a sum of nonspherical pseudo-atomic densities. These consist of a spherical-atom (or -ion) charge density obtained from multi-configuration Dirac–Fock (MCDF) calculations[81] with variable orbital occupation factors to allow for charge transfer, and a small nonspherical part in which local symmetry-adapted spherical harmonic functions were used, which is expressed by:

$$\rho^a(r) = \rho^s(r) + \sum_{lm} P_{lm\pm} N_{lm\pm} R_l(r) y_{lm\pm}(\theta, \phi) \qquad (23)$$

here $\rho^s_{cu} = \rho^s_{Cu^+} + (1-q)(\rho^s_{Cu} - \rho^s_{Cu^+})$ and $\rho^s_O = \rho^s_O + q(\rho^s_{O^{2-}} - \rho^s_O)$ with q as the charge transfer from Cu to O; $R_l(r) = r^{n_l}\exp(-\alpha r)(n_3 = 3; n_4 = 4)$ is the radial

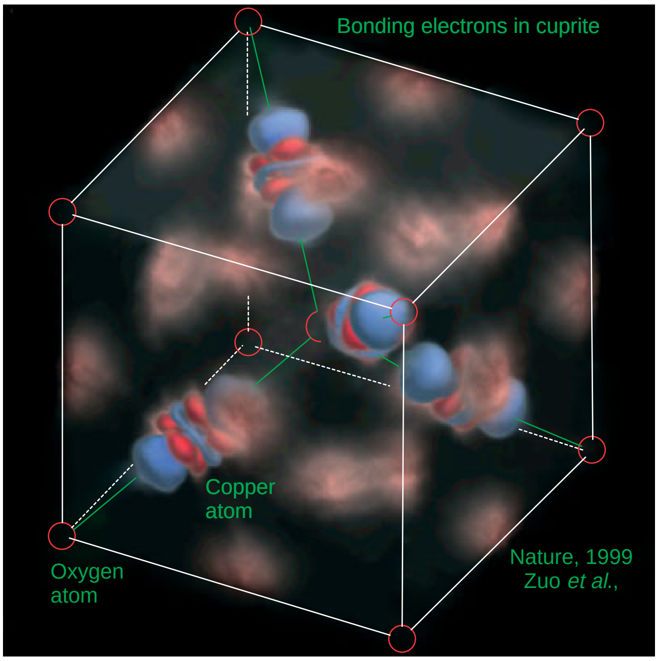

Figure 18 A 3-D rendering that reveals the details of chemical bonding and d_z^2 orbital-like holes in Cu_2O. The amount of charge redistribution is very small and its detection requires a high degree of experimental accuracy. In this picture, the small charge differences between the measured crystal charge density derived from CBED and that derived from superimposed spherical O^{2-} and Cu^+ ions are shown. The red and blue colors represent excess electrons and holes, respectively

function with population coefficient $P_{lm\pm}$; $N_{lm\pm}$ is the density-normalization coefficient. In addition atomic vibrations were accounted for using the Charlier–Gram expansion for the temperature factor. Refinements with and without anharmonic terms in the temperature factor clearly show the importance of an anharmonic term for Cu, especially for high order reflections with $s = \sin\theta/\lambda > 1.0$ (Å^{-1}). In either case the charge transfer from Cu to O is refined to 1.01(5) (i.e., Cu^+ and O^{2-}).

Figure 18 shows a three-dimensional plot of the difference between the static crystal charge density obtained from the multipole fitting to experiment, and superimposed spherical O^{2-} and Cu^+ ions calculated by the MCDF method. The O^{2-} ion was calculated using a Watson sphere of 1.2 Å radius. The electron density difference shown in Figure 18 would be zero everywhere if cuprite were purely ionic (i.e., consisted of spherical ions). The difference, here seen unambiguously for the first time, confirms earlier theoretical speculation[82] that a covalent contribution exists. The correspondence between our *experimental* map and the classical diagrams of d_z^2 orbitals sketched in textbooks is striking. All our difference maps show strong nonspherical charge distortion around the copper atoms, with the characteristic shape of d orbitals, and excess charge in the interstitial region. There is little variation around oxygen

in both the experimental and the theoretical results, which suggests that an O^{2-} anion description is valid. The most significant difference between experiment and theory is around Cu, and the charge in the interstitial region. The charge modification around Cu in the experiment is broader and larger than the theory. The experimental map also shows a large ($\sim$0.2e/Å^3) positive peak in the unoccupied tetrahedral interstitial region of the four neighboring Cu atoms, which suggests strong Cu^+-Cu^+ covalent bonding.

The nonspherical charge density around Cu+ can be interpreted as due to the hybridization of d electrons with higher-energy unoccupied s and p states. Among these states, hybridization is only allowed for d_z^2 and 4s by symmetry, and when this happens part of the d_z^2 state becomes unoccupied (''d hole''). These states are responsible for the spatial distribution of the deficiency in the map shown in Figure 18. The complementary empty states are important for electron energy loss spectroscopy (EELS) (*see* ***High Resolution Electron Energy-Loss Spectroscopy***) which probes empty states. The experimental studies reveal that the unoccupied states are predominately Cu-d character for the Cu $L_{2,3}$ edge; theory shows that they originate from hybridized d_z^2 orbitals. This theoretical interpretation, based on the calculated partial density of states (DOS) of the one-electron band structure, is supported by the generally good agreement with experimental spectroscopy of both occupied and unoccupied states.[83,84] From the charge density, we estimate the hybridization coefficient between d_z^2 and 4s, $|x| \sim 0.36$, so that about 0.22 electrons are removed from d_z^2 states.

4 ACKNOWLEDGEMENT

The author thanks DOE BES (DEFG02-01ER45923 and DEFG02-91ER45439) and NSF DMR Career 0449790, which provided several examples here, for supporting his research. The author also thanks Dr. Jing Tao for use of the examples of CuO and $LaCaMnO_3$, which came from her Ph.D. research and Prof. Spence for use of a part of his annotated book and web list for electron diffraction.

5 ABBREVIATIONS AND ACRONYMS

CBIM = convergent-beam imaging; CBED = convergent-beam electron diffraction; CCD = crystal charge density; CL = camera length; CNT = carbon nanotubes; CO = charge ordering; CTF = contrast transfer function; CVD = chemical vapor deposition; DC = diffraction compared; DQE = detector quantum efficiency; EELS = electron energy loss spectroscopy; EMS = electron multiple scattering; EXAFS = extended X-ray absorption fine structures; FEG = field emission guns; FEM = fluctuation electron microscopy; GHW = gaussian half width; GIF = gatan imaging filter; G−M = gjonnes and moodie; GOF = goodness of fit; HEED = high-energy electron diffraction; HOLZs = high order laue zones; HREM = high-resolution electron microscopy; HV = high-vacuum; IPs = imaging plates; LACBED = large-angle convergent-beam electron diffraction; LCMO = $La_{0.50}Ca_{0.50}MnO_3$; LEED = low-energy electron diffraction; MCDF = multi-configuration dirac−fock; NED = nanoarea electron diffraction; PARODI = parallel recording of dark-field images; RDF = radial distribution function; RHEED = reflection high-energy electron diffraction; RT = room temperature; SAED = selected area electron diffraction; SRs = superlattice reflections; STEM = scanning transmission electron microscopy; SWNT = single-wall nanotube; TED = transmission electron diffraction; TEM = transmission electron microscopes; THEED = transmission high-energy electron diffraction; ZOLZ = zero order laue zone.

METHOD SUMMARY

Acronyms, Synonyms

- High-resolution Electron Energy-Loss Spectroscopy
- Electron Energy-Loss Spectroscopy.

Measured physical quantities

- the number of counts (intensity) as a function of the energy loss of inelastically backscattered low-energy electrons.

Information available

- the vibrational modes, and the corresponding energies, of species at the interface: substrate, physisorbed adsorbate, chemisorbed adsorbate, adsorbate−adsorbate interactions.

Information not available, limitations

- The properties are not related to the vibrational modes of the interfacial species.

Examples of questions that can be answered

- What molecular species are present on the surface?
- What is the mode of bonding between the adsorbate and the substrate?
- How does the surface chemical bond influence the vibrational properties of the adsorbate?
- What is the surface coverage of the adsorbed species?

Major advantages

- extremely sensitive; limit of detection is ca .0.01% of a monolayer
- broad spectral range; typically, 50 (6.2 meV) to 4000 cm^{-1} (496 meV)

- impact-scattering mechanism not restricted by selection rules; in combination with dipole scattering, all vibrational modes may be discernible
- nondestructive.

Major disadvantages

- an ex situ method requiring an ultrahigh vacuum environment
- comparatively low resolution: typically, $30\,cm^{-1}$ (3.7 meV); at best, $4\,cm^{-1}$ (0.5 meV)
- backscattering may be inhibited by cationic species.

Sample constraints

- The sample surface must be conductive and relatively smooth.

1 INTRODUCTION

A vast amount is now known, at the atomic level, about heterogeneous processes at gas–solid interfaces. Yet, three decades ago, research in solid surface science was mired in traditional thermodynamic and kinetic experiments that were not able to yield molecular level information. Fundamental issues, such as the molecular structure and chemical composition of the surface complex, could not be adequately addressed by the data generated from the classical methods. It was not until the development of highly surface-specific empirical tools that tangible gains in the study of the gas–solid interface were achieved.

The main difficulty in surface characterization lies in the exceedingly low population of surface atoms (10^{15} atoms cm^{-2}) relative to that of bulk species (10^{23} atoms cm^{-3}). Experiments intended to examine the physical and chemical properties of surfaces must employ techniques that interact only with the outermost layers. For example, standard structural tools such as (nongrazing incidence) X-ray diffraction are not applicable to single-crystal surfaces since X rays penetrate deeply into the material and yield information on the bulk rather than the surface.

The majority of interfacial characterization techniques take advantage of the unique surface sensitivity of low-energy electrons. Such surface specificity arises because the mean free path of an electron through a solid is dependent upon its kinetic energy.[1,2] In particular, an electron whose kinetic energy is between 10 and 500 eV can traverse no more than 2 nm within the solid. Hence, the ''interrogation'' of low-energy electrons emergent from a sample will bear information that is specific only to the surface.

A solid subjected to a beam of electrons of primary (incident) energy E_p gives rise to backscattered (primary) and emitted (secondary) electrons. The energy distribution of these electrons can be divided into four regions based upon the origin of the scattered electrons. These regions correspond to the following: (i) True secondary electrons, are created from multiple inelastic interactions between the incident and bound electrons; these electrons give rise to an intense broad band at the lower end of the spectrum. (ii) Auger electrons which, along with primary electrons inelastically scattered by surface electronic states, are responsible for the small peaks in the medium-energy range. (iii) Primary electrons, which are inelastically scattered upon interactions with surface vibrational states; peaks associated with these electrons reside close to the elastic peak as their energy losses are comparatively small. (iv) Primary electrons, which are scattered elastically; such electrons, comprise only a small percent of the total incident electrons, and they generate the elastic peak at E_p. Regions (ii) to (iv) of the energy spectrum have been exploited in modern surface-structural and interfacial-elemental analysis. The elastic peak, for example, is used in diffraction experiments. The peaks in Region (iii) form the basis of high-resolution electron energy-loss spectroscopy (HREELS).

2 TECHNICAL BACKGROUND

2.1 Energy-Loss Mechanisms

Almost all of the electrons incident at a solid surface undergo inelastic events that cause them to be backscattered at energies lower than their initial or primary energy E_p. If E_l is the energy lost to the surface, peaks would appear in the spectrum at energies $\Delta E = E_p - E_l$. Such peaks, commonly referred to as energy-loss peaks, originate from core-level ionizations, valence-level excitations, plasmon losses, or vibrational excitations.[1,2] Since $E_{vibrational} < 4000\,cm^{-1}$ (0.50 eV)[a], the vibrational energy-loss peaks lie close to the elastic peak and can be observed only if electron-energy discrimination is carried out at high resolution.

Two mechanisms give rise to high-resolution electron energy-loss (HREEL) spectra[1–8]: dipole scattering and impact scattering. In dipole scattering, the incident electron may be treated similarly to an electromagnetic (infrared) wave that interacts, at long range, with oscillating dipoles created by the vibration of species at the surface. Dipole-scattering HREELS is thus governed by the well-known harmonic-oscillator[b]

infrared selection rules: At ambient temperatures, (i) only fundamental transitions are allowed; and (ii) only vibrations accompanied by a change in dipole moment are observed.

On metal surfaces, two additional selection rules apply. The first is that only vibrations perpendicular to the surface are HREELS active. This rule follows from two phenomena unique at metal surfaces[3–8]: (i) Electromagnetic waves polarized perpendicularly to the plane of incidence (parallel to the plane of the surface) undergo a 180° phase shift upon reflection. That is, at the metal surface, the out-of-phase electric-field vectors of the incident and reflected waves cancel each other; as a result, no field exists that can couple with dipoles that oscillate parallel to the surface. (ii) The dynamic dipole moment generated by an oscillator that vibrates in the surface-parallel direction is cancelled by that of its image dipole (Figure 1); hence, there the net dynamic dipole moment is zero. On the other hand, if the real dipole is oriented perpendicularly to the surface, its dynamic dipole moment is reinforced by that of its image dipole. This selection rule is the same as that for infrared reflection-absorption spectroscopy (IRAS).[c]

The second dipole-scattering selection rule states that the intensity is at a maximum when the angle of collection is the same as the angle of (specular) reflection. This selection rule is illustrated in Figure 2; the intensity of the dipole-scattered peak at 130 meV (1050 cm^{-1}) falls precipitously as soon as the collection angle deviates from the specular angle. Figure 2 also shows that the angular dependence of the elastic peak is the same as that of the dipole-scattered peak.

The mechanism for impact scattering at solids is rather complex as it involves the penetration of the incident electron into the adsorbed molecule; the theoretical treatment requires a quantum mechanical formalism. The transfer of energy from the incident electron to a vibrational mode occurs, within a very short time, while the electron is inside the molecule. The dipole-scattering selection rules do not apply to impact scattering. Theoretical considerations have predicted, and experimental studies have confirmed, the following ''propensity rules'' for this mechanism[4]: (i) Impact scattering

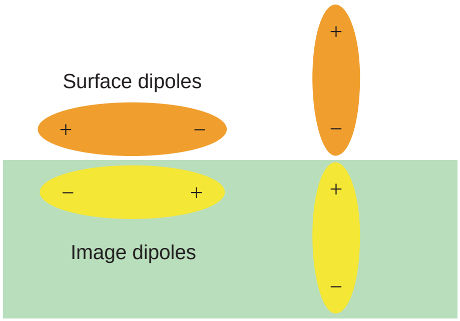

Figure 1 The dynamic electric moment of the dipole oriented parallel to the metal surface is cancelled by that of its image dipole. In the vertical orientation, the dynamic electric moments of the surface and image dipoles reinforce each other

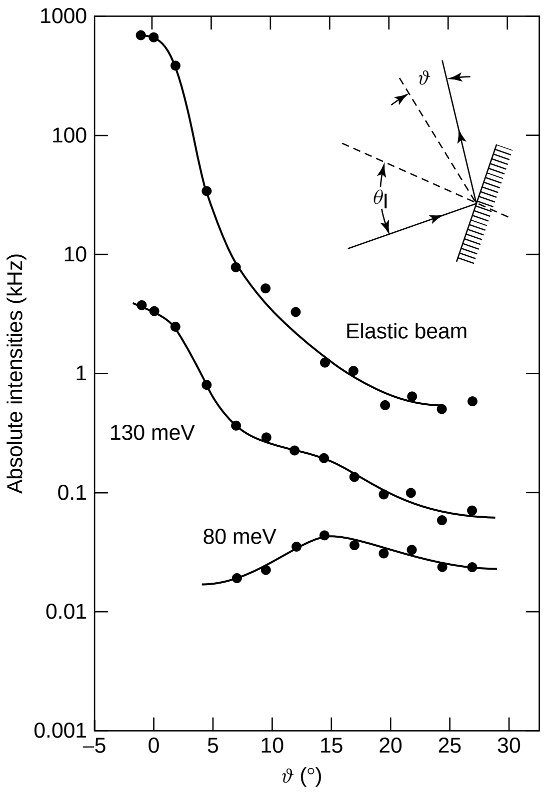

Figure 2 The influence of off-specular angle (φ) on the absolute peak intensities in dipole scattering (130 meV) and in impact scattering (80 meV). (Published in Electron Energy Loss Spectroscopy and Surface Vibrations, Ibach H & Mills D L, © Elsevier 1982)

vanishes in the specular direction; that is, impact-scattered peaks can be observed only if detection is at angles removed from the specular direction. The dependence of impact scattering on the off-specular scattering angle (φ), where φ is the deviation of the collection angle from the angle of (specular) reflection, is shown in Figure 2.[4] Impact scattering (80 meV (645 cm^{-1})) is most prominent when $\varphi \sim 15°$. (ii) Impact scattering is more likely to be dominant, even at low off-specular angles, at higher vibrational energies. (iii) Strong dipole scatterers are weak impact scatterers; conversely, weak dipole scatterers are strong impact scatterers.[d]

It is clear that the combination of specular and off-specular HREELS provides a means for the complete identification of the normal modes of an adsorbed molecule; considerations based upon point-group and space-group theory would, of course, be required. HREELS is an extremely sensitive technique. The limit of detection for strong dipole scatterers such as CO can be as low as 0.0001 monolayer; for weak scatterers such as hydrogen, the limit is 0.01 monolayer. In comparison, IRAS for chemisorbed CO, a strong infrared absorber, is restricted to coverages above 0.1 monolayer. HREELS studies of non-CO organic molecules adsorbed at atomically smooth surfaces are abundant; similar experiments using IRAS are meager. The energy accessible to HREELS

ranges from 50 (6.2 meV) to 4000 cm^{-1} (496 meV); common IRAS detectors are not useful below 600 cm^{-1} (74 meV). On the other hand, IRAS has higher-resolution (nominally 4 cm^{-1}) than HREELS (typically 30 cm^{-1} (3.7 meV)), although resolutions of up to 4 cm^{-1} (0.25 meV) have been claimed for the latest models of (Ultrahigh-resolution electron energy-loss spectroscopy (UHREELS)) instruments.[7] The primary limitation of HREELS is that the apparatus is quite specialized, rather delicate and requires an ultrahigh vacuum (UHV) environment; IRAS can be carried out under ambient conditions. It has recently been observed that countercations present in the adsorbed layer may block low-energy electron backscattering.[8]

2.2 Instrumentation

Figure 3(a) shows a schematic diagram of a first-generation HREEL spectrometer.[3] In this model, the energy of incident electrons can be varied from 1 to 10 eV. To afford high-resolution, energy monochromation and analysis are done either with a cylindrical mirror analyzer, cylindrical deflector, or spherical deflector analyzers in combination with retarding-field optics. Off-specular collection of the backscattered electrons is afforded by rotation of either the sample or the analyzer. Owing to extremely low signals (10^{-10} A), continuous dynode electron multiplier detectors are employed. Figure 3(b) is a photograph of an UHREELS spectrometer.[7] This model consists of an electron gun, a two-stage monochromator, a single-stage energy analyzer, and a channel electron multiplier detector. Both energy monochromation and energy analysis are carried out with 127° cylindrical deflection analyzers. The incident electrons have an initial energy spread of 0.3 eV. The two- stage monochromator serves to narrow the energy spread to <1 meV and generate a highly monoenergetic beam of low-energy electrons (typically 1 to 10 eV). A zoom lens system focuses and accelerates the electron beam onto the sample. The backscattered electrons are passed through a separate zoom lens for focusing and deceleration before they are sorted out by a single-stage energy analyzer into the detector. The signal is fed to a preamplifier as pulses for electron counting. The analyzer is designed to be rotatable from 0° to 78° for off-specular (impact-scattering) measurements.

3 SELECTED APPLICATIONS

3.1 Inorganic Molecules

3.1.1 Carbon Monoxide

Carbon monoxide is the most widely used molecular probe in the study of the coordination chemistry and catalytic reactivity of metal surfaces. The chemisorption of CO at transition-metal surfaces is similar to the coordinate-covalent bond formation in homogeneous metal–carbonyl complexes.[9–11] The interaction initially involves a σ bond formed by the electron-pair donation from a filled spσ ligand orbital to an unoccupied dσ metal orbital; this is followed by a π bond created by the electron-pair back-donation from a filled dπ (or dpπ) metal orbital to an empty $2\pi^*$ ligand orbital.[9,10] As a result of the surface coordination, the C≡O bond is weakened and ν_{CO}, the vibrational frequency of the C≡O stretch mode (2142 cm^{-1} (266 meV) in the gas phase) undergoes an appreciable redshift. The larger the extent of the back-donation, the stronger the metal–carbon (M–C) interaction, and the weaker the C≡O bond. The degree of π back-donation is also heightened by an increase in the number of surface atoms bridged by the CO ligand. In the latter case, multiple M–C bonds will be expected; for example, CO chemisorbed on a threefold hollow site will most likely be bonded to three different metal atoms. Consequently, ν_{CO} will display strong dependence on site geometry[11]: At ''atop'' (onefold) sites, ν_{CO} lies in the range from 2000 (248 meV) to 2130 cm^{-1} (264 meV); at twofold bridge sites, ν_{CO} falls between 1840 (228 meV) and 1960 cm^{-1} (242 meV); and for threefold bridge sites, ν_{CO} appears in the range from 1800 (223 meV) to 1920 cm^{-1} (238 meV). HREELS has been employed in the study of CO chemisorption on most transition metals.[12–26] Bimetallic[22] and oxide surfaces[23,24] relevant in catalytic oxidation have also been investigated.

Since the infrared absorptivity of the C≡O stretch mode is fairly large, IRAS has also enjoyed widespread use in the study of CO chemisorption. However, for the investigation of the metal–carbon vibrational mode, IRAS may not be the technique of choice since the frequency of this mode (ν_{M-CO}) lies below 400 cm^{-1} (50 meV), a region in which nonsynchrotron-based sources are quite weak and wide-range photoconductive detectors suffer degraded sensitivity. Studies on the metal–carbon stretch mode may be more reliably investigated by HREELS, although (infrared) sum-frequency generation also seems viable.[27] The expectation is that, since ν_{CO} is dependent upon adsorption-site geometry, ν_{M-CO} will likewise be influenced by it. For example, on Rh(111), it has been found that ν_{M-CO} was highest when the ligand was coordinated on a onefold site and lowest when located on a threefold site.[28] This observation may appear inconsistent with the fact that linearly bonded CO has the weakest metal–carbon bond. But it must be noted that an atop site attached CO has only one M–C bond, whereas a threefold-site-bonded CO would have three distinct bonds with three different metal atoms. While the combined strength of the three bonds would be greater than just one bond, the vibrational energy of each of the three (degenerate) bonds would, individually, not be as high. Of course, the role of dipole–dipole interactions in the observed frequency shift cannot be discounted since the shifts become pronounced at near-monolayer coverages where lateral interactions become significant.[28]

(Reprinted from http://www.lktech.com/products/els5000.html, courtesy of LK Technologies, Inc)

Two other HREELS studies of dipole–dipole coupling will be mentioned. One focused on Ni(100) and involved the determination of the effect of temperature and coverage on ν_{CO}.[13] The results are displayed in Figure 4. The peak near 50 meV (400 cm^{-1}) was associated with ν_{M-CO} and the peaks at 240 (1920 cm^{-1}) and 250 meV (2016 cm^{-1}) were assigned, respectively, to ν_{CO} at twofold and atop sites. At 150 K, only one peak, due to bridge-bonded CO, was observed

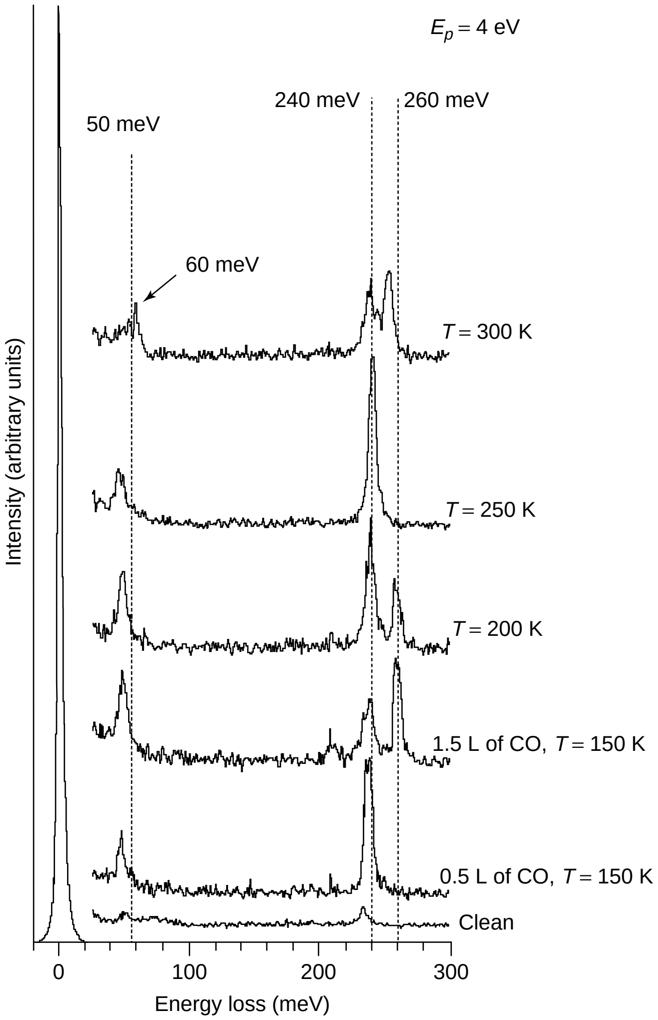

Figure 4 HREEL spectra of CO on Ni(100) for 0.5 L and 1.5 L of CO and thermal behavior of the 1.5 L CO in the 150–300 K range. (Reprinted from Formoso, Marino, Chiarello, Agostino, Caruso and Colavita,[13] © Elsevier 2006)

at submonolayer coverages. At near-monolayer coverage, a second prominent peak emerged at 260 meV (2097 cm^{-1}). The latter was not assigned to atop site-bonded CO since ν_{CO} for that is only 250 meV. A dipole–dipole interaction between adjacent CO molecules was thus postulated. It was thought that this type of coupling would weaken the metal–CO bond because of reduced π-back donation; the latter, in turn, would strengthen the C≡O bond and lead to the blueshift of ν_{CO}. Further evidence for the dipolar interactions was provided by the decrease in the intensity of the 260-meV peak as the temperature is raised; an increase in temperature tends to disrupt dipole–dipole coupling. At 300 K, CO coordinated at twofold and atop sites, devoid of dipole–dipole interactions, were indicated.

The other study examined the influence of Sn adatoms on the dipole–dipole interactions at Pt single-crystal surfaces.[22] On Pt(110), CO was bonded predominantly on atop sites at near-monolayer coverages. The same mode of coordination was found for the Pt(110)-(1 × 2)-Sn surface. When the CO coverage was further increased on the Sn-free surface, an upward shift to 260 meV was observed for ν_{CO},[22] a result that served as an indicator of the presence of dipole–dipole interactions. No similar blueshift in ν_{CO} was noted on Pt(110)-(1 × 2)-Sn, most likely because CO does not bind strongly on the interfacial Sn atoms; it was noted that the coverage of CO decreased when the amount of coadsorbed Sn was increased.

3.1.2 Dioxygen

When dioxygen is chemisorbed on a transition-metal surface, an electron pair is donated from a filled 2π orbital of O_2 to a vacant $d\sigma$ orbital on the metal, followed by back-donation from a filled $d\pi$ (or $dp\pi$) metal orbital to an empty $2\pi^*$ orbital on dioxygen. As a result, the O=O bond is weakened considerably.[29–40] For example, at 100 K, chemisorption of O_2 on most metals is molecular, but the vibrational frequency of the O–O stretch mode (ν_{OO}) is drastically redshifted, 630 cm^{-1} (78.1 meV) on Ag(110),[40] 870 cm^{-1} (108 meV) on Pt(111),[38] and 850 cm^{-1} (105 meV) on Cu(111),[33] relative to that in the gas phase 1580 cm^{-1} (196 meV). At room temperature, O_2 is dissociatively chemisorbed as oxygen atoms on the same metals.

While O_2 adsorption has been investigated for a variety of substrates,[29–40] Ag and Pt have received widest attention; Ag because of its superior selectivity toward ethylene epoxidation, and Pt for its singularly high catalytic efficiency in almost all types of exhaustive oxidation reactions. The interaction of O_2 with Ag(110) was found to yield four distinct adsorption states that depended upon the temperature: a physisorbed (condensed) layer at $T < 40$ K, two molecularly chemisorbed phases between 60 K and 180 K, and a dissociatively chemisorbed (atomic) state at $T > 180$ K.[41] The first molecularly chemisorbed species, labeled α-O_2,[37] may be generated from the physisorbed state by a temperature increase to 60 K; however, α-O_2 is not dissociated to atomic oxygen at higher temperatures. It was thought that lateral interactions within the preformed physisorbed layer induced a precursor orientation that enabled conversion to α-O_2. The other molecular species, tagged as β-O_2, was formed when the Ag surface was dosed directly from the gas phase at $T > 60$; evidently, under these conditions, the physisorbed layer that is favorably oriented toward α-O_2 formation is not the initial product. Above 180 K, β-O_2 undergoes dissociative chemisorption to oxygen adatoms.

Similar results were obtained for Pt(111): four temperature-dependent adsorption states of O_2 were also formed.[38,42,43] The two molecularly chemisorbed forms identified were (i) a superoxo-type (O_2^-) species bonded at twofold bridge sites and characterized by ν_{OO} of 870 cm^{-1} (108 meV), and (ii) a peroxolike (O_2^{2-}) species more strongly coordinated ($\nu_{OO} = 690$ cm^{-1} (86 meV)) at threefold

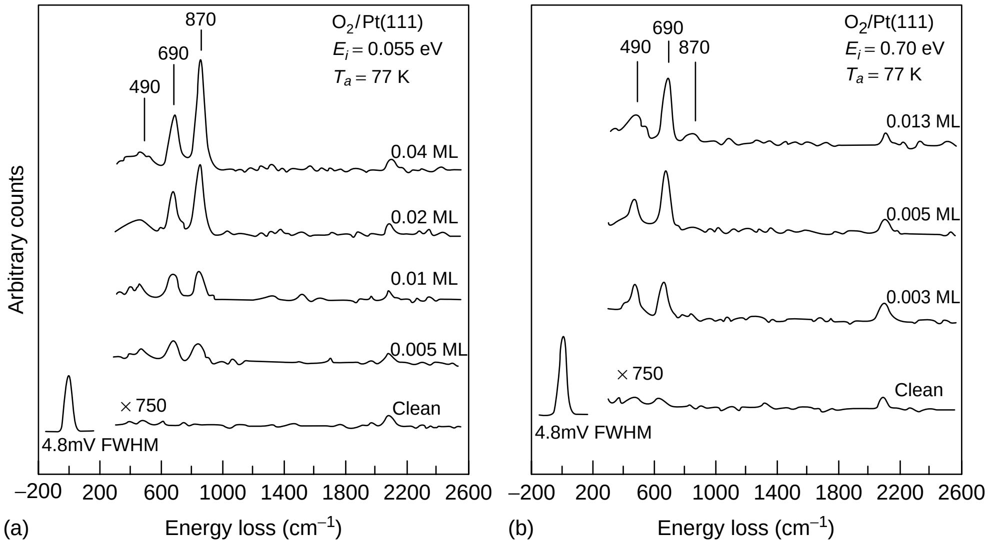

Figure 5 HREEL spectra of low-coverage doses of: (a) low incident energy (0.055 eV) oxygen, and (b) high incident energy (0.70 eV) oxygen on Pt(111) surfaces. (Reprinted with permission from P. D. Nolan, B. R. Lutz, P. L. Tanaka. J. E. Davis and C. B. Mullins. *J. Chem. Phys.* **111**:3696 (1999). © 1999 by the American Institute of Physics)

hollow sites. Experiments that combined HREELS with O_2-molecular-beam techniques indicated that high incident energies promoted the formation of the peroxo species (Figure 5a). At lower impact energies, both species were generated but the fraction of the superoxo species increased when the O_2 dosage was increased (Figure 5b). It was postulated that the O_2 molecules of higher energy are able to overcome the activation barrier for the two-electron metal-to-ligand charge transfer in the production of the peroxo species.

3.1.3 Water

As the most widely utilized solvent, studies of the adsorption of water at various surfaces abound. In such investigations, the emphasis has been on (i) its propensity toward dissociation, (ii) its structure in the adsorbed state, and (iii) its chemistry in the presence of other coadsorbed species. Although IRAS and HREELS have been employed in such studies, the former is limited to ultrathin films because of the strong infrared absorptivity of the O−H stretch mode; condensed multilayers can only be investigated by HREELS.[44]

The HREEL spectrum of water adsorbed on Pt(100) in multilayer amounts resembles that of ice. In submonolayer quantities, three ν_{OH} peaks were observed at 2850 (353 meV), 3380 (419 meV), and 3670 cm^{-1} (455 meV) respectively, these were assigned to O−H stretch modes in metal-bonded hydroxyls, hydrogen-bonded water, and water devoid of intermolecular interactions.[44] It is known that hydrogen bonding leads to a decrease in the O−H stretch frequency (ν_{OH}). When the oxygen is coordinated to the metal, the decrease in ν_{OH} is more profound. In fact, the presence of the lowest frequency ν_{OH} peak suggests that a fraction of the adsorbed water has undergone dissociation. On Ru(0001), three ν_{OH} peaks at 2935 (364 meV), 3290 (408 meV) and 3500 cm^{-1} (434 meV) were also observed at submonolayer coverages. Unexpectedly, however, the 408-meV peak was present even when the interfacial water existed as a bilayer.[45] This result prompted the conjecture that partial decomposition had likewise taken place within the bilayer. A subsequent theoretical investigation, however, showed that the 2935 cm^{-1} peak would still be possible in a bilayer that was completely molecular; as illustrated in Figure 6,[46] two structural types of hydrogen-bonded water are possible in the bilayer.

Interfacial water was studied on Pd(100) and on Pd(100)-(1 × 1)-O surfaces. At 10 K and submonolayer coverages, the interfacial water was found to exist as monomers[47] at both surfaces. When the temperature was increased to 110 K, hydrogen-bond formation between the water molecules transpired on the clean surface but not on the oxided metal. Evidently, oxygen coadsorbed on the metal disrupted hydrogen bonding between the water molecules. Such disruption, however, does not appear to occur when the surface oxygen is part of a nonmetallic species: When water was adsorbed on ultrathin SiO_2 films, hydrogen-bonded water was observed even at submonolayer coverages; evidently, the adsorbate−adsorbate hydrogen bonds are stronger than the substrate−adsorbate interactions.[48]

The adsorption of water on Ni(100) was compared with that on Pd(110) surfaces.[49] It was noted that the Pd−OH_2 bond is substantially weaker than the Ni−OH_2 bond, a result consistent with the fact that a molecular bilayer structure is formed on Pd(110) but not on Ni(100).

Work has also been published on other interfacial materials and structures that include (i) α-Cr_2O_3(001)/α−Fe_2

3.1.4 *Organometallic Compounds*

Interest in the structure of adsorbed organometallic compounds stems from their capabilities as research-laboratory and industrial catalysts. In view of its inherent surface sensitivity and dramatically enhanced resolution, UHREELS has recently become a viable technique in the acquisition of fingerprint spectra[60,61] of adsorbed organometallic compounds such as the metallocenes.[62–65]

Ferrocene has recently been utilized in the synthesis of carbon nanotubes.[66] In this context, HREEL spectroscopic measurements have been carried out on the adsorption of ferrocene on graphite[67]; silver substrates have also been examined.[63,68,69] On Ag(100), ferrocene was found to exist as a weakly bound molecular entity at low temperatures.[68] Loss peaks at 60.4 (487 cm^{-1}) and 93.2 meV (752 cm^{-1}) that were prominent in the HREEL spectra collected at specular angles were not observed at off-specular angles (Figure 7), a result which strongly suggests that the two loss features are exclusively dipolar in character. The peak at 60.4 meV was assigned to the antisymmetric iron–cyclopentadienyl (Fe–Cp) stretch, and the peak at 90.3 meV was ascribed to the out-of-plane C–H bend frequency, γ_{CH}.[69] For the two modes to be dipole active, both must have a vibrational-mode component that is perpendicular to the silver surface; this can be satisfied only if the ferrocene molecule is adsorbed in an ‘‘upright’’ orientation in which both Cp rings are oriented parallel to the surface (Figure 7).[63,68,69] On graphite at 140 K, a similar orientation for adsorbed ferrocene was inferred from the HREEL spectra.[67] More importantly, the frequencies of the loss peaks were found to be nearly identical to those of the gas-phase absorption peaks; the absence of adsorption-induced frequency shifts provides ample evidence that ferrocene was only physisorbed on the graphite surface.

The adsorption of iron(0) pentacarbonyl was recently studied on a Si(111)-(7 × 7) surface.[70] The interest in $Fe(CO)_5$ lies in its availability as a source gas for the chemical vapor deposition of $FeSi_2$, a critical microelectronics material.[71] Even at temperatures as low as 100 K, $Fe(CO)_5$ already underwent dissociative adsorption to yield a linear iron monocarbonyl (FeCO) surface complex. The prominent loss peaks that appeared at 53 meV (428 cm^{-1}), 81 meV (653 cm^{-1}), and 255 meV (2056 cm^{-1}) were assigned to the Si–COFe, Fe–CO, and C≡O stretch modes, respectively. These peaks were shown to arise only via dipole scattering which, because of the dipole selection rule, indicates that the adsorbed FeCO is oriented vertically with the CO moiety bonded to the Si surface.

3.1.5 *Fullerene*

The growth and chemistry of C_{60}[72] films on transition metal[73,74] and semiconductor surfaces[75–77] has been extensively studied because of potential industrial applications. The surface coordination of fullerene with

transition-metal surfaces involves the donation of electrons from the π orbitals of the ligand to the d orbitals of the metal accompanied by the back-donation of electrons from a metal d orbital to the ligand π^* orbital. The π-electron back-donation significantly alters the chemical properties of the surface-attached C_{60}. Because of its high symmetry, there are more than just a few degenerate and IR-inactive vibrational modes.[78,79] However, most of these modes are observable in HREELS especially when detection is conducted at both specular and off-specular angles.[80]

Alkali-doped fullerides that exhibit superconductivity have received considerable attention. The spectral fingerprints of these materials show vibrational-mode-specific frequency shifts and intensity variations related to electron donation from the intercalated metal atoms to the C_{60} molecules (Figure 8a). HREELS of K-doped C_{60} thin films adsorbed on Ag(111) and Cu(111) showed loss peaks, barely visible for the undoped monolayer that increased when the dopant concentration was increased. This trend was thought to be a consequence of the charge transfer from the (electropositive) K atom to C_{60}.[81] The existence of positive K^+ ions and negative C_{60}^- ions may have been established by the appearance of a prominent optical-phonon loss peak brought about by the collective oscillations of the cations against the anions (Figure 8b).

Studies on fluoro–fullerenes ($C_{60}F_x$) were recently undertaken because of the interest in such materials as cathodes in Li batteries.[83] A recent HREELS-based work focused on the interaction between $C_{60}F_x$ and the silicon surface.[84,85] The spectrum of $C_{60}F_x$ thin layers deposited on Si(111)-(7 × 7) revealed a weak but well-defined loss feature at 107 meV. This peak was attributed to a Si–F stretch mode, which implied that the Si surface was able to defluorinate $C_{60}F_x$ and form a Si–F selvedge on the silicon substrate. The Si–F bond is rather strong and renders the substrate chemically inert toward further adsorption of $C_{60}F_x$.[84] The defluorination process is enhanced by an increase in temperature.[85]

3.2 Organic Molecules

3.2.1 *Ethylene*

The structure and reactivity of ethylene chemisorbed on transition-metal surfaces are of fundamental importance in surface science and heterogeneous catalysis. HREELS has been foremost among the surface characterization techniques employed; in fact, the first vibrational spectroscopic study of ethylene chemisorbed on Pt(111) was carried out with electron energy-loss spectroscopy (EELS)[86] almost a decade before IRAS was employed.[87,88]

At temperatures below 200 K, two types of ethylene-derived surface species have been identified. One is a di-σ-bonded species that results when the C=C double bond

is broken to form two C–metal bonds; the other is a π-bonded species in which the ethylene molecule remains intact. At higher temperatures, a third species, ethylidyne, may be generated on close packed face-centered cubic (111) surfaces.

The di-σ-bonded species has been observed on Pt(111),[89] Pt(100),[90] Fe(110),[91] Ru(001),[92] Si(100)[93,94] and Ni(*hkl*).[95–97] The HREEL spectrum of di-σ-bonded ethylene is characteristic of aliphatic (sp^3-hybridized) compounds with a C–H symmetrical stretch at ca. 3000 cm^{-1} (372 meV) and a CH_2 wag and C–C stretch in the region from 1170 cm^{-1} (145 meV) to 1830 cm^{-1} (227 meV); a peak near 450 cm^{-1} (55.8 meV) has been attributed to a metal–C stretch mode.[98] The π-bonded species has been found on Cu(100),[99] Pd(*hkl*)[100–103] as well as on hydrogen or oxygen pretreated surfaces.[104–107] The HREEL spectrum of the π-adsorbed species bears features reminiscent of the infrared spectrum of the ethylene ligand in Zeise's salt, $K[(C_2H_4)PtCl_3]$[108] with the C–H symmetric stretch at 3000 cm^{-1}, and a CH_2 wag and the C=C stretch in the region near 1530 cm^{-1} (190 meV); the metal–C stretch was found at 300 cm^{-1} (37 meV).[98]

When either the di-σ-bonded or the π-coordinated species is warmed to room temperature, ethylidyne ($\equiv C-CH_3$) is generated[89,109,110]; this surface compound is rather stable since the anchored carbon is bonded to three different metal atoms. The HREEL spectrum of chemisorbed ethylidyne is characterized by vibrational modes of C_{3v} symmetry; the C–H stretch is at 2900 cm^{-1} (360 meV), the CH_3 wag and C–C stretch within the 1400 (174 meV) to 1800 cm^{-1} (223 meV) interval, and the M–C stretch near 425 cm^{-1} (52.7 meV).[98] Although the complete mechanism of the ethylene to ethylidyne conversion is not known, it is thought to involve an initial dehydrogenation step followed by hydrogen migration; ethylidene ($=CH-CH_3$) was proposed as an intermediate in the transformation reaction at Pt(111).[111]

The adsorption of ethylene on clean and oxygen pretreated Pd(111) surfaces was recently studied[107]; the results in terms of HREEL spectra, are shown in Figure 9. As anticipated, ethylene was chemisorbed at 100 K as a di-σ-bonded species on the clean metal (Figure 9a). On the oxygen precoated surface, however, a π-coordinated complex was obtained (Figure 9b). At 300 K, ethylene chemisorption always resulted in an ethylidynic complex regardless of whether or not the surface was pretreated with oxygen (Figure 9c). When the di-σ-bonded or the π-attached species was warmed to 450 K, quantitative desorption of starting material (C_2H_4) occurred without dehydrogenation; no ethylidyne species was produced from either structure during the temperature increase.

Adsorption of ethylene on Rh(100) presaturated with hydrogen produced a π-bonded species at low temperatures.[105] The degree of sp^2-to-sp^3 rehybridization upon chemisorption was expressed in terms of a ''$\pi\sigma$ parameter'' derived from the HREEL spectrum via the mixing of the C–C (or C=C) stretch and the CH_2 scissor modes.[112] The $\pi\sigma$ parameter, which was normalized to zero for pure sp^2 hybridization (C_2H_4) and to unity for pure sp^3 hybridization ($C_2H_4Br_2$), was estimated to be 0.39 for chemisorbed C_2H_4; in comparison, a $\pi\sigma$ parameter of 0.38 was obtained for Zeise's salt. The close agreement

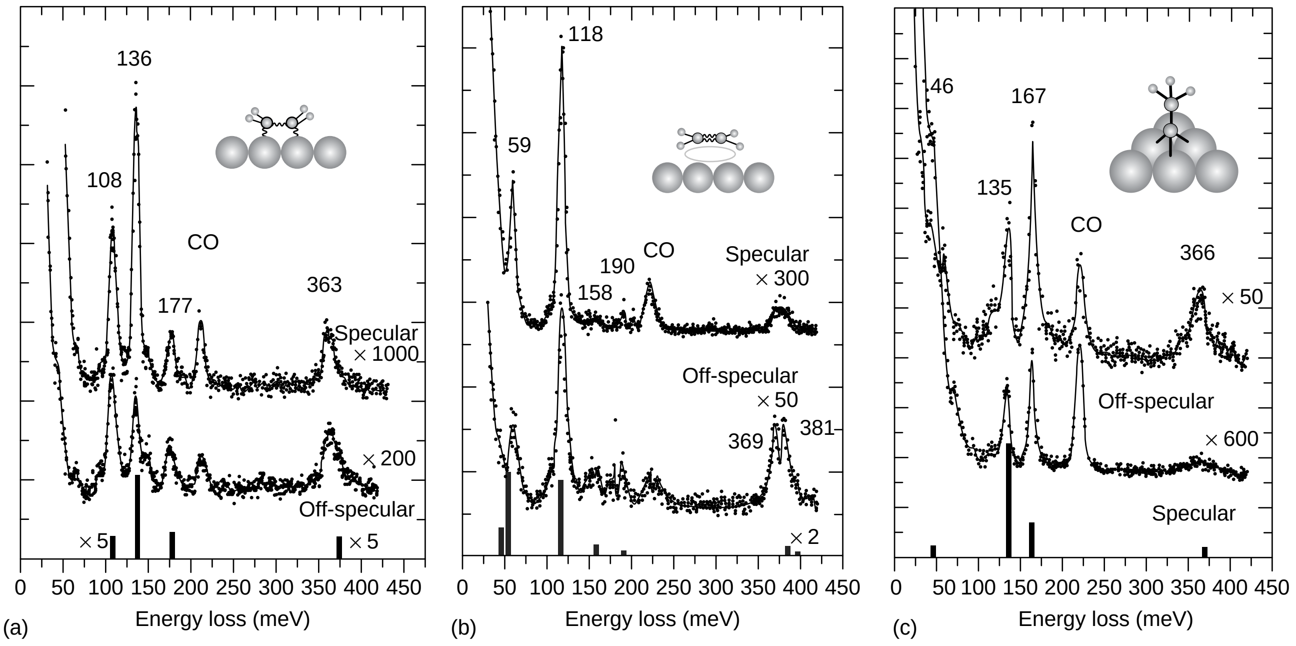

Figure 9 Specular and off-specular HREEL spectra of (a) Pd(111) surface exposed to C_2H_4 at 100 K; (b) Pd(111)-2 × 2-O surface exposed to C_2H_4 at 100 K; and (c) Pd(111) exposed to C_2H_4 at 300 K. between the two $\pi\sigma$ parameters provides additional evidence that the ethylene molecule is bound to the surface as a π-bonded ligand. It was also reported in the same work that an ethyl intermediate was formed from π-bonded ethylene by insertion of preadsorbed H atoms, a process that is initiated even at temperatures below 110 K. At 110 K $< T <$ 200 K, evolution of gaseous ethane was observed, but further thermal treatment resulted in the rupture of the carbon–carbon bond.

3.2.2 Methanol

Research activity on methanol has been vigorous because of its commercial importance as an alternative feedstock in fuel cells. When CH_3OH is chemisorbed on a catalytic surface at ambient temperatures, it is usually present as a methoxy intermediate; the latter then undergoes extensive decomposition to yield a product distribution that depends upon the temperature. A tabulation of products generated under various experimental conditions such as metal catalyst and decomposition temperature is given in Table 1; HREELS and temperature programmed mass spectrometry were used to generate the data.

3.2.3 Aromatic Compounds

An immediate issue in the chemisorption of aromatic compounds is whether the phenyl ring is oriented parallel or perpendicular to the plane of the metal surface. In this regard, the intensity of the out-of-plane C–H bend (γ_{CH}) relative to the in-plane C–H stretch (ν_{CH}) provides a direct diagnostic indicator of adsorbed aromatic orientation.[130–132] At specular angles, the dipole selection rule states that ν_{CH} for a ring chemisorbed completely flat would be EELS-inactive; only the γ_{CH} mode would exhibit EELS activity. At off-specular angles, the impact-scattering selection rules are less restrictive and all modes would conceivably be EELS-active, although peaks obtained at specular angles would tend to vanish as the off-specular angle φ is increased.

Early studies with smooth polycrystalline Pt electrodes indicated that aromatic compounds such as *p*-diphenols

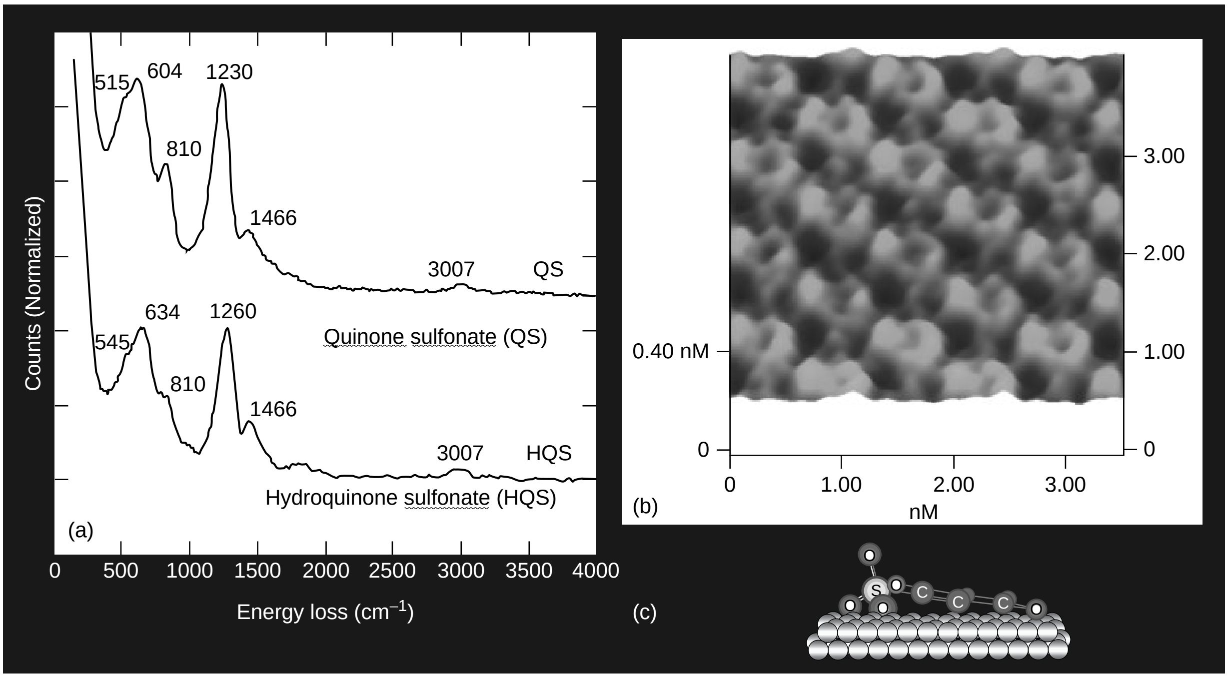

Figure 10 HREEL spectrum (a), in situ scanning tunneling microscope image (b), and molecular model (c) of quinone sulfonate chemisorbed on Pd(100)

are chemisorbed in discrete, nonrandom orientations that depend upon interfacial factors such as the solution concentration of the aromatic and the composition of the supporting electrolyte.[133–135] For example, when chemisorbed from dilute (0.1 mM) solutions, a molecular layer of horizontally oriented (η^6-coordinated) quinonoid species is formed; at higher concentrations (2 mM), a layer of vertically oriented (2,3-η^2-bound) aromatic molecules is generated. The orientational assignments made from measured adsorbed-molecule cross sections have since been verified by independent experiments foremost of which has been HREELS; work with the diphenols has been carried out with Pt and Pd single crystals.[136–139]

Figure 10 shows HREEL spectra of a Pd(111) electrode emersed[e] from aqueous solutions that contained either 0.1 mM hydroquinone sulfonate or 0.1 mM benzoquinone sulfonate.[132] Four features are most notable: (i) the spectra are identical whether the starting material is the diphenol or the quinone; (ii) there is a pronounced out-of-plane C−H bend (γ_{CH}) at 810 cm^{-1} (100 meV); (iii) no O−H stretch (ν_{OH}) is observed near 3600 cm^{-1} (446 meV); and (iv) there is a small but noticeable in-plane C−H stretch (ν_{CH}) at 3007 cm^{-1} (373 meV). These results indicate that, upon surface coordination, the diphenolic species undergoes a two-electron, two-proton oxidation to form essentially flat-chemisorbed benzoquinone; the small ν_{CH} peak, however, indicates that the aromatic ring is not completely flat, but is slightly tilted. The combination of HREELS and electrochemical (in situ) scanning tunneling microscopy[140] has been used to deduce the adsorbed−molecule orientation of the sulfonated quinone (Figure 10). Recent HREELS and thin-layer electrochemical measurements[141] have demonstrated that, at a tenfold increase in solution concentration, hydroquinone is chemisorbed on Pd(111) in an edgewise orientation reminiscent of an *o*-benzyne organometallic complex.[133–135]

The desorption and decomposition of benzene has been studied on Pt(111) and on Sn-modified Pt(111) for comparative purposes.[142] On the former surface, only a portion of the chemisorbed benzene desorbs upon heat treatment; the remainder is dehydrogenated to form a layer of carbon on the surface. On the Pt(111)-Sn alloys, only physisorption takes place.

The cyclization reaction of acetylene at ambient temperatures to form benzene on Pd(111) has recently been reinvestigated in an attempt to gain insights into its mechanism.[143] It has been claimed that, at low exposures of acetylene, only ethylidyne is formed. At higher exposures, benzene is formed, albeit at low coverages, as indicated by appearance of the ν_4 band of benzene at 720 cm^{-1}.

More recent work on the chemisorption of aromatic molecules has focused on new materials (e.g., Mo(112)-c(2 × 2)-SiO_2 and Mo_2C/Mo(100)) and with various benzene derivatives (e.g., C_6H_5I and C_5NH_5).[144–147]

3.2.4 Polymers

Only feeble attempts were initially made two decades ago in the application of HREELS to the study of polymer surfaces. The efforts did not become more earnest until a

decade later. The use of HREELS has primarily been focused on the following aspects related to polymer films deposited on metals as well as to surfaces of the polymer films themselves: surface morphology, interfacial composition, the scattering mechanism, and the strength of the polymer–substrate bond. The utility of HREELS to probe polymer-surface morphology rests on the observation that elastic peaks due to electrons backscattered from hydrogen atoms can be correlated with the hydrogen content at smooth surfaces.[148]

Systems that employed HREELS for interfacial-composition determinations included: poly(ethylene oxide)-polystyrene diblock copolymer on Si wafers[149]; formaldehyde poly(oxymethylene) films on Cu(100)[150]; and Langmuir–Blodgett films of 4,4'-oxydianiline-pyromellitic dianhydride polyimide on Au and on highly ordered pyrolytic graphite.[151]

HREELS experiments with bisphenol-A polycarbonate, high-density polyethylene, and poly(2-vinylpyridine) suggested that, although dipole and impact scattering are prominent in polymer films, negative-ion resonance scattering cannot be discounted.[152] Investigations with highly oriented poly(tetrafluoroethylene) likewise indicated appreciable negative-ion resonance impact scattering with a maximum cross section at an incident electron energy of around 4 eV.[153]

The use of vibrational spectroscopy to monitor the strength of polymer adhesion on foreign substrates is based upon adsorption-induced frequency shifts and intensity changes in the free polymer modes and the emergence of new spectral peaks; the latter, due to metal–polymer bonds, generally appear at energies lower than 75 meV that can be accessed only by HREELS. It was found, for example, that Pd is inert toward polyimide, but Cr is quite reactive.[154] The interaction between aluminum deposited onto a polyimide film was also investigated by HREELS. When the Al coverage was $< 10^{14}$ atoms cm^{-2}, the reaction was limited to Al with the carbonyl group to form a C–O–metal complex. At a twofold increase in coverage, Al–O and Al–C bonds were formed; at intermediate coverages, no polymer–Al reactions transpired but bond breaking processes in the polymer occurred.[155]

3.2.5 *Self-Assembled Monolayers*

Technological and scientific interest in self-assembled monolayers (SAMs) lie in their applicability in many areas such as corrosion protection, biomimetic membranes, and chemical sensors.[156] The driving force in the facile formation of SAMs is the high affinity of an end group for the metal substrate. Organosulfur compounds such as alkanethiol and dialkyl disulfides have been widely studied because they spontaneously form highly ordered structures on transition-metal surfaces such as Au and Pt. IRAS, Raman scattering, sum-frequency generation and HREELS are among the vibrational spectroscopy techniques employed to probe the structure and organization of monolayer and bilayer SAMs.[157] HREELS has the unique advantage in that the metal–sulfur stretch mode occurs at low frequencies inaccessible by the other methods; hence, a determination of the adsorption sites of the organosulfur compounds is possible only with HREELS.[158,159] In addition, the degree of order in SAMs can be addressed uniquely by HREELS via a comparison of the specular and off-specular HREEL spectra.[160]

A vast majority of HREELS work has been focused on Au(111) and Au(100) surfaces.[161–163] The HREEL spectrum of alkanethiols surface coordinated on Au can be divided into the following group-frequency regions: 200 (24.8 meV) to 360 cm^{-1} (44.6 meV) for the Au–S stretch region; 620 (77 meV) to 740 cm^{-1} (91.7 meV) for the C–S stretch region; 1000 (124 meV) to 1100 cm^{-1} (136 meV) for the C–C stretch region; 1200 (149 meV) to 3000 cm^{-1} (372 meV) for the C–H stretch region; and 700 (86.9 meV) to 900 cm^{-1} (112 meV) for the C–H wag region). The absence of an S–H peak in the spectrum indicates that alkanethiol chemisorption involves the loss of an S–H bond to form an M–S bond accompanied by the evolution of H_2 gas.

The effect of alkyl chain length on the structure of alkanethiols on Au(111) was studied with $CH_3(CH_2)_{n-1}SH$, where $n = 2$, 4, 6, 8, 10, 11, 12, 14, 15, 16, and 18).[164] The results, in terms of HREEL spectra, are displayed in Figure 11. It is most interesting to note that the intensity of CH_3 σ-deformation mode at 1380 cm^{-1} (171 meV) is profoundly dependent on the number of carbons in the alkyl chain: It is present only when the number of carbon atoms is even (cf., the spectra labeled C_{10}, C_{12} and C_{16}); it is absent when the number is odd (cf., the spectra labeled C_{11} and C_{15}). This ''odd–even'' trend is caused by the fact that the orientation of the CH_3 head is parallel to the surface for odd number of carbon atoms but perpendicular when the number is even (cf., the inset in Figure 11). As dictated by the dipole selection rules, only the oscillator that has a component perpendicular to the surface (as in the even number chain) would show HREELS activity. It can also be seen in the frequency region below 220 cm^{-1} (27.3 meV) that more than one peak, separated by about 30 cm^{-1} (3.7 meV) are present; this indicates the existence of multiple adsorption sites for the subject alkanethiols on Au(111).

Octanethiol SAMs on Au(111) have been found to undergo an adlattice transition from a $c(4 \times 2)$ to a $(6 \times \sqrt{3})$ structure after long-term storage. HREELS was one of the techniques employed to examine the cause for the transitions.[165] It was established that the structural transitions were caused by the dynamic surface diffusion of the sulfur anchor group between multiple adsorption sites. The adsorption-site exchange also resulted in orientational changes in alkyl chains.[164]

The properties of octadecanethiol SAMs on three different gold substrates, Au on Si, Au(111), and Au(100), were studied by HREELS for comparative purposes.[132,140,141] The angular distribution of the elastic peak from the SAM on the Au on Si film was found to be at least 5 times broader than those on Au(111) and Au(100). This suggests

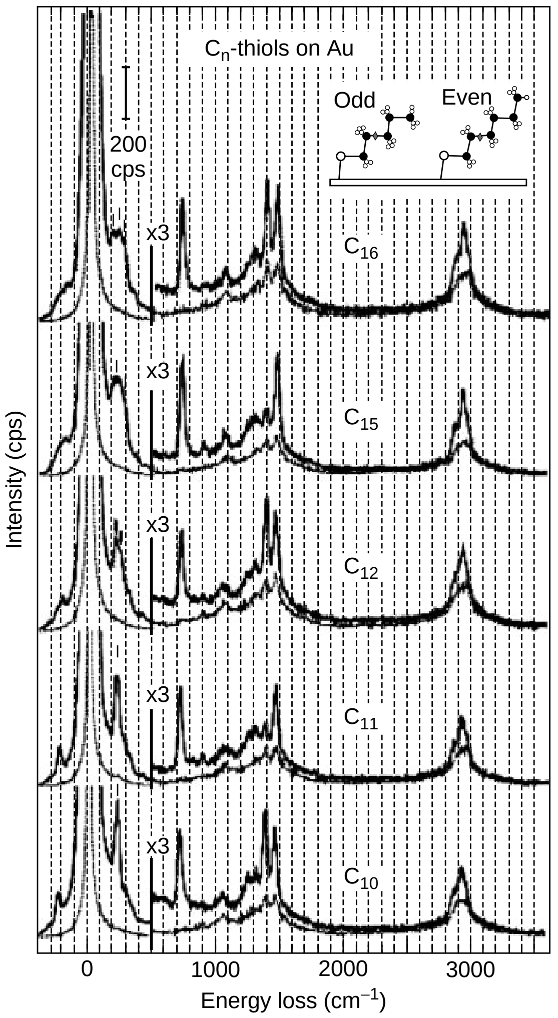

Figure 11 Odd–even effect on HREEL spectra of various alkanethiol SAMs on Au. The specular spectra and the off-specular spectra were plotted as solid and dotted lines, respectively. (Reprinted with permission from Kato, Noh, Hara and Kawai.[158] © 2002 American Chemical Society)

that the SAM on the Au film was far less ordered than on Au(111) and Au(100). An analysis of the dipole scattering and impact scattering contributions to the HREEL spectra provided evidence that the CH_2 (rocking and scissoring) and CH_3 (bending) modes are predominantly dipole scatterers, whereas the C–C and C–H stretching modes are primarily impact scatterers.[165]

Thiophenols and thiophenol derivatives chemisorbed on well-defined electrode surfaces have also been studied by HREELS.[2] The cyclic voltammetric peaks for the quinone/hydroquinone redox reaction of the 2,5-dihydroxythiophenol immobilized on the Pt surface was much broader than for the unadsorbed species; the broadening vanished when a methylene group was placed between the—SH group and the phenyl ring. These results indicated strong substrate mediated adsorbate–adsorbate interactions. Such interactions, however, were not manifested in the HREEL spectrum. This suggested that the adsorbate–adsorbate interactions were purely electronic in nature, devoid of vibrational (or vibronic) perturbations.

5 ABBREVIATIONS AND ACRONYMS

EELS = electron energy-loss spectroscopy; HREEL = high-resolution electron energy-loss; HREELS = high-resolution electron energy-loss spectroscopy; UHREELS = ultrahigh-resolution electron energy-loss spectroscopy; IRAS = infrared reflection-absorption spectroscopy; SAMs = self-assembled monolayers; UHV = ultrahigh vacuum; Cp = cyclopentadienyl group φ = off-specular scattering angle.

6 END NOTES

a. $1\,eV = 8066\,cm^{-1} = 96.48\,kJ\,mol^{-1}$.

b. HREELS generally does not possess enough sensitivity to detect higher-order effects due to mechanical and/or electrical anharmonicity.

c. In IRAS, the surface is irradiated at near-grazing incidence and the quantity of absorption is obtained from the attenuation of the intensity of the reflected beam. Adsorbed molecule orientation can be determined directly from the spectrum since the metal–surface dipole selection rule states that only vibrations with components perpendicular to the surface are active.

d. A third mechanism, first observed in gas-phase electron-impact scattering, has been referred to as negative-ion resonance. In this process, an electron is trapped, within 10^{-15} s, inside the molecule in a negative-ion state. For chemisorbed molecules, however, the adsorbate-substrate chemical bond and the electron–surface interactions can dramatically alter the resonance properties.[6] Hence, for HREELS at metal surfaces, this mechanism is quite rare; it will not be treated further in this article.

e. In electrochemical surface science, emersion is a term used to indicate the removal of an electrode from solution under potential control.

METHOD SUMMARY

Acronyms, Synonyms

- Magnetic Circular Dichroism
- Magnetic Optical Rotatory Dispersion

Measured physical quantities

- The difference in absorbance of left and right circularly polarized incident radiation (MCD), or the extent of the rotation of a beam of plane polarized light (MORD), with the sample located in a magnetic field aligned parallel to the axis of light propagation is observed.

Information available

- Ground and excited state orbital and spin degeneracies can be observed.
- Spectral band polarizations based on a qualitative analysis of the spectral bands can be determined in terms of the Faraday $\mathcal{A}_1$, $\mathcal{B}_0$ and $\mathcal{C}_0$ terms. The magnitudes of these Faraday terms have well defined theoretical interpretation.
- Identification of the individual split components due to the Zeeman splitting of the ground and excited states following absorption of lcp and rcp light.
- Spectral determination of the field-induced mixing of zero-field states and a ground state population adjustment as a result of Zeeman splitting.
- Quantitative analysis provides values for the ground and excited state magnetic dipole moments and the g-factors based on determination of the Faraday terms and the dipole strength of the corresponding electronic absorption band.
- Transition metal ion oxidation and spin states, and coordination environments from the geometry can be determined through prediction of expected MCD signals for each specific case.
- Axial and rhombic zero-field splitting parameters of Kramers doublet ground states and ligand field splitting parameters of non-Kramers doublet degenerate ground states can be determined from the variable temperature variable field data.

Information not available, limitations

- Spectra of lower symmetry species lacking a threefold or higher symmetry axis contain significantly less information.

Examples of questions that can be answered

- What are the symmetries of the ground and excited states?
- Do the experimentally derived state degeneracies and band polarizations match those predicted by theoretical calculations?

- What is the electronic structure of the atom, ion or complex?
- What is the oxidation state of the metal?
- Is the metal spin state high, intermediate or low?
- Is the ligand an anion or cation radical and/or is the metal paramagnetic?

Major advantages

- MCD spectroscopy provides key orbital and spin state degeneracy information that cannot be derived from electronic absorption and NMR spectroscopy.
- X-ray MCD spectroscopy based on L-edge absorption experiments can be used to analyze localized spin states at specific metal sites.

Major disadvantages

- The technique remains highly specialized due to the use of expensive electro- or superconducting magnets and cryogenic equipment.

Sample constraints

- The samples must be optically transparent and not cause depolarization of the incident light.

1 INTRODUCTION

Magnetic circular dichroism (MCD) spectroscopy provides information about the spin and orbital angular momenta associated with ground and excited electronic states. The MCD technique is complementary to electron paramagnetic resonance (EPR) spectroscopy (*see* ***Electron Paramagnetic Resonance (EPR) Spectroscopy***), which can provide key information about the electron spin state of paramagnetic complexes, and often provides the key to understanding the optical spectroscopy (*see* ***Electronic Spectroscopy***) of high symmetry ions and complexes. This, in turn, provides an important insight into the electronic structure. MCD spectroscopy is based on the Faraday effect in which a beam of plane polarized light is rotated either clockwise or counterclockwise during transmission through certain substances due to differences in the refractive indices for left circularly polarized (lcp) and right circularly polarized (rcp) light, when a magnetic field is aligned parallel to the axis of light propagation. Prior to the 1960s and the development of the photoelastic modulators required to create alternating beams of lcp and rcp from plane polarized light, magnetic optical rotatory dispersion (MORD) spectroscopy, which is based on the wavelength dependence of the Faraday effect experiment, was the primary electronic absorption-based technique used to study magnetic optical activity. However, a major restriction of MORD spectroscopy is that all components in the cuvette contribute significantly to the observed signal at any wavelength; this is particularly a problem with the signal from the solvent. In MCD spectroscopy, only the absorbing species contributes an MCD signal, dramatically simplifying the spectral data.

MCD spectra are recorded by mounting a magnet into the sample compartment of a circular dichroism (CD) (*see* ***Circular Dichroism (CD) Spectroscopy***) spectrometer, in the Faraday alignment with the applied field parallel to the axis of light propagation. A superconducting magnetic ($B \approx 0$–11 T) is required to perform the full range of spectral measurements associated with the technique at room and cryogenic temperatures, but less expensive electro- ($B \approx 0$–1 T) and permanent magnets can also be used in many instances particularly for measurements at room temperature.

2 TECHNICAL BACKGROUND

The major difference between MCD spectroscopy, and the nuclear magnetic resonance (NMR) (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Inorganic/Organometallic Molecules***, ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Metallobiomolecules***) and EPR techniques is that the MCD technique is not based on resonance between spin states, but is instead based on the wavelength dependent absorption of circularly polarized light into excited electronic states. MCD spectra are recorded by mounting a magnet into the sample compartment of a CD spectrometer. In contrast with natural CD, which requires a specific form of asymmetry, the Faraday effect is an intrinsic property of all matter. The UV-visible absorption and MCD spectra of a molecular complex contain the same set of spectral bands, but the band morphologies are different due to the effect of the applied magnetic field and the use of a differential absorbance intensity scale from the CD spectrometer used for the measurements.

2.1 Magnetism and Optical Spectroscopy

Predicting the optical spectrum requires the solution of the Schrödinger wave equation in terms of the states (Ψ_A) and energy levels (E_A) of the system and the Hamiltonian (H):

$$H\Psi_A = E_A\Psi_A \tag{1}$$

since this allows calculation of the observables in the spectrum, namely the transition energy and the oscillator strength of the transition dipole moment between states A and J:

$$M_{AJ} = \langle\Psi_A|m|\Psi_J\rangle \tag{2}$$

Analysis of the optical spectral data rests on the fact that absorption or emission of a photon of light with specific wavelength properties results in a redistribution of charge within a molecule based on a transition moment which couples the ground and excited electronic states, resulting in a new stationary electronic state. A linear displacement of charge induces an electric dipole transition moment, while a magnetic dipole transition moment is induced by any circular motion of electric charge. Electric dipole moments (m) are usually the dominant factor in the observed absorbance or oscillator strengths of bands in UV-visible absorption spectroscopy, because they tend to be ca. 5 orders of magnitude stronger than magnetic dipole moments (μ). In the case of chiral molecules, absorption of a photon results in both magnetic and electric dipoles, as there is a helical redistribution of electronic charge. Enantiomers preferentially absorb either lcp and rcp light based on the handedness of the helical redistribution of electronic charge. This differential absorbance of lcp or rcp forms the basis of CD spectroscopy.

The main selection rules for electronic absorption spectroscopy are based on whether a transition is spin ($\Delta S = 0$) allowed and/or Laporte ($\Delta l = \pm 1$) allowed. An additional selection rule based on the magnetic quantum number, which in simplistic terms can be stated as only $\Delta M_J = 0, \pm 1$ transitions are allowed, plays a major role in the case of MCD spectroscopy but is not such a significant factor in UV-visible absorption spectra in the absence of an applied field. An incident photon can provide a maximum of one quantum of orbital angular momentum ($J = 1$ and $\Delta M_J = \pm 1$), since the electric and magnetic vectors of the electromagnetic wave can rotate a maximum of once per wavelength, and the total angular momentum within an isolated system must be conserved in both magnitude and direction based on Newton's third law of motion. Absorption of a photon by an aromatic π system, for example, results in both a linear and a circular redistribution of charge within the xy plane. Although strong excited state magnetic dipoles are induced, there is no net CD signal since in the absence of a chiral center the absorbance of lcp and rcp light is equally likely. When a magnetic field is applied, however, the induced magnetic dipoles couple with and against the applied field, and a wavelength dependence is introduced.

2.2 Zeeman Splitting of States

Pieter Zeeman was the first to study the effect of an applied magnetic field on atomic emission spectra. Since a perpendicular applied field was subsequently typically used within Zeeman (excited state emission) spectroscopy the normal Zeeman effect is usually described in terms of parallel (‖) and perpendicular (⊥) plane polarized bands (Figure 1). It should be noted, however, that Zeeman also studied the parallel magnet alignment used within MCD spectroscopy. In Zeeman's words[1] during his Nobel prize lecture in 1902 describing results obtained for emission from the 5d orbital of Cd to the 5p orbital, "*. . . But let us first consider the rays which run parallel with the lines of force . . . . The opposite circular oscillations of the electrons excite two circularly polarized rays rotating in opposite directions, one having a longer and the other a shorter period of oscillation than the original spectral line. The original spectral line splits up under the action of the magnetic field into two components which are circularly polarized in opposite directions. The light source emits two-color light. . .*". The modern MCD experiment in many respects, then, is simply the reverse of Zeeman's emission spectroscopy experiment (Figure 1) in that differential absorbance of lcp and rcp photons is induced by the Zeeman splitting of states. When Zeeman studied metals with unpaired electrons he observed what is now referred to as the anomalous Zeeman effect with multiple emission lines appearing both in the presence and absence of an external magnetic field. This represented direct spectral evidence that spin and orbital angular momenta of the individual electrons couple to provide the total angular momentum quantum numbers, J and M_J, for the electronic state based on the L, M_L, S, and M_S quantum numbers and demonstrated that an applied magnetic field can be used to derive key quantitative information about state degeneracies.

In the case of the lighter atoms ($Z < 40$), spin-orbit coupling is relatively weak and the L and S quantum numbers can be combined according to the Russell–Saunders coupling scheme (as opposed to the strong-field $j - j$ coupling scheme observed in the case of heavier atoms where the spin-orbit coupling is stronger) to give the total angular momentum of the state $J(J = L + S)$. When a magnetic field is applied, there is a lifting of state degeneracies into $2J + 1$ microstates based on the M_J quantum number for orientation relative to the applied field. The Zeeman splitting of the states can then be defined:

$$\Delta E = \frac{e}{2m_e}(L_z + 2S_z)B = g_L\mu_B M_J B \tag{3}$$

The factor of 2 for S_z is related to the g-factor (g_L), which was demonstrated empirically during early

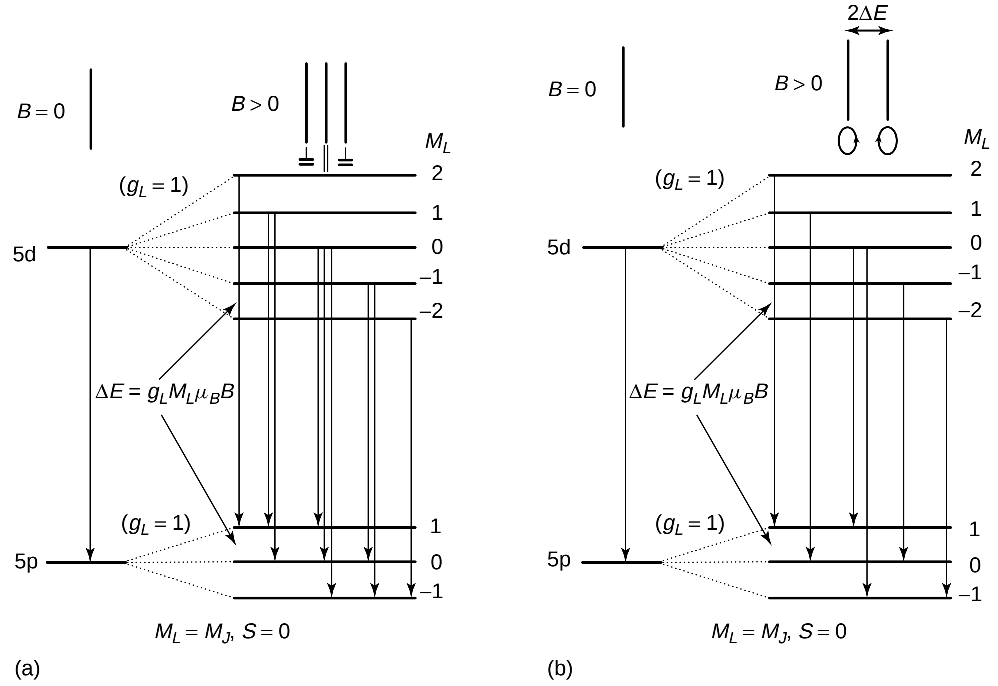

Figure 1 The normal Zeeman effect. The emission from an atomic lamp source placed within a magnet observed perpendicular (a) and parallel (b) to the lines of force. It should be noted that when $S = 0$ and the Russell–Saunders spin coupling mechanism is applicable, $J = L$, and $M_J = M_L$ as shown here. (Reprinted from Mack, Stillman and Kobayashi,[2] © Elsevier 2007)

spectroscopic studies to be

$$g_L = \frac{1 + J(J+1) + S(S+1) - L(L+1)}{2J(J+1)} \quad (4)$$

Since the g-factor associated with orbital angular momentum has a value of 1 if $S = 0$, the factor does not always have to be included. The value for the z-component of the magnetic moment aligned with the axis of light propagation is defined as

$$\mu_z = -\mu_B(L_z + 2S_z) \quad (5)$$

In the case of cyclic aromatic molecules, absorption of an lcp or rcp photon results in either a left- or right-handed redistribution of charge within the π-system, since the total orbital angular momentum within the system must be conserved. The magnetic field lines induced by the circular redistribution of charge all point along the z-axis at the center of the ligand creating a magnetic dipole moment perpendicular to the plane of the π-system. Within the MCD experiment the splitting of the optically accessible microstates of an excited state is:

$$\Delta E = 2g_L \mu_B M_J B \quad (6)$$

The factor of two is based on the fact that the microstate accessed by a photon of one handedness will be stabilized due to an alignment of the magnetic dipole moment with the applied field, while that accessed by a photon of the opposing handedness will be destabilized since the magnetic dipole is aligned against the field (Figure 2).

2.3 CD and ORD Spectroscopy

Left handed photons were originally defined as positive within CD spectroscopy (Figure 3) since the electric vector rotates counterclockwise from the positive y-axis to the positive x-axis within a right-handed set of axes. Within the CD experiment, the incident plane polarized beam becomes elliptically polarized due to the differential absorbance of lcp and rcp light. While the ϕ unit for rotation of the plane polarized beam in optical rotatory dispersion (ORD) spectroscopy (Figure 3) is a measure of the rotation of the electric and magnetic vectors per unit field, concentration, and distance, the θ ellipicity unit in CD spectroscopy is defined in degrees based on the tangent of the ratio of the minor to major axis of the elliptical path followed by the electric vector within the xy plane when viewed toward the light source. Initially the θ unit was adopted by CD spectroscopists so that results could be readily compared to ORD data via Kramers–Kronig transformations. However, since θ is proportional to the differential absorbance of lcp and rcp light, differential absorbance (ΔA_{l-r}) has been increasingly adopted in CD spectroscopy in recent years.

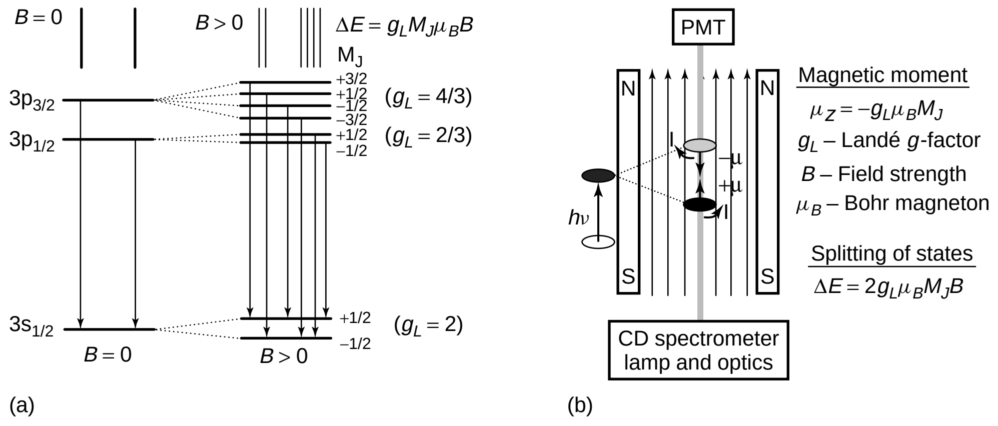

Figure 2 The direction of the induced magnetic moments within a cyclic polyene excited state can be derived from Ampere's Rule (right-hand rule) for a solenoid (i.e., for current in a loop). When the fingers of the right hand are curled in the flow direction for conventional current flow (i.e., for a positive charge carrier) the induced magnetic dipole moment is aligned in the direction the thumb is pointing. The MCD magnet's sample horizontal bore is surrounded by a solenoid to generate a high magnetic field, typically of 1–7 T, with field lines running from the south to north parallel to the axis of light propagation in the sample compartment of the CD spectrometer. (Reprinted from Mack, Stillman and Kobayashi,[2] © Elsevier 2007)

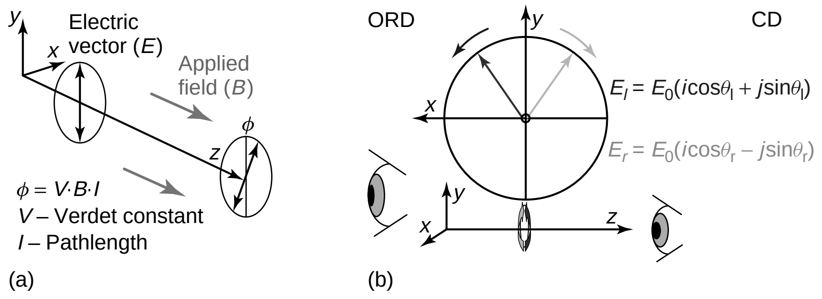

Figure 3 The Faraday Effect within magnetic optical rotatory dispersion (MORD) spectroscopy. A plane polarized beam is rotated by a magnetic field applied parallel to the axis of propagation. The rotation is defined as positive if the beam is rotated to the right in a clockwise direction when viewed toward the source (a). The original definition of lcp and rcp within CD spectroscopy—light plane polarized in the *yz*-plane can be described in mathematical terms as being comprised of left or right circularly polarized components of equal phase and amplitude (b). The perspective is depicted schematically toward the source. (Reprinted from Mack, Stillman and Kobayashi,[2] © Elsevier 2007)

3 APPLICATIONS

3.1 Measuring MCD Spectra

The recommended unit for MCD spectroscopy, $\Delta\varepsilon_M$, is based on the extinction coefficient for differential absorbance of a 1 M solution of the solute at a field strength of 1 T. The original θ ellipicity unit is still sometimes used. The conversion factors are $\theta = 32.98\Delta A$, where θ is expressed in units of mdeg or $[\theta]_M = 3298\Delta\varepsilon_M$ where, $[\theta]_M$ is expressed in units of deg·cm^2·dmol^{-1}. Room temperature spectral measurements are usually measured in solution, ideally in a solvent which is optically transparent in the 280–1000 nm region.

More highly resolved data can be obtained by measuring samples in the vapor phase either at room temperature in the case of volatile compounds or at temperatures as high as 500 °C in the case of thermally stable complexes like metallophthalocyanines. The absence of an organic solvent allows spectral bands to be measured to the UV cut-off of the spectrometer, near 200 nm.

Spectral measurements at cryogenic temperatures are often obtained from vitreous solvent mixtures in which the solute is randomly oriented with respect to the axis of light propagation. The level of depolarization of the frozen MCD samples can be determined by comparing the CD spectra of a standard CD active solution, for example, a nickel (+)-tartrate solution placed before and after the sample. The natural CD and zero-field baseline effects due to the optical quality of the frozen sample can be corrected by subtracting the corresponding zero-field scan at each temperature. Cryogenic temperature spectra have also been recorded using Shpol'skii (shock-frozen n-alkane solutions) and argon matrices. Narrow bandwidths are achieved, making the resolution of vibrational

bands much easier than in vitreous solutions but the analysis is complicated by the fact that, unlike in vitreous solutions, the alignment of the sample is usually not random. Multiple sites can exist, each with a different overall energy, resulting in a series of overlapping spectral bands, one for each site.

Solid state spectra from thin films on quartz disks are relatively easy to measure at all temperatures but the spectral data are complicated by the broadening that arises due to the Davydov effect. While this enables spectra to be recorded over a wavelength range down to 200 nm, the spectral envelopes are not at all similar to the spectral bands observed in either the vapor or solution phases. An alternative technique that mixes the matrix isolation and thin film advantages is to dissolve the solute into polymers. The subsequent cast film may allow distortion-free and solvent-reduced spectral measurements at a range of temperatures.

3.2 Analysis of the Three Faraday Terms

The modern theoretical background to MCD spectroscopy is based on the earlier research on MORD spectroscopy, which involved an estimation of the magnitudes of the three so-called Faraday terms, $\mathcal{A}$, $\mathcal{B}$, and $\mathcal{C}$, used to quantify the effect of the applied field on the Zeeman splitting of the absorption bands for lcp and rcp light, the field-induced mixing of zero-field states, and the Zeeman splitting-based ground state population adjustment, respectively. Although MORD spectroscopy was developed first, MCD spectroscopy became the dominant technique after photoelastic modulators became available because there is greater resolution of the component spectral bands within the MCD experiment and there is typically no signal due to the solvent and cell, a significant factor that had to be compensated for in MORD experiments. In MORD spectroscopy, a positive ϕ value denotes rotation of a plane polarized beam in a clockwise or right-handed direction when viewed toward the source, while in contrast absorption of incident lcp light results in a positive signal within the MCD intensity definition. When the existing MORD conventions were initially adopted in MCD spectroscopy this led to negative MCD ΔA_{l-r} intensity being associated with positive Faraday term values so Stephens and Schatz later modified the intensity equations to better fit MCD spectroscopy. In any review of the MCD literature the conventions used by different authors need to be carefully checked.[2]

In the case of MCD spectroscopy, for a fully allowed electronic transition based on the rigid shift, Born–Oppenheimer, and Franck–Condon approximations, the intensity equation, according to the modified conventions recommended by Stephens, Piepho and Schatz,[3,4] is

$$\frac{\Delta A_{l-r}}{E} = 152.5Bcl\left[\mathcal{A}_1\left(-\frac{\mathrm{df}}{\mathrm{dE}}\right) + \left(\mathcal{B}_0 + \frac{\mathcal{C}_0}{\mathrm{kT}}\right)f\right] \tag{7}$$

ΔA_{l-r} is the differential absorbance of lcp and rcp light, B is the field strength, cl is the product of the concentration (mol.L^{-1}) and pathlength (cm), E represents the energy coordinate in cm^{-1} and is used here to signify that the expression is for the entire spectral band rather than for just one wavelength, while f is a normalized band shape function (normally a Gaussian-shaped curve).

The dipole strength of the absorption intensity in the absence of an applied field is

$$\mathcal{D}_0 = \frac{3.062\times 10^{-3}}{\nu_{\max}}\int \varepsilon\,\mathrm{d}\nu \approx \frac{\langle A\rangle_0}{326.6cl} = \frac{\langle \varepsilon\rangle_0}{326.6} \tag{8}$$

where $\mathcal{D}_0$ is expressed in (debye)^2 units (D^2), $\nu_{\max}$ is the band center energy in cm^{-1} and $\langle A\rangle_0$ is the zeroth moment of the intensity for the entire absorption band. The right-hand side of the equation is valid for any symmetrical band shape. It is important to note that throughout this section energies are in cm^{-1} and field strengths are in tesla (T). In practical terms absorption and MCD spectra are normally reported in terms of extinction coefficients ε (M^{-1} cm^{-1}) and $\Delta\varepsilon_{\mathrm{M}}$ (M^{-1} cm^{-1} T^{-1}) based on Beer's Law.

3.3 Identification and Analysis of Faraday A Terms in the Spectra of Porphyrins with Excited State Degeneracy and Near Degeneracy

The $\mathcal{A}_1$ term arises from the Zeeman splitting of an orbitally degenerate excited state (Figure 4). There is a highly distinctive first derivative band shape due to the separation of the individual band centers of the lcp and rcp light absorbing bands. A consideration of equation (5) makes it clear that the $\mathcal{A}_1$ term intensity is based on the relative magnitudes of the combined orbital (L_z) and spin (S_z) angular momenta of electrons within the ground and excited states, labeled as A and J, respectively:

$$\mathcal{A}_1 = -\frac{1}{d_A}\sum \langle \mathrm{J}|\mu_z|J\rangle - \langle \mathrm{A}|\mu_z|A\rangle\left(\left[m_{-1}^{\mathrm{AJ}}\right]^2 - \left[m_{+1}^{\mathrm{AJ}}\right]^2\right) \tag{9}$$

where $\left[m_{-1}^{\mathrm{AJ}}\right]$ and $\left[m_{+1}^{\mathrm{AJ}}\right]$ are the electric dipole matrix elements associated with the absorption of rcp and lcp light, respectively, while d_A relates to the degree of degeneracy of the excited states. The sign convention for handedness used in the subscripts of the matrix elements is the opposite of that used in ΔA_{l-r}. The literature for MCD spectroscopy can be somewhat confusing unless the reader is aware that the classical optics definition used within CD and MCD spectroscopy is based on a perspective toward the light source, while physicists usually favor a perspective along the axis of light propagation. When describing an MCD spectrum use the style, ''positive $\mathcal{A}_1$ term'' for a derivative-shaped signal that is positive to high energy of the cross-over point. For example, the MCD spectrum of zinc octaethylporphyrin (ZnOEP) contains two intense xy-polarized positive $\mathcal{A}_1$ terms at 401 and 564 nm (Figure 4).

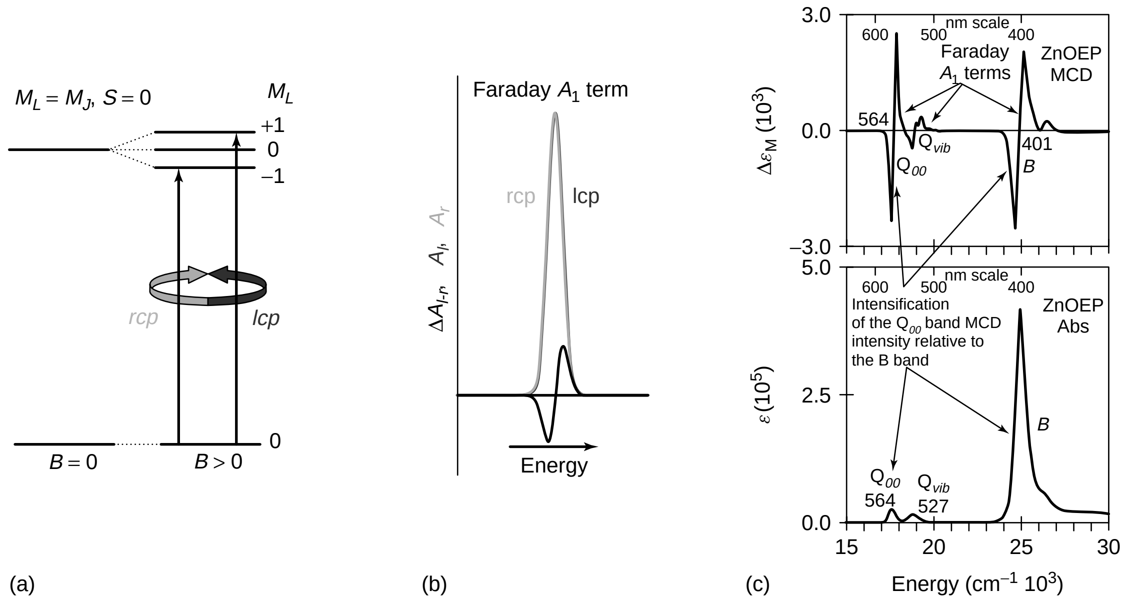

Figure 4 Selection rules for the absorption of lcp and rcp light based on a transition between an orbitally nondegenerate ground state and an orbitally degenerate excited state within a magnetic field applied parallel to the axis of light propagation (a). A derivative-shaped Faraday $\mathcal{A}_1$ term is observed due to the Zeeman splitting of states and the associated energy separation of bands based on the $\Delta M_L = \pm 1$ selection rule (b). (Reprinted from Mack, Stillman and Kobayashi,[2] © Elsevier 2007.) We note that in this example, since $S = 0$ for closed shell atoms or molecules, $J = L$, and $M_J = M_L$. Absorption and MCD spectra of zinc octaethylporphyrin (ZnOEP) in $CHCl_3$ (c). The MCD spectrum is dominated by derivative-shaped $\mathcal{A}_1$ terms. (Reproduced with permission from J. Mack, Y. Asano, N. Kobayashi, M. J. Stillman, *J. Am. Chem. Soc.*, 2005, **127**, 17697–17711. © 2005 American Chemical Society)

The Gaussian-shaped $\mathcal{B}_0$ term arises from second order effects based on the field-induced mixing of the zero-field states via magnetic dipole transition moments (Figure 5). $\mathcal{B}_0$ terms completely dominate the MCD spectrum when there is no threefold or higher rotation axis, since there are no orbitally degenerate states that can be split due to the Zeeman effect. $\mathcal{B}_0$ terms are also present in the spectra of high symmetry complexes but tend to be significantly less intense than the $\mathcal{A}_1$ and $\mathcal{C}_0$ terms, since there is a dependence on the energy separation of states J and K (ΔE_{KJ}) mixed by the field. $\mathcal{B}_0$ term intensity, in the absence of significant field-induced mixing between the ground and excited states, is:

$$B_0 = \frac{2}{d_A}\Re e \sum \frac{\langle \mathrm{J}|\mu_z|K\rangle}{\Delta E_{KJ}}\left(\left[m_{-1}^{\mathrm{AJ}}\right]\left[m_{+1}^{KA}\right] - \left[m_{+1}^{\mathrm{AJ}}\right]\left[m_{-1}^{KA}\right]\right) \quad (10)$$

When a structural modification results in a small (relative to the spectral bandwidth) zero-field splitting of what would otherwise be an orbitally degenerate $\pi\pi^*$ excited state, the resulting derivative-shaped signal is often referred to as a pseudo-$\mathcal{A}_1$ term (Figure 5). The MCD spectrum of tetrabenzotetraazachlorin contains both a pseudo-$\mathcal{A}_1$ term at 341 nm and a coupled pair of oppositely signed $\mathcal{B}_0$ terms at 605 and 749 nm, due to the differing effects of the symmetry lowering structural changes on the major electronic transitions, relative to the spectrum of ZnOEP (Figures 4 and 5). In the absence of the band polarization information that can be derived from the MCD spectrum, the assignment of the 605 nm band as the high energy component of a pair of symmetry-split x- and y-polarized bands would be much more problematic.

3.4 Identification and Analysis of Faraday *C* Terms in the Spectra of Phthalocyanines with Ground State Degeneracy

The $\mathcal{C}_0$ term (Figure 6) arises from the Boltzmann population distribution across a degenerate ground state and, therefore, shows a strong $1/kT$ temperature dependence (equation 7). In many cases, $\mathcal{C}_0$ terms are associated with the presence of an open-shell transition metal. When the splitting of the microstates is small relative to the spectral bandwidths of the lcp and rcp light-specific absorption bands the $\mathcal{C}_0$ term is essentially Gaussian-shaped. $\mathcal{B}_0$ terms can be readily distinguished from $\mathcal{C}_0$ terms by measuring spectra at both room and cryogenic temperatures since they lack a $1/kT$ temperature dependence.

$$\mathcal{C}_0 = -\frac{1}{d_A}\sum \langle \mathrm{A}|\mu_z|A\rangle \left(\left[m_{-1}^{\mathrm{AJ}}\right]^2 - \left[m_{+1}^{\mathrm{AJ}}\right]^2\right) \quad (11)$$

The temperature dependence of the MCD spectrum of $Na[(CN^-)_2Fe^{III}Pc(-2)]$ (Figure 6) is due to the Faraday $\mathcal{C}_0$ terms associated with the ^2E_g ground state. The signal saturates at low temperature and/or high field when the lowest energy microstate is preferentially populated.

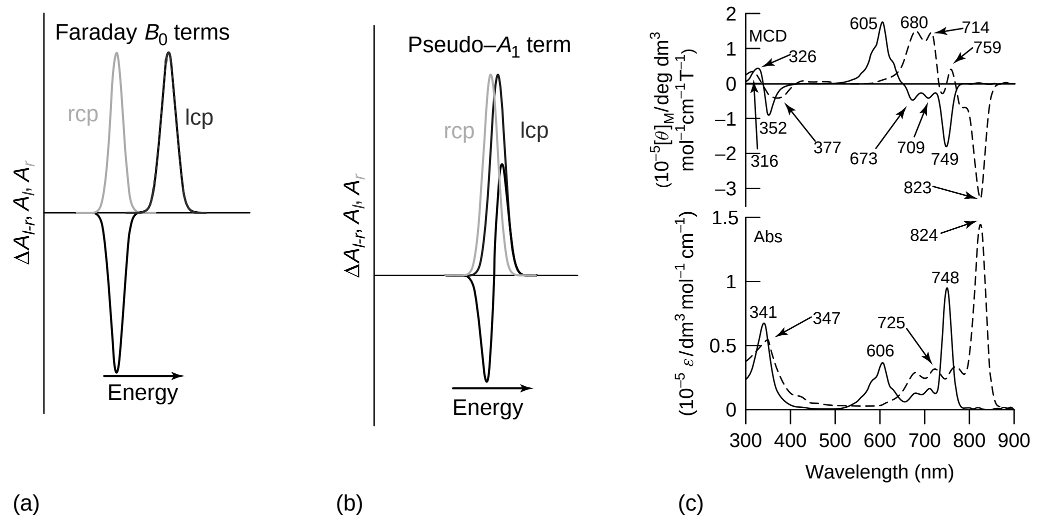

Figure 5 The appearance and the intensity of coupled Faraday $\mathcal{B}_0$ terms (a) depends upon the extent of the zero-field splitting (ZFS) of states relative to the bandwidth. The splitting of the +ve and −ve Gaussian-shaped MCD signals (black) is determined by the energy separation of the lcp and rcp light absorption bands (dark and light gray) that arise within the applied field due to field-induced mixing of states via a magnetic dipole transition moment. When it is relatively minor the two coupled Faraday $\mathcal{B}_0$ terms form a pseudo $\mathcal{A}_1$ term (b). (Reprinted from Mack, Stillman and Kobayashi,[2] © Elsevier 2007.) The MCD and absorption spectra of tetrabenzotetraazachlorin (c, solid lines) and tetranaphthotetraazachlorin (c, broken lines) in chlorobenzene. (Reproduced from Fukuda *et al. Chem. Eur. J.* (2004) **10**, with permission of Wiley-VCH)

Comparison of equations (8), (10), and (11) for $\mathcal{A}_1$, $\mathcal{B}_0$, $\mathcal{C}_0$ with equation (12) for the dipole strength of the absorption band, $\mathcal{D}_0$, demonstrates that the electric dipole contribution is cancelled out within $\mathcal{A}_1/\mathcal{D}_0$, $\mathcal{B}_0/\mathcal{D}_0$ and $\mathcal{C}_0/\mathcal{D}_0$ ratios:

$$\mathcal{D}_0 = \frac{1}{d_A}\sum\left[m_{\pm 1}^{\mathrm{AJ}}\right]^2 \tag{12}$$

Since $\mathcal{D}_0$ can be derived from the corresponding UV-visible absorption spectra, the MCD technique can be used to directly quantify the magnetic moments associated with the ground and excited states. In instances where $S = 0$ and $g_L = 1$, the z-component of the magnetic dipole moments for the ground and excited states can be derived directly from the $\mathcal{A}_1/\mathcal{D}_0$ and $\mathcal{C}_0/\mathcal{D}_0$ ratio:

$$\mu_z(\text{excited state}) = -\frac{\mathcal{A}_1}{\mathcal{D}_0} \quad \mu_z(\text{ground state}) = \frac{\mathcal{C}_0}{\mathcal{D}_0} \tag{13}$$

The method of moments analysis has since been used extensively to derive the magnetic moments of the ground and/or excited states from MCD spectral data by determining the intensity of the MCD and UV-visible absorption bands. In instances where the bands overlap extensively, spectral band deconvolution techniques have also been used.

3.5 MCD Spectroscopy of Inorganic Ions

MORD and MCD spectroscopy have both been used to answer key questions about the electronic structure of inorganic ions, testing the validity of molecular orbital (MO) models of the electronic structure based on the ground and excited state degeneracy information that can be derived from the Faraday $\mathcal{A}_1$ and $\mathcal{C}_0$ terms. Since the MCD experiment usually entails the use of an expensive superconducting cryomagnet, cooled with liquid helium to keep the magnet coil operational and to obtain the cryogenic temperature measurements required in the sample compartment to analyze Faraday $\mathcal{C}_0$ terms, the MCD technique is generally not available in many laboratories around the world and is not a standard spectroscopic technique performed regularly at most university chemistry departments. In recent decades most of the work on inorganic ions has been carried out in the North American context by Prof. W. Roy Mason at Northern Illinois University. For example, in recent years, he has used MCD spectroscopy to assign the spectral bands within the optical spectra of a variety of centered gold cluster complexes, including $M(AuPPh_3)_8^{2+}$, $M =$ Pd or Pt (D_{4d} centered crown structure), and $Au(AuPPh_3)_8^{3+}$ (D_{2h} centered icosahedral fragment structure).[5,6] Spectra were measured from acetonitrile solutions at room temperatures and from nitrate salts in thin films made by casting poly(methylmethacrylate) dissolved in CH_2Cl_2 and then making measurements at cryogenic temperatures. These films, which could be cooled reversibly to 10 K with no cracking, showed no sign of excessive strain or birefringence. The presence of Faraday $\mathcal{A}_1$ terms enabled spectral features to be assigned, which could not be resolved from the absorption spectrum alone and detailed models of the electronic structure to be formulated for the first time.

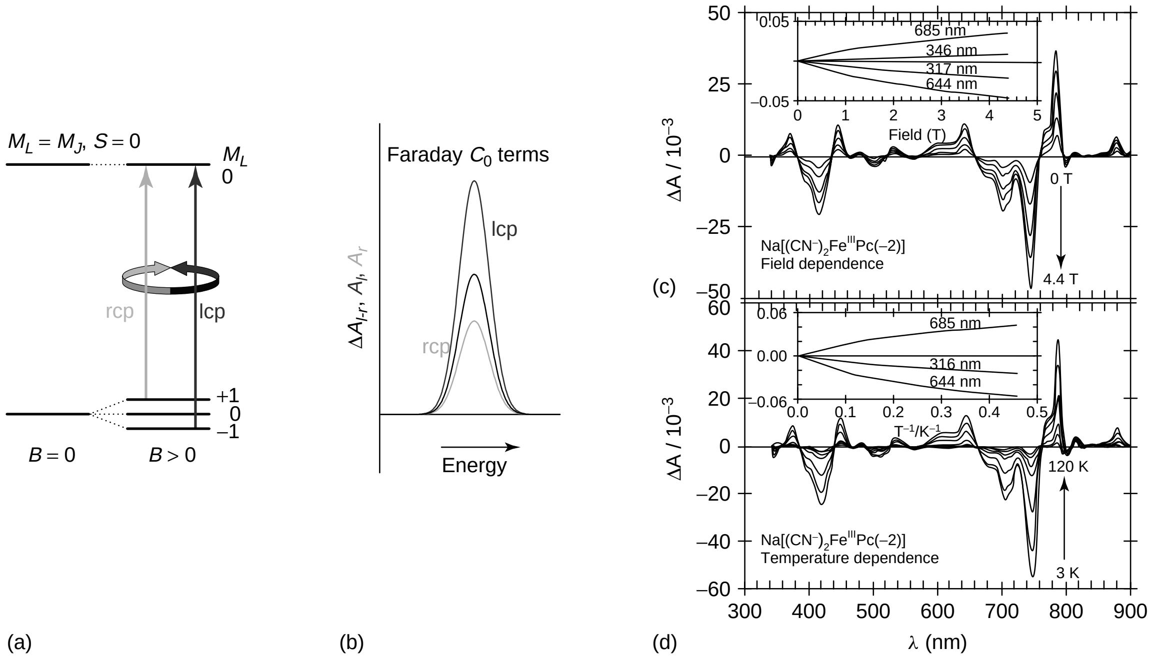

Figure 6 Selection rules (a) for the absorption of circularly polarized light based on a transition between an orbitally degenerate ground state and an orbitally nondegenerate excited state within a magnetic field applied parallel to the axis of light propagation. $\mathcal{C}_0$ terms are extremely temperature sensitive. The $\mathcal{C}_0$ term has a $1/kT$ temperature dependence since the ground state microstates are populated according to a Boltzmann distribution. At very low temperatures, a symmetric Gaussian-shaped Faraday $\mathcal{C}_0$ term (b) is observed because only the lowest split state contributes to the MCD. Understandably, the intensity of this $\mathcal{C}_0$ term dominates the MCD spectrum at low temperatures. At temperatures above the temperature that the lowest state exists with 100% of the population, the measured $\mathcal{C}_0$ term shape begins to become asymmetric due to the separation of the band centers of transitions absorbing lcp and rcp light, until both states are equally populated at very high temperatures at which point an $\mathcal{A}_1$-term-like derivative band will be observed. In this example $S = 0$ so $M_L = M_J$. (Reprinted from Mack, Stillman and Kobayashi,[2] © Elsevier 2007.) MCD changes observed for a 1 mm glass of $Na[(CN^-)_2Fe^{III}Pc(-2)]$ (c) when the temperature is held constant at 3.8 K and the magnetic field is varied between 0 and 4.4 T (the inset displays the change in MCD intensity versus magnetic field at four wavelengths) and (d) when the temperature is varied between 3 and 120 K under a constant 3.92 T magnetic field (the inset displays the change in MCD intensity versus temperature at three wavelengths). 3.6 MCD Spectroscopy and Perimeter Molecular Orbital (MO) Models for Heteroaromatic π-Systems and Metal Complexes

One of the most active areas of MCD research in the past few decades has been the study of the electronic structure of aromatic and heteroaromatic π-systems both within molecules in proteins and as ligands in inorganic and bioinorganic metal complexes. In the late 1940s, Platt[7] proposed a free electron model for describing the π-system perimeter MOs of benzene based on the M_L quantum number and a $M_L = 0, \pm 1, \pm 2, 3$ sequence in terms of ascending energy. The highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) of benzene have $M_L = \pm 1$ and ± 2 nodal properties and can be linked by an allowed $\Delta M_L = \pm 1$ and a forbidden $\Delta M_L = \pm 3$ transition, referred to as these as the B and L bands, respectively. The L band lies at lower energy based on Hund's second rule. Moffitt[8,9] subsequently developed a linear combination of atomic orbitals (LCAO)-based cyclic perimeter model of a wide range of aromatic cyclic polyenes and noted that in the case of heteroaromatic polyenes the nodal patterns of structural homologs derived from the same charged or uncharged parent C_nH_n perimeter are consistently retained and demonstrated that MO model-based methods for predicting the energies and relative intensities of the major spectral bands can be simplified on this basis. Michl[10,11] later developed a qualitative and quantitative perimeter model for predicting the signs of the Q and L bands within the MCD spectra of a wide range of aromatic and heteroaromatic π-systems and demonstrated that this could be used to derive key information about geometry and electronic structure even in the case of low symmetry molecules and complexes. It is important to note that Michl used the original MORD spectroscopy based definitions for the three Faraday terms.[2]

In the case of metal porphyrin complexes, $C_{16}H_{16}^{2-}$ can be viewed as the parent perimeter based on a 16-atom 18 π-electron system with an $M_L = 0, \pm 1, \pm 2, \pm 3, \pm 4, \pm 5, \pm 6, \pm 7, 8$ MO sequence in ascending energy based on the inner ligand perimeter. In the 1960s, Gouterman[12] developed a 4-orbital LCAO model for metal porphyrin complexes with the

HOMOs and LUMO having $M_L = \pm 4, \pm 5$ nodal properties resulting in a forbidden Q transition ($\Delta M_L = \pm 9$) at lower energy and an allowed B transition ($\Delta M_L = \pm 9$) at higher energy. On this basis, MCD spectroscopy provided conclusive evidence that the Q bands were of $\pi\pi^*$ rather than $n\pi^*$ origins based on the ratio of the observed $\mathcal{A}_1/\mathcal{D}_0$ ratios (Figure 4) and that the π-system HOMOs are accidentally nearly degenerate, resulting in a π-system with ideal D_{16h} properties despite the D_{4h} symmetry of the porphyrin ligand.

3.7 Band Deconvolution as a Tool in the Quantitative Analysis of MCD Spectral Data-Application to the Spectra of Porphyrins and Phthalocyanines

The Stillman group[13–15] has used MCD spectroscopy to fully assign the optical spectra of both main group and transition metal phthalocyanines (tetraazatetrabenzoporphyrins) and their anion and cation radical species to resolve the component spectral bands within broad spectral envelopes. The requirement that the same band widths and band centers be used to fit the bands which comprise both the UV-visible absorption and MCD spectra removes much of the ambiguity normally associated with band deconvolution techniques (Figure 7). This approach helped to identify the presence of two overlapping Faraday $\mathcal{A}_1$ terms in the 300–400 nm region of the spectra of metal phthalocyanines based on a study involving a wide range of different axial ligands. Structural modifications result in a substantial separation of the $1a_{1u}$ and $1a_{2u}$ HOMOs so that the π-system no longer has ideal D_{16h} symmetry properties. The band nomenclature for phthalocyanines was modified to include B1 and B2 bands. In the case of π-anion radical species such as $[MgPc(-3)]^-$ and $[ZnPc(-3)]^-$, a partially filled $1e_g^*$ LUMO would be expected to have a partially occupied orbitally degenerate ground state. When MCD spectra were recorded at room and cryogenic temperatures, there was no significant temperature dependence observed beyond some band sharpening due to the presence of hot bands (Figure 8).

Since a $1/kT$ temperature dependence is expected in the case of Faraday $\mathcal{C}_0$ terms this represented definitive evidence that the MCD spectrum is completely dominated by Faraday $\mathcal{B}_0$ terms and that the ground state is subject to a substantial static Jahn–Teller effect. The intense pairs of oppositely signed coupled Faraday $\mathcal{B}_0$ terms identified the major electronic bands within the spectrum and enabled a detailed band assignment. The presence of negative $\mathcal{A}_1$ terms in the spectrum of zinc tetraphenyltetraacenaphthoporphyrin (Figure 8), provided direct spectral evidence that steric hindrance between the peripheral substituents results in a reversal of the alignment of the excited state magnetic

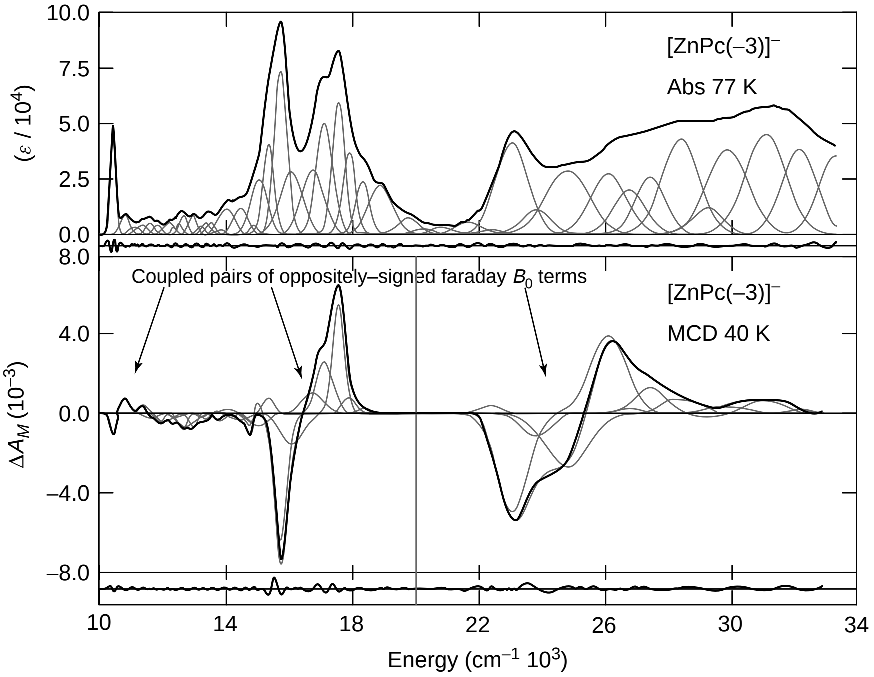

Figure 7 Complete set of 45 bands required to fill the absorption and MCD band envelopes of the phthalocyanine-ring-reduced radical anion species $[ZnPc(-3)]^-$. The absorption spectrum was recorded at 77 K, and the MCD spectrum at 40 K. The bands were fitted using Gaussian-shaped bands with the identical band centers and bandwidths for pairs of absorption and MCD bands. A weak, Faraday $\mathcal{A}_1$ term located at 14 860 cm^{-1} is due to a residual 1% impurity of neutral ZnPc(−2). Experimental data (solid line); fitted data (broken line). moments relative to planar metal porphyrins such as ZnOEP. Spectral band deconvolution analysis was used to quantify the magnitude of the magnetic moments based on the $\mathcal{A}_1/\mathcal{D}_0$ ratios.

3.8 MCD Spectroscopy of Heme Proteins

Since the mid-1960s, MCD spectroscopy has found considerable use in biochemistry for studying heme proteins, such as myoglobin and hemoglobin, and other biologically significant transition metal complexes. MCD spectroscopy has consistently provided key ground and excited state degeneracy information that cannot easily be derived from an analysis of UV-visible absorption spectra and theoretical calculations alone. The complex band morphologies arising from the three Faraday terms result in major changes within the overall MCD spectrum. In contrast, only relatively minor changes in band centers and intensities are typically observed in the UV-visible absorption spectra.[16–19] Since there is a partially filled set of d orbitals, ligand-to-metal charge transfer (LMCT), and metal-to-ligand charge transfer (MLCT) bands are observed in both the absorption and MCD spectra in addition to the $\pi \rightarrow \pi^*$ bands. The ligand field splitting of the d orbitals in metal porphyrinoid complexes tends to be essentially tetragonal based on the tetradentate nature of the porphyrin ligand and some form of axial ligation from above and below the ring. In an O_h symmetry environment the ligand field splitting (Δ_{OCT}) is typically of the order of $10\,000\,cm^{-1}$. Most six coordinate D_{4h} symmetry porphyrinoid complexes are axially distorted ($x = y \neq z$) so that the degeneracy of the e_g and t_{2g} levels is lifted, while lower symmetry porphyrinoids contain a rhombic distortion ($x \neq y \neq z$) in which there is a complete lifting of d orbital degeneracy. In the case of Fe^{II} and Fe^{III} complexes, the spin state of the central metal is determined by the nature of axial ligation from above and below the ring. Strong ligands such as CO and CN^-, which act as π-acceptors based on back bonding, result in low-spin complexes by increasing the separation of the e_g and t_{2g} orbitals, while weak ligands, which act as π-donors, such as F^-, reduce the separation and result in a high-spin state with $S > 1/2$. In the case of Fe^{III} hemes, ligation with azide (N_3^-) can also result in an intermediate spin state with $S = 3/2$. In complexes where there are unpaired electrons so that $S > 0$, spin-orbit coupling (Figure 9) results

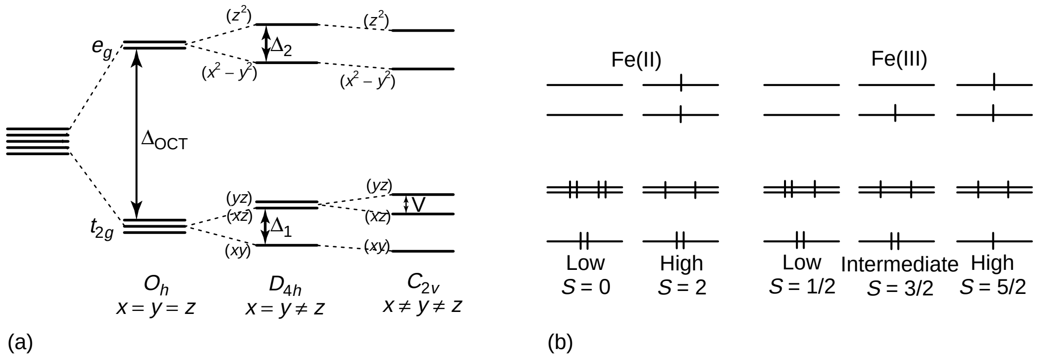

Figure 9 The crystal field splitting of Fe^{II} and Fe^{III} d orbitals in cubic O_h, tetragonal D_{4h} and rhombic C_{2v} environments (a). Only the latter two are typically observed for metal porphyrinoid complexes. The axial and rhombic ligand field parameters are denoted as Δ and V. The low-, intermediate- and high-spin states for Fe^{II} and Fe^{III} based on a tetragonal environment (b). (Reprinted from Mack, Stillman and Kobayashi,[2] © Elsevier 2007)

in zero-field splitting (ZFS) of state degeneracies in addition to the ligand field effects on orbital degeneracy, which are related to the axial and rhombic distortions to the coordination sphere of the central metal.

The spectra arising from the low, intermediate, and high-spin states of Fe^{II} and Fe^{III} porphyrin complexes (e.g., in heme proteins) depend on the nature of axial ligation from above and below the ring as well as the configuration interaction between the main $\pi \rightarrow \pi^*$ and charge transfer states. This results in characteristic ‘‘fingerprint patterns’’ that can be used to derive information,[16–19] which can help to provide answers to questions such as: (i) How many ligands are attached to the iron and what is the nature of these coordinating ligands (for example, in the case of a protein, nitrogen from a histidine, or a sulfur from a cysteine)? (ii) Is the spin state of the iron, which relates to the binding strength of the axial ligand present, high, intermediate, or low? (iii) What is the oxidation state of the central iron? (iv) Can the heme iron be readily oxidized or reduced? (v) And finally, can axial ligands approach and bind to the iron?

Key information about the ground state degeneracy can be derived by determining whether the MCD spectrum contains Faraday $\mathcal{C}_0$ terms with a $1/kT$ temperature dependence (Figure 10). For example, in the case of Fe^{II} and Ru^{II} porphyrinoid MCD spectra, the absence of temperature dependence is consistent with the presence of a low-spin d^6 central metal configuration with $S = 0$. For heme proteins, this configuration can normally be obtained through reduction with $Na_2S_2O_4$ and the addition of a strong axial ligand. The MCD spectra of low-spin d^6 porphyrinoid complexes, such as Fe^{II}Pc and Ru^{II}Pc, are dominated by Faraday $\mathcal{A}_1$ terms and are typically similar to those of the main group metal and closed shell d^{10} Pc complexes, complicated somewhat by the presence of MLCT and LMCT in addition to the main $\pi \rightarrow \pi^*$ transition observed for main group metal complexes.

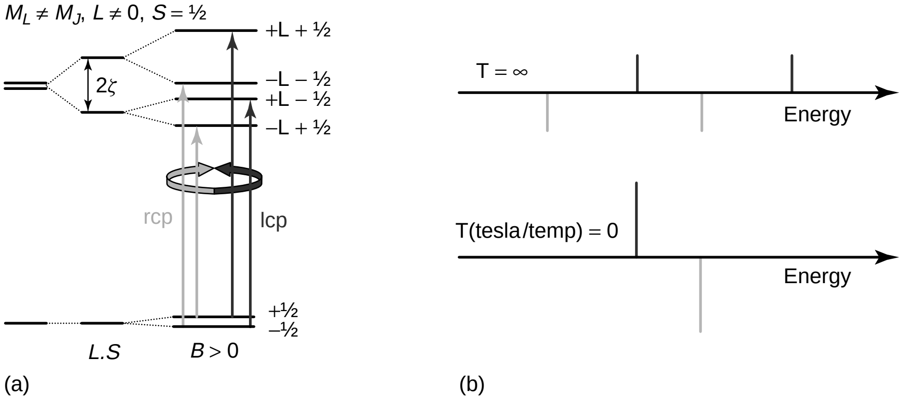

Figure 10 The origin of the Faraday $\mathcal{C}_0$ term from Kramers doublets for the ground and excited states of a paramagnetic complex with $S = 1/2$, a nonorbitally degenerate ground state and orbitally degenerate excited state (a). Temperature dependent, derivative-shaped signals can result when the ground state is orbitally nondegenerate and the excited state is orbitally degenerate (b). (Reprinted from Mack, Stillman and Kobayashi,[2] © Elsevier 2007)

In the case of Fe^{III} hemes with d^5 central metal configurations, LMCT bands in the near infra red (IR) (1000 to 2000 nm) are an ideal probe for determining the extent of rhombic splitting of the $d_{(yz)}$ and $d_{(xz)}$ orbitals (Figure 9). Thomson[20,21] has reported combined EPR, MCD and UV-visible absorption spectroscopic studies which demonstrate that the near IR region LMCT bands for a series of low-spin Fe^{III} hemes can be used to determine the nature of the axial ligands. Because $S = 1/2$, the ground and excited states of low-spin d^5 complexes will split into Kramers doublets within an applied magnetic field with $M_S = -1/2$ and $M_S = +1/2$. At high temperature and low field, the lcp and rcp bands tend to cancel, resulting in a weak MCD signal (Figure 10). As the temperature is lowered or the applied field is increased, the Boltzmann population of the higher sublevel decreases and the $\mathcal{C}_0$ term, therefore, increases in intensity. During measurement of vitreous solutions at cryogenic temperatures (1–4 K) and high field strengths (4–7 K), the lowest component of the ground state will often be populated and the MCD signal will saturate.

Although it is possible in principle to derive the ground state g-factor value by measuring the $\mathcal{C}_0/\mathcal{D}_0$ ratio from the Method of Moments analysis, this is usually not practical, as the absorption bands lack a baseline-to-baseline band envelope or due to overlap with bands associated with other metal centers or chromophores. It should be noted that in some instances, excited state parameters also have to be carefully considered. For example, when ground state degeneracy (and the associated Boltzmann distribution of population across microstates within an applied magnetic field) is introduced by spin degeneracy into what would otherwise be a Faraday $\mathcal{A}_1$ term (Figure 11) a temperature dependent, derivative-shaped signal is observed for $\mathcal{C}_0$ term intensity.

The intensity mechanism for a single isotropic Kramers doublet ground state is

$$\Delta A = 152.5 \tanh\left(\frac{g_L \mu_B B}{kT}\right) \times \left(\left[m^{AJ}_{-1}\right]^2 - \left[m^{AJ}_{+1}\right]^2\right) \qquad (14)$$

The analysis is complicated by the fact that, in the case of porphyrinoids, the molecular symmetry is usually axial rather than isotropic. The g-factor values are therefore different, parallel ($g_{\parallel}$), and perpendicular ($g_{\perp}$), to the applied field, but are averaged (g_{av}) out in solution due to random orientation.

Schatz *et al.*[22] demonstrated that for a D_{4h} symmetry complex with $S = 1/2$ Kramers doublet ground states such as those associated with low-spin Fe^{III} porphyrinoids, the zeroth moment of $\mathcal{C}_0$ term intensity for an axial complex with $g_x \approx g_y$ in the linear limit is given by

$$\langle \Delta\varepsilon \rangle_0 = \frac{K\mu_B B}{3kT} \times \frac{g_{\parallel}[m^{AJ}_{+}]^2}{2} \qquad (15)$$

where $m^{AJ}_{+} \equiv 1/\sqrt{2(m_x + i m_y)}$.

At saturation:

$$\langle \Delta\varepsilon \rangle_0 = \left(K\left[m^{AJ}_{+}\right]^2\right) \frac{\cosh(\alpha)}{\sinh^3(a)} \times \left(\frac{\sinh(2\alpha)}{4} - \frac{\alpha}{2}\right) \qquad (16)$$

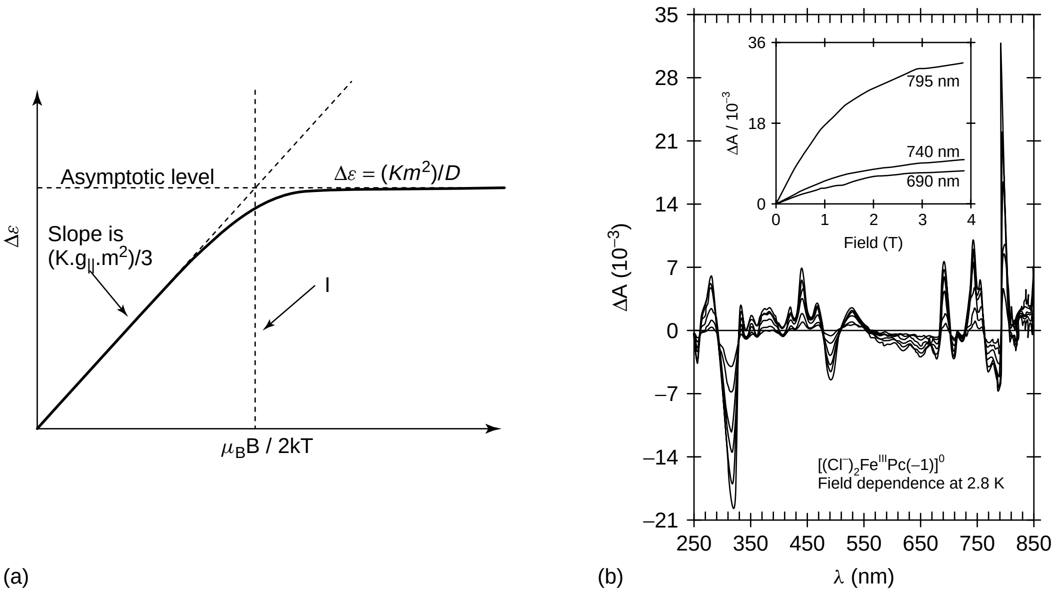

Figure 11 Analysis of an MCD magnetization curve based on equations (15)–(19) (a). (Reprinted from Mack, Stillman and Kobayashi,[2] © Elsevier 2007.) Field dependence of the MCD spectra recorded at 2.8 K from a 1 mm pathlength frozen CH_2Cl_2/C_4H_8Cl solution of $(Cl^-)_2Fe^{III}Pc(-1)$ as the magnetic field strength was varied from 0 to 4 T (b). The inset displays the change in MCD spectral intensity at three wavelengths (690, 740, 795 nm). The spectrum contains Kramers doublet based signals since both the metal and the ligand contain unpaired electrons. (Reproduced with permission from E. A. Ough, Ph.D. Thesis, University of Western Ontario 1994)

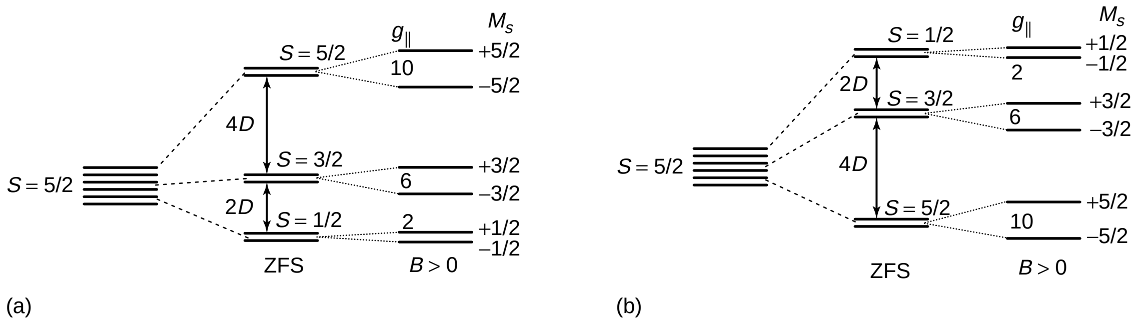

Figure 12 The ZFS of the ground state of a D_{4h} symmetry metal porphyrinoid complex with $S = 5/2$ based on the axial parameter, D. When D is positive, the $S = 1/2$ microstates are stabilized (a), while if D is negative, the $S = 5/2$ microstates are stabilized (b). (Reprinted from Mack, Stillman and Kobayashi,[2] © Elsevier 2007)

where K is a proportionality factor, and α is related to the degree of anisotropy in the g-factor values:

$$\frac{g_\parallel}{g} = \sigma = \cosh(\alpha) \tag{17}$$

$$\frac{1}{L} = \frac{\cosh(\alpha)}{\sinh^3(\alpha)} \times \left(\left(\frac{\sinh(2\alpha)}{4} - \frac{\alpha}{2}\right) - \left(\frac{\alpha}{2}\right)\right) \tag{18}$$

The ratio of the slope to the MCD intensity at saturation defined by an intercept value, I, can be used to derive the expression:

$$g_\parallel = \frac{3I}{L} \tag{19}$$

Thomson[23] demonstrated that is possible to use magnetization curves of $\Delta\varepsilon$ plotted against $\mu_B B/2\ kT$ (Figure 12) based on $\mathcal{C}_0$ term temperature dependence studies at cryogenic temperatures (typically 2 to 50 K) and applied field strengths of 1 to 6 T, to derive values for $g_\parallel$ and $g_\perp$ based on the expressions:

$$g_\parallel = \frac{1}{\sqrt{3}}\sqrt{g_x^2 + g_y^2 + g_z^2} \tag{20}$$

$$g_\perp = \frac{1}{\sqrt{2}}\sqrt{g_x^2 + g_y^2} \tag{21}$$

Band polarization information can also be derived since the slope of the magnetization curves should be the same for all x/y- or z-polarized transitions.

In the case of the $S = 5/2$ ground states of high-spin Fe^{III} complexes, there is a ZFS of the $M_S = \pm 1/2, \pm 3/2, \pm 5/2$ microstates due to spin-orbit coupling based on the axial (D) and rhombic (E) ZFS parameters within the spin Hamiltonian, H, with the central metal (Figure 13) and equation (22):

$$H = D\left(S_z^2 - \frac{1}{3}S^2\right) + E\left(S_x^2 - S_y^2\right) \tag{22}$$

In the early 1980s, Stephens *et al.*,[24] demonstrated that the magnitude of D could be derived by fitting a plot of $\Delta\varepsilon$ against T^{-1} from cryogenic temperature MCD spectral data of a high-spin Fe^{III} tetraphenylporphyrin with a set of quadratic equations based on a least squares fitting approach, since the MCD signal is the sum of the MCD signals of the three sets of Kramers doublets which are populated according to a Boltzmann distribution based on the magnitude and sign of D. An analysis of the temperature dependence over a temperature range in which kT is comparable to the magnitude of the ZFS (typically $<20\ cm^{-1}$) enables D to be calculated.

Analysis of $S = 2$ ground states associated with high-spin d^6 configurations of Fe^{II} are considerably more challenging than the Kramers doublet based systems which arise from d^5 configurations, since the even spin ground states are EPR silent. In 1980, Thomson and Johnson[23] reported multiple nested magnetization curves (Figure 13) for the ground state of high-spin Fe^{II} myoglobin but did not attempt a detailed analysis due to the complexity of the field-induced mixing of the ZFS components. During the 1990s, Solomon[25,26] developed techniques for analyzing variable temperature variable field (VTVF) MCD spectra for non-Kramers doublet ground states as part of a wide-ranging study of nonheme iron enzymes. Solomon has demonstrated that it is possible to calculate values for the ligand field splitting properties, Δ and V (Figure 9) of the t_{2g} set of orbitals of high-spin $S = 2$ Fe^{II} complexes derived from analysis of nested magnetization curves (Figure 13) based on experimentally obtained values of the zero-field rhombic splitting (δ) of the $M_S = \pm 2$ level and $g_\parallel$.

In addition, work by Solomon's group at Stanford University on copper binding active sites has been particularly significant in terms of establishing the power of variable temperature and field studies.[27] The unique spectral and structural features of the copper–protein active sites and their intermediates have been studied in depth based on a wide range of different spectroscopic techniques. This has provided detailed insights into the nature of these sites that

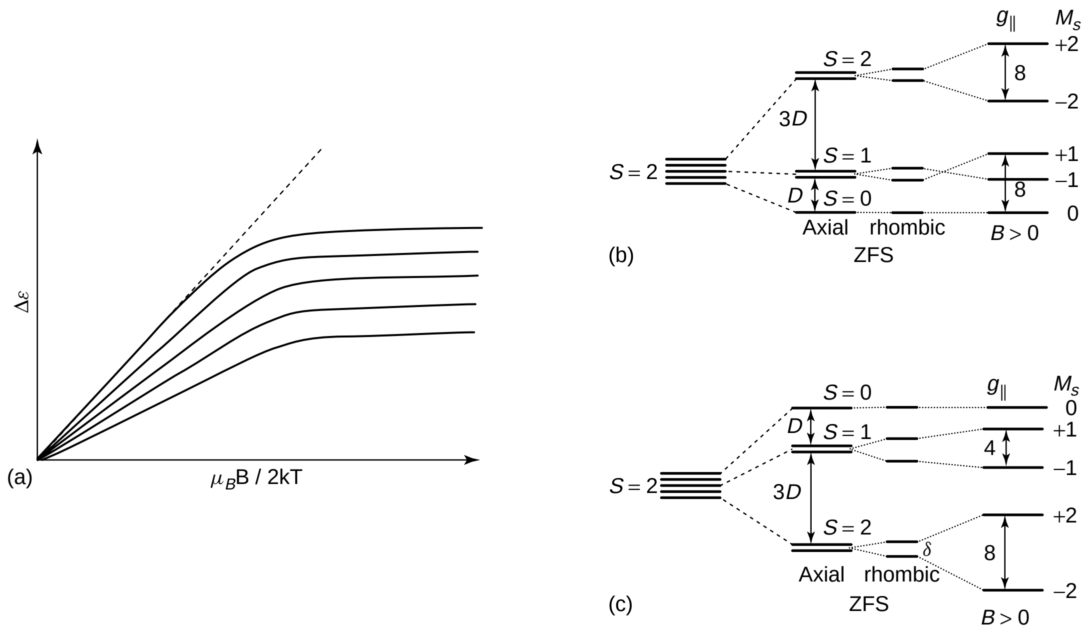

Figure 13 When there is a non-Kramers doublet ground state, complex nested magnetizations are observed at different temperatures (a). The ZFS of the ground state of a D_{4h} symmetry metal porphyrinoid complex with $S = 2$ based on positive (b) and negative (c) values for the axial parameter, D. (Reprinted from Mack, Stillman and Kobayashi,[2] © Elsevier 2007)

has enhanced the understanding of their contributions to the unique catalytic functions in biology.

Although the focus of this section has primarily been on iron and copper complexes, probably the most important transition metals biologically studied by the MCD technique, variable temperature and field dependence studies have also been carried out for complexes of other transition metals such as cobalt and manganese and the techniques described for iron and copper can easily be applied to other metals based on the nature of the ground state. MCD spectroscopy has the key advantage, over other techniques used to study bulk magnetic properties of an entire sample, that spectral bands associated with specific metal centers can be studied in isolation.

3.9 X-ray MCD Spectroscopy

In recent years the use of MCD spectroscopy has been extended beyond the UV-visible-near IR region to synchrotron-based L-edge absorption experiments. Initially X-ray MCD was only used to investigate ferromagnetic systems, because paramagnetic systems required very high fields and/or very low temperatures to saturate the magnetization properties of the sample. In 2001, Cramer[28] successfully extended this earlier work to the Ni center of Fe–Ni hydrogenase in *Desulfovibrio desulfuricans* by utilizing temperatures <1 K and a 2 T magnetic field as a new approach to determining localized spin states at specific metal sites within the proteins. Since then a number of similar studies have been reported.

3.10 Key Features in Selecting MCD Spectroscopy as a Technique with which to Probe the Electronic Structure of Atoms, Ions and Molecules

MCD spectroscopy is and will continue to be a valuable spectroscopic probe for molecules and metal complexes of high symmetry. The technique is complementary to EPR spectroscopy and provides key ground and excited state degeneracy information that is required to fully understand the electronic structure and assign the associated optical properties. Even when the symmetry is lowered substantially, Michl's perimeter model approach can be used in the case of aromatic and heteroaromatic molecules, to analyze the optical properties in the readily accessible UV-visible-near IR regions based on the orbital angular momentum properties associated with the ring current of the heteroaromatic π-system. Since the same spectral bands are also observed in the UV-visible absorption spectrum, MCD spectroscopy can be used to derive quantitative values for the magnetic moments associated with the ground and/or excited states.

4 ABBREVIATIONS AND ACRONYMS

CD = circular dichroism; EPR = electron paramagnetic resonance; HOMO = highest occupied molecular orbita; IR = infra red; LCAO = linear combination of atomic orbitals; LUMO = lowest unoccupied molecular orbital; lcp = left circularly polarized; LMCT =

ligand-to-metal charge transfer; MLCT = metal-to-ligand charge transfer; MCD = magnetic circular dichroism; MO = molecular orbital; MORD = magnetic optical rotatory dispersion; NMR = nuclear magnetic resonance; OEP = octaethylporphyrin; ORD = optical rotatory dispersion; Pc = phthalocyanine; rcp = right circularly polarized; TPP = tetraphenylporphyrin; VTVF = variable temperature variable field; ZFS = zero-field splitting; ZnOEP = zinc octaethylporphyrin.

METHOD SUMMARY

Acronyms, Synonyms

- Inductively coupled plasma mass spectrometry (ICP-MS)
- Inductively coupled plasma optical emission spectrometry (ICP-OES)

Measured physical quantities

- ICP-OES: emission spectra of atoms and ions in the gas phase; wavelengths (λ, nm) and peak intensity as output current of the transducer (I, nA);
- ICP-MS: atomic mass spectra of the generated ions: accurate mass measurement based on m/z values, and peak intensity as counts per second (cps).

Information available

- ICP-OES: quantification of more than 70 elements present at the concentration levels from part-per-billion up to weight percent in a single run after calibration (2 min);
- ICP-MS: quantification of more than 70 elements present at the concentration levels from part-per-trillion up to part-per-million in a single run after calibration in time comparable to that in ICP-OES.

Information not available, limitations

- This is a destructive analysis and structural information is lost.
- There are troublesome spectral interferences, spectral line overlapping in ICP-OES, and polyatomic interferences in ICP-MS.
- ICP-OES: atomic/ionic spectral lines must be within the range 160–800 nm. Gaseous elements, halogens, and carbon are not determined. There are poor detection limits for biologically important elements (As, Se, Pb, Th, etc.) in the radial viewing spectrometers.
- ICP-MS: ionization energy of elements must be lower than that for Ar (15.8 eV). The determination of nonmetals is possible only with modern instruments and detector lifetime is limited.

Examples of questions that can be answered

- What is the element profile in a given material?
- Is this environment (air, water, soil, living organisms) contaminated with metals?
- Are people living in this area exposed to metals in air, water, and/or food?
- Is this dairy product a good source of essential elements?
- What is the pharmacokinetics of metal or metal-tagged drug in the living organism?
- Is this plant a good candidate for phytoremediation of heavy metals and or metalloids?
- Are the levels of wear metals in the motor oil from this airplane acceptable?
- What are the trace impurities in semiconductor materials (ICP-MS)?
- What are the chromatographic elution profiles of the elements in the sample?

Major advantages

- ICP-OES: this is a well-established technique, easily adopted for routine determinations of metals in geochemical, environmental, biological samples and in the preventive maintenance of aircraft and vehicle lubricants. The quantitative information on major, minor, and trace elements is obtained with high-speed, good accuracy, and precision.
- ICP-MS: this is the primary detection technique in the determination and speciation of trace elements. It has excellent selectivity, sensitivity, multielement and isotopic capability and easy coupling with different separation techniques (especially low-flow and low-volume chromatographic methods). Modern instruments enable practically interference-free response over the wide range of element concentrations in a variety of samples and quantification of metalloids and nonmetals.

Major disadvantages

- ICP: elevated cost, low efficiency of sample introduction via pneumatic nebulization, poor tolerance of plasma to organic solvents, and high salt contents;
- ICP-MS: elevated cost (although less than most molecular MS instrumentation), possibly troublesome polyatomic interferences, low ionization efficiency for biologically important elements (Se, S, P, halogens), and, in most commercially available instruments, sequentially scanning nature of mass analyzer and detection system.
- ICP-OES: elevated, but lower cost with respect to ICP-MS; common interferences caused by the overlapping of spectral lines; detection limits that are 2 to 3 orders of magnitude higher with respect to ICP-MS.

Sample constraints

- Liquid samples are typically analyzed, gaseous phase from hydride generation is easily accepted, and solids can be introduced as slurries or after appropriate pretreatment procedure aimed at solubilization and/or preconcentration of the analytes. However, laser ablation techniques continue to increase in popularity.
- When the liquid sample is directly introduced to ICP, about 2–3 mL is needed to complete the measurement.

1 INTRODUCTION

Optical emission spectrometry (OES) is the oldest multielemental atomic spectrometric technique. The analytical applications are based on the spontaneous emission of photons from gaseous atoms and ions that have been generated from the sample and then thermally excited. Because the excited atom or ion only emits light of certain wavelengths, specific atomic or ionic spectra are produced, enabling qualitative evaluation of elements in the sample. A calibration curve relating the intensity of spectral line with the concentration can be used for the quantification of a given element. In principle, the emission source should provide a high rate of atomization and excitation of as many elements as possible, including those with low and high excitation energy. It should also assure reproducible atomization and excitation to yield good accuracy and precision in single-element and multielement analyses. Furthermore, it is desired that atomization and excitation occur in an inert chemical environment to minimize possible interferences. Different flame, spark, and arc sources have been used as the excitation sources since the beginning of the twentieth century; however, none of these approximates the full list of conditions listed above. It was not until mid-1960s when the analytically useful plasma sources were developed, substantially improving the capabilities of OES. The first commercially available inductively coupled plasma optical emission spectrometry (ICP-OES) was introduced in 1974 and since then the revival of OES can be noted.

Inductively coupled plasma (ICP) is an electrically neutral, highly ionized gas composed of ions, electrons, and neutral species. Typically, it is sustained by a stream of argon, which is energized with a radiofrequency (RF) electromagnetic field. Owing to the high temperature in the observation zone (6000–7000 K), efficient and reproducible

atomization, excitation, and ionization occur for a variety of elements in different chemical matrices. The high temperature avoids chemical interferences, and the ICP presents high stability and less noise than other excitation sources. ICP-OES is characterized by complex spectra. For example, the 70 elements typically determined give rise to at least 70 000 emission lines in the 160–800 nm wavelength range. A consequence of this high density of spectral information is the need for high resolving power (bandpass at least 0.01 nm, or $\lambda/\Delta\lambda \geq 100\,000$). Optical spectrometers are typically equipped with grating monochromators and can operate in sequential or simultaneous multichannel mode.

Since high ionization is achieved in the ICP, it has also been explored as the ionization source for atomic mass spectrometry. The first inductively coupled plasma mass spectrometry (ICP-MS) publication was by Houk *et al.* in 1980.[1] Similar to ICP-OES, in most applications, the liquid sample is introduced into the plasma as an aerosol. This aerosol is carried by the stream of argon, which punctures the plasma, forming a central channel where atomization and ionization take place. In contrast to typical optical instruments, with the mass spectrometer the plasma torch is mounted horizontally, enabling the extraction of ions into a vacuum system. In the mass analyzer, fast moving ions are separated according to their mass-to-charge ratio (m/z). Consequently, mass spectra obtained are much simpler and easier to interpret as compared to optical emission spectra and isotope-specific detection becomes possible. In a relatively short time, ICP-MS has become recognized as a powerful tool and primary detection technique for element determination and speciation.[2–5]

In Table 1, the principle features of ICP-OES and ICP-MS techniques are presented. As can be observed, each technique presents specific capabilities and limitations, which determine their applications in the analysis of real-world samples. In the following sections, the basic principles of ICP-OES and ICP-MS are described with a special focus on the recent technological and methodological developments. An overview of their applications in inorganic and organometallic analysis is also presented.

2 TECHNICAL BACKGROUND

Even though the physicochemical backgrounds of ICP-OES and ICP-MS are substantially different, in both techniques the ICP serves as the analytical cell. Consequently, the same introduction systems can be used, yet some differences should be noted owing to specific selectivity and sensitivity of each technique. In this section, basic aspects of ICP-OES and ICP-MS are introduced.

2.1 Inductively Coupled Plasma

In Figure 1, the scheme of ICP assembly is presented. The plasma is formed within a quartz torch, which consists of three concentric tubes through which argon gas is introduced at different flow rates. A RF electromagnetic field (27.12 or 40.68 MHz) is generated at the top of the torch using a ‘‘load coil’’.

When the argon stream enters through the outer tube of the torch (10–16 L min^{-1}) the plasma is ignited by a spark discharge and the charged particles are forced to flow in a closed annular path. These fast moving ions and electrons collide with other atoms of argon to produce further ionization. High thermal energy results from the resistance of charged particles to their flow and the plasma becomes self-sustained. The argon stream flowing by the external tube is used to cool the torch as well and also helps to center and stabilize the plasma because of the helical gas flow. The liquid or gaseous sample is introduced into plasma through the inner torch tube (argon flow 0.5–1.5 L min^{-1}) and the thermal energy causes sample atomization, excitation, and ionization. The intermediate argon flow (auxiliary gas, 0–1.5 L min^{-1}) is optional and it is recommended for high organic solvent content. The plasma contains various ‘‘regions’’ where different steps of the excitation/ionization process are carried out. The region at the base of the plasma, closest to the nebulizer flow, is called the *preheating zone* (PHZ). This region is involved in desolvation of the aerosol, leaving the salt form of the analyte. Subsequent vaporization of the salt

Table 1 Comparison of the ICP-OES and ICP-MS techniques

	ICP-OES	ICP-MS
ICP function	Excitation source (mounted vertically or horizontally)	Ionization source (mounted horizontally)
Interface ICP spectrometer	Radial or axial view of spontaneous emission occurring in ICP	Ion extraction from ICP
Spectrum type	Electromagnetic: atomic/ionic emission lines *complicated*	Mass spectra: m/z of ions *simple*
Resolution	Grating monochromator	Mass analyzer
Common detectors	Photomultiplier tubes, photodiode array	Electron multipliers, Faraday cup
Analytical information	Multielemental	Multielemental
Qualitative analysis	Wavelength	m/z value
Quantitative analysis	Peak intensity at specific (λ photocurrent)	Peak intensity at specific m/z (counts per second)
Isotope capabilities	No	Yes
Detection limits	Part-per-billion levels	Part-per-trillion levels
Linear dynamic range	Up to 6 orders of magnitude	Up to 9 orders of magnitude
Interferences	Chemical–no Spectral–yes	Chemical–no Spectral–yes

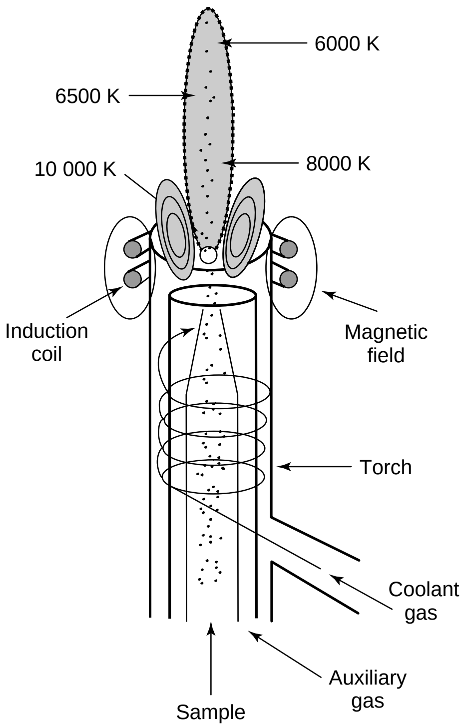

Figure 1 Inductively coupled plasma

produces a gas phase, which is then atomized. The initial radiation zone (IRZ) and the normal analytical zone (NAZ) are involved in the excitation and radiation of the sample. A toroidal region at the base of the plasma is formed by the puncture of nebulized sample, called the *inductive region* (IR).

The advantages of ICP as an ionization/excitation source include high temperatures, relatively long analyte residence times, high electron density, efficient ionization (for most elements), good stability, and a relatively inert environment. In addition, singly charged positive element ions are primarily generated (with the exception of those with low second ionization energy, like barium), so the mass spectra obtained are simple. Assuming an electron density of $10^{15}\,cm^{-3}$ and a source temperature of 7500 K, Houk calculated that more than 50 elements (mainly metals) form singly charged positive ions to an extent >90%.[2] For metalloids and some nonmetals, good ionization yields were also obtained. Thus, the calculated ionization yields for As, Se, P, S, and Br, whose first ionization potentials are 9.81, 9.75, 10.49, 10.36, and 11.81 eV (15.8 eV for Ar), were 52, 33, 33, 14, and 5% respectively.[2] Most of the elements have second ionization energies higher that 15 eV (except Ba and light rare earths), so the atomic doubly charged ions are not abundant in the plasma. It should be noted that the emission lines of singly charged ions are often the most useful analytical lines in ICP-OES.

In contrast to the numerous advantages, high solvent and/or salt loads considerably alter the stability of the plasma and its excitation/ionization characteristics, which imposes more rigorous requirements for sample composition.

The most obvious difference in ICP assembly in OES and MS is its vertical or horizontal mounting, respectively. A larger diameter plasma torch (9–27 mm) is typically used in OES in order to increase the residence time of analytes in the plasma. On the other hand, a long residence time is not convenient for ICP-MS, because it favors the formation of doubly charged ions.

2.2 Sample Introduction

The vast majority of ICP-based analyzes are performed on liquid samples that are introduced to the plasma in the form of an aerosol. In this case, sample introduction system consists of four parts: (i) a nebulizer, which generates an aerosol; (ii) a spray chamber, which filters the aerosol and transports it to the plasma; (iii) a desolvation system to reduce the mass of solvent reaching the plasma; (iv) an injector tube to introduce the aerosol into the plasma base.

Different types of nebulizers are commercially available and their detailed descriptions can be found elsewhere.[6–8] In Figure 2, general schemes of pneumatic and ultrasonic nebulizers are presented. In the concentric pneumatic nebulizer, both the gas stream and the liquid flow in the same direction (Figure 2a), while in the cross flow and Babington nebulizers, the two streams are at right angles to each other (Figure 2b,c). When the gas travels at a high flow rate, it creates a drop in pressure near the tip, which draws the liquid through the inner tube and a sample emerges as an aerosol. In the ultrasonic nebulizer (USN, Figure 2d), a thin film of the solution flows over the surface of a piezoelectric transducer and is converted to the aerosol by the high-frequency vibrations from the transducer. The common shortcoming of the above nebulizers is low transport efficiency. This important parameter depends primarily on the mean droplet size of the aerosol and on the distribution of the droplet size. It should also be noted that the ionization capabilities of the plasma depend inversely on the particle size of the aerosol. In a conventional concentric nebulizer at typical solution uptake rates ($1-2\,mL\,min^{-1}$), only 1–2% of the solution aspirated makes its way to the plasma. In the USNs, the transport efficiency is usually higher (10–30%). To improve the ''quality'' of the aerosol traveling to the plasma, different designs of spray chamber have been developed. The most common are double-pass or Scott-type, cyclonic, and single-pass chambers (Figure 3).[8]

Finally, several desolvation systems have been proposed to reduce the solvent loading to the plasma, thus improving its performance and avoiding interferences. Most desolvation systems comprise two steps: (i) heating, in which the solvent is totally or partially evaporated from the aerosol droplets; and (ii) removal of solvent vapor from the aerosol stream. More detailed information can be found elsewhere.[8]

The analysis of microsamples and coupling ICP with different liquid separation techniques require low-consumption introduction systems. In principle, for standard-sized analytical columns, the flow rate in liquid

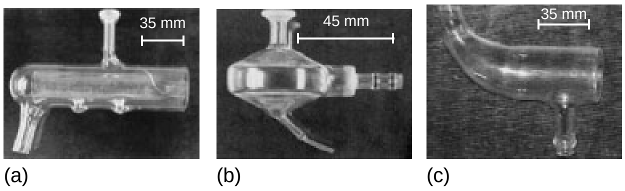

Figure 3 Different designs of spray chamber: (a) double pass; (b) cyclonic; (c) single pass. (Reproduced with permission Mora, Maestre, Hernandis and Todoli[8] © 2003, Elsevier)

chromatographic separation (0.5–1.2 mL min^{-1}) is compatible with the aspiration rate of traditional pneumatic nebulizers, so the column outlet can be connected directly with the liquid inlet of the nebulizer using polymeric or stainless steel tubing. However, low transport efficiency of traditional pneumatic nebulizers is an important limiting factor. Furthermore, in such coupling the composition of the column effluent can affect the performance of the plasma.[10–12] The increased efficiency of sample introduction to ICP can be achieved by using microconcentric nebulizer (MCN), hydraulic high pressure nebulizer (HHPN), direct injection nebulizer (DIN), high-efficiency nebulizer (HEN) or direct injection high-efficiency nebulizer (DIHEN).[6,7,9] These are low-flow devices and are particularly well suited for microbore and capillary liquid chromatography (LC). The commercially available MCNs operate at flow rates of 10–100 µL min^{-1}, yielding a transport efficiency close to 50%.[13–16] The DIN was developed by Shum *et al.*[17]; this nebulizer is positioned inside the ICP torch and its nozzle is placed only a few millimeters from the base of the plasma. The sample uptake requires a flow rate in the range 30–150 µL min^{-1} at relatively high gas flow rate (1 L min^{-1}). The DIN does not use a spray chamber and thus offers 100% analyte transport efficiency, low dead volume (<2 µL), rapid wash-in and wash-out times, low memory effects, enhanced sensitivity, and improved precision as compared to nebulizer–spray chamber arrangements. However, easy clogging of the DIN capillary hinders the introduction of elevated salt/buffer concentrations. Plasma cooling has also been observed.[18] An alternative low-flow design is the HEN, which is composed of a small capillary and a spray chamber. The efficient formation of uniform fine droplets is achieved at 40–100 µL min^{-1} sample flow rate (gas flow rate 1 L min^{-1}, as in the DIN). The designs of HEN and DIN have been combined and modified to produce a simple and low-cost DIHEN. The DIHEN offers optimal sensitivity at 1–100 µL min^{-1} sample flow rate and significantly lower injector gas flow rates (0.25 L min^{-1}). It should be stressed that, in spite of higher transport efficiency, the analyte(s) mass introduced to plasma through the low-consumption devices is generally low, so they are more frequently used in ICP-MS rather than in ICP-OES applications.

The introduction of gaseous samples is another possibility in ICP-based spectrometric techniques. The clear advantage is excellent transport efficiency; however, the applications are limited to the volatile forms of elements. There are several reviews available on gas chromatography

(GC) coupling to ICP,[19,20] and on the applications of hydride generation,[21,22] electrothermal vaporization (ETV),[23] and laser ablation techniques.[24,25] Finally, the introduction of slurries in the analysis of different solid samples should be mentioned.[26]

2.3 Inductively Coupled Plasma Optical Emission Spectrometry

The emission spectra produced in a plasma can be observed using radial, axial, or dual-view configurations. In most commercial instruments, the plasma torch is in a vertical position and spectral data are collected using the side view of the analytical zone (Figure 4). Since only this plasma region is observed, the contribution of spectral and background interferences is generally low, but the sensitivity is relatively poor.

For axial configuration, the torch is moved to the horizontal position and spectral information is collected from the central channel of the plasma. The viewing path is longer with respect to the radial configuration, so the detection limits are improved, typically by a factor of 5–10. However, spectral and matrix-induced interferences are more severe in the axial view. In particular, high concentrations of easily ionized elements (EIE) affect the ionization of other elements in the plasma, causing considerable suppression of the ionic emission lines. Another possible interference is due to the self-absorption effects occurring in the cooler tail plume of the plasma. As a consequence, the axial configuration is not recommended for the analysis of samples containing a wide range of elements at different concentrations. Some commercial instruments have a dual-view system, which enables one to select the configuration according to the sample composition.[27]

As already mentioned, the emission spectra generated in ICP-OES are remarkably rich. Thus, high resolving power is required in order to minimize spectral interferences. Optical spectrometers are typically equipped with grating monochromators based on conventional or echelle-type gratings. In brief, conventional plane grating has a high groove density (up to 3600 grooves mm^{-1}), the radiation strikes the broad faces of the grooves, the diffraction angle is low (10° 22′) and the first-order spectral line typically is used. The required spectral bandwidth (0.01 nm) is achieved by using a large number of grooves and large focal length ($\geq$0.5 m). With the echelle grating, high resolution is achieved by using low groove density (70 grooves/mm) and larger blaze angle (>45°), so the constructive interference is more intense at higher spectral orders (usually 10–1000). The overlapping orders are separated with the use of an auxiliary dispersing element (prism or low-dispersion grating), yielding a two-dimensional, high-resolution spectrum. The focal plane has wavelengths dispersed in the horizontal direction and ordersorted in the vertical direction. An echelle monochromator often provides a spectral bandpass nearly 10 times smaller (higher resolution of about 1 order of magnitude) than that of a conventional plane grating with a similar focal length.[28] The additional advantage here is that ultimately a line spectrum is replaced with a series of stacked broken lines resulting in a two-dimensional array eliminating the need for long focal lengths as well as allowing an easy focus onto 2D-array detectors.

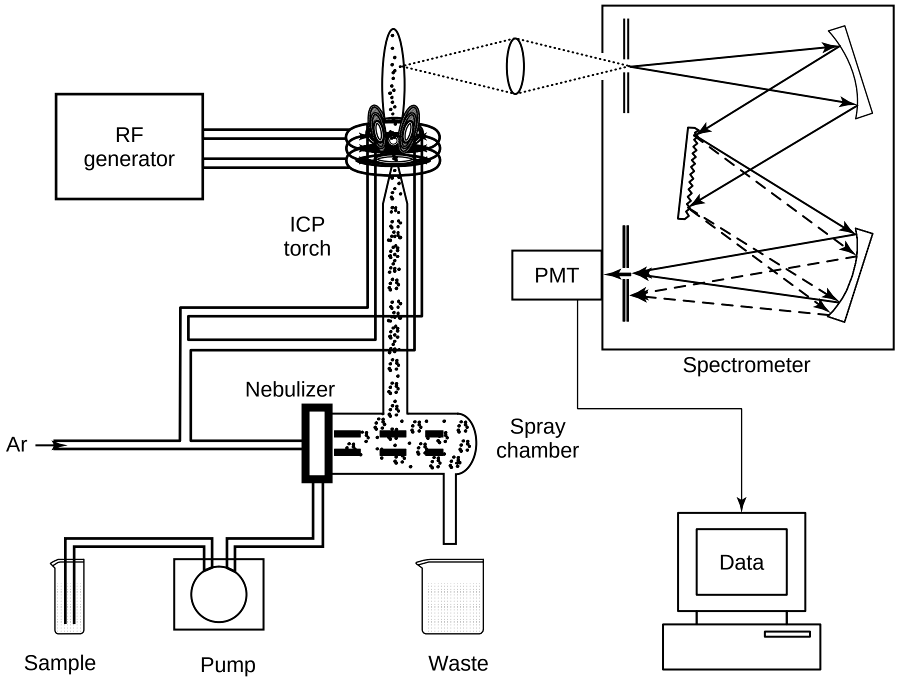

Figure 4 Schematic diagram of ICP-OES instrument

The ICP-OES spectrometers can be adapted either for sequential or simultaneous multielement measurements. In most sequential instruments, one or a few photomultiplier tubes (PMT) are used for detection. Scanning can be accomplished by changing the grating angle at the fixed position of the PMT. In another design, the PMT is rapidly moved along the focal curve of the Rowland circle. The strong point of sequential instruments is high sensitivity of the PMT and the flexibility for measuring the signal at any wavelength. However, only one element is measured at a time, so multielement analysis requires a longer observation time, and thus a larger sample volume. The analytical performance is compromised at high sample throughput and special care is needed to assure good reproducibility of wavelength selection.

In simultaneous spectrometers, the grating, the entrance, and the exit slits are typically fixed on the Rowland circle (Paschen–Runge mount). The detectors and gratings are stationary and the slit positions are tuned for preselected wavelengths. The number of lines is limited by the size of PMTs and the polychromator geometry (up to 60 PMTs). Since all target elements are detected simultaneously, such instruments are faster and more accurate, but only for a predictable set of analytes and potential interferences. The development of solid-state detectors has overcome the limitations of sequential and PMT-based polychromators. Thus, simultaneous spectrometers equipped with charge-coupled or charge injection devices have essentially unlimited possibilities for elemental analysis with better detection limits, precision, and higher throughput than sequential instruments.

In spite of high temperatures in the ICP, several interferences occur in OES. The recombination of argon ions with electrons results in continuum background emission, which becomes important at low analyte concentrations and hence, needs to be corrected. In addition, owing to the complexity of emission spectra, line overlapping is frequently observed. The simplest way to circumvent this problem is to select different analytical line(s) at a wavelength(s) with no background interference. A more efficient solution to the problem of spectral interferences is in the use of high-resolution instruments and/or advanced background correction systems. A common chemical interference is the effect of EIE. These elements have low ionization potentials (e.g., alkaline and alkaline earth elements) and, if present at high concentrations, they may suppress or enhance the emission signal of the target element. The effect of EIEs can be reduced by sample dilution, appropriate selection of instrumental conditions (forward power, viewing height, etc.), and/or mathematical correction.[29]

2.4 Inductively Coupled Plasma Mass Spectrometry

For mass spectrometric measurements, the ions must be extracted from the ICP, which operates at atmospheric pressure, into a vacuum system. A cooled nickel or platinum sampler cone (1 mm diameter), mounted at the entrance to the spectrometer, is used for this approach. In the low-pressure region behind the cone, gas expansion occurs and a fraction of the ions pass through another cone (skimmer), while the majority of the argon is pumped away. Finally, the ions are focused into a more direct path to the mass analyzer using a series of ion ''lenses'', which are simply a series of electrodes, held at variable dc voltages. After separation of ions according to their mass-to-charge ratio (m/z) in the mass analyzer, the detector (channel electron multiplier, Faraday cup, or discrete dynode electron multiplier) converts the ion stream into an electrical signal, which can be correlated through the calibration procedure to the concentration of targeted elements within the sample.[30,31] The most popular mass filter in ICP-MS instruments is the quadrupole analyzer, which gives better than unit mass resolution over a mass range up to $m/z = 300$. A schematic of a quadrupole-based ICP-MS instrument is shown in Figure 5.[9]

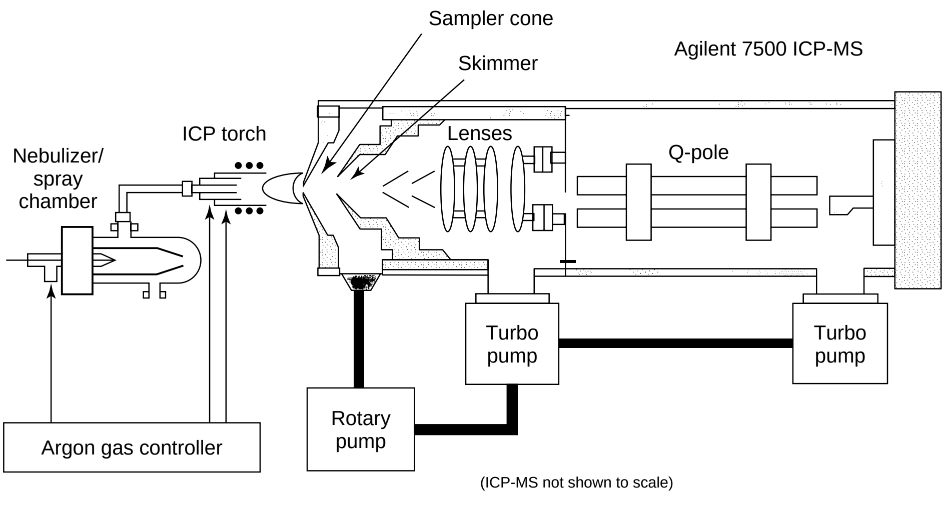

Figure 5 Schematic diagram of a quadrupole-based ICP-MS instrument. (Reprinted from Kannamkumarath, Wrobel, B'Hymer and Caruso[9] © 2002, with permission from Elsevier)

Typical shortcomings of ICP-MS, especially in the early applications, were due to severe polyatomic interferences, low ionization efficiency for biologically important elements (Se, S, P, halogens), and the sequentially scanning nature of the mass analyzer and detection system. When aqueous solutions are aspirated into the ICP, typical background spectra contain signals of several ions such as $OH^+ (m/z = 17)$, $OH_2^+ (m/z = 18)$, $OH_3^+ (m/z = 19)$, $O_2^+ (m/z = 32)$; $ArH^+ (m/z = 41)$, $ArO^+ (m/z = 56)$, $Ar_2^+ (m/z = 80)$ and those formed by less abundant isotopes of Ar, O, and H. Additionally, depending on the plasma operating conditions and also on the composition of sample, different charged species originating from plasma argon, air, and/or sample may be generated with possible isobaric overlap between their m/z values and those of the target ions. In Table 2, common polyatomic interferences observed for some elements are listed.[4,32]

The need for reliable results of total element determinations and, in particular, increasing research interest in speciation analysis have spurred instrumental and methodological development, thus considerably extending the scope and capabilities of ICP-MS. Actual strategies used to enhance the performance of ICP-MS include the following: (i) optimization of plasma operating conditions, (ii) high-resolution instruments, (iii) collision/reaction cell technology, and (iv) isotope analysis. With regard to plasma operating conditions, using reduced RF forward power (500–800 W) and increased nebulizer Ar flow rates (1.5–1.8 L min^{-1}), the plasma becomes ''cooler'', hindering generation of interfering Ar-based ions.[33,34] The weak point of the cold-plasma strategy is the increased contribution of polyatomic charged species originating from the sample matrix. Such interference can be avoided by separating the analyte from the potentially interfering sample components, prior to its introduction to ICP-MS.[35] Thus, different chromatographic, extraction, and dialysis procedures have been reported for the elimination of chloride ions prior to As determination/speciation.[36]

Table 2 Typical isobaric interferences in ICP-MS elemental analysis

Element	The most abundant isotopes	Interfering species
Arsenic	^{75}As (100%)	$^{40}Ar^{35}Cl^+$
Chromium	^{52}Cr (83.79%)	$^{40}Ar^{12}C^+$
Cobalt	^{59}Co (100%)	$^{42}Ca^{16}O^1H^+$, $^{43}Ca^{16}O^+$
Copper	^{63}Cu (69.17%)	$^{46}Ca^{16}O^1H^+$
Iron	^{56}Fe (91.75%)	$^{40}Ar^{16}O^+$, $^{40}Ca^{16}O^+$, $^{23}Na^{35}Cl^+$
Nickel	^{58}Ni (68.08%)	$^{42}Ca^{16}O^+$
Phosphorus	^{31}P (100%)	$^{15}N^{16}O^+$, $^{14}N^{16}OH^+$, $^{12}CH_3{}^{16o+}$, $^{62}Ni^{2+}$
Sulfur	^{32}S (95.02%)	$^{16o_2}+$, $^{14}N^{18}O^+$, $^{15}N^{16}OH^+$
Selenium	^{78} Se (23.77)	$^{40}Ar^{38}Ar^+$, $^{31}P_2^{16o+}$
	^{80} Se (49.61)	$^{40}Ar_2{}^+$, $^{79}BrH^+$
	^{82} Se (8.73)	$^{40}Ar_2H_2{}^+$, $^{12}C^{35}Cl_2{}^+$, $^{34}S^{16}O_3{}^+$, $^{82}Kr^+$, $^{81}BrH^+$, $^{65}Cu^{17}O^+$, $^{64}Zn^{18}O^+$, $^{68}Zn^{14}N^+$

The commercial availability of high-resolution ICP-MS (inductively coupled plasma high-resolution mass spectrometry (ICP-HRMS)) instruments has enabled a significant advance in the analysis/speciation of nonmetal elements. Mass analyzers typically used are composed of either magnetic sector or double-focusing sector device.[37,38] In the magnetic sector, a field is perpendicular to the ion beam from the plasma. The trajectory of the ions in a circular path depends on mass-to-charge ratio, permitting the separation of different elements and isotopes. In double-focusing sector mass analyzers, the ions are additionally subjected to an electrostatic field with the resultant trajectory being dependent on the energy of the ion. The resolving power ($R = m/\Delta m$) of ICP-HRMS can be changed (between 300 and 10 000), as compared to the range of 300–400 typically offered by traditional quadrupole mass analyzers.[39] The desired resolution is achieved by selecting different entrance and exit slit widths. The narrower slit widths used to yield higher resolution also limit the number of ions transmitted to the detector, subsequently reducing sensitivity. An important benefit from sector field instruments is a high signal-to-noise ratio, as a result of very good ion transmission (high sensitivity at low R) and low background (<0.2 $ions^-$/s). As a consequence, detection limits in the range of picogram per liter are typically obtained in the low resolution mode.[40,41] Finally, the excellent precision (0.1–0.5% RSD) of ICP-HRMS should be mentioned. These instruments have dramatically enhanced the analytical capabilities of ICP-MS by increasing the number of elements that can be effectively measured.[3,36,42] In particular, ICP-HRMS technology has been used to mitigate polyatomic interferences in the determination of biologically important As, Fe, P, S, and Se.

The common limitation of the quadrupole and sector field analyzers for multielemental and liquid separation ICP-MS applications is their sequentially scanning character. When the instrument is operated in such noncontinuous manner, the duty cycle is reduced, producing lower signal-to-noise ratio, poorer precision, and also lower mass resolution for the increasing number of elements/isotopes monitored.[43] Logically, longer observation time can be used to circumvent this problem. However, when ICP-MS is used as an element-specific detector for LC, ions are generated from relatively fast transient events and the observation time is restricted by chromatographic peak width. Recently available ICP-time of flight (TOF) mass spectrometers with scan rates up to 20 000 spectra/s can overcome this drawback, because, rather than time-consuming scanning from one mass to the other, the mass filter distinguishes the different isotopes by their individual (m/z-dependent) time of flight to the detector.[35,44] For simultaneous detection of an entire atomic mass range, ICP has also been used with the quadrupole ion traps (QIT), Fourier transform ion cyclotron resonance mass spectrometers (FTICR), and multichannel mass spectrometers.[22,40,45]

Over the past decade, the development of quadrupole ICP-MS instruments equipped with collision/reaction cells inserted between the ion optics and the mass filter has

offered an interesting alternative to high-resolution systems for the removal of polyatomic interferences.[46] Conceptually, a collision/reaction cell for ICP-MS provides adequate conditions for controlled reaction or conversion of the interfering species or the analyte itself, which results in a change of their m/z and thereby enables determination of the element at quadrupole resolution.[43] A collision/reaction cell instrument essentially resembles the configuration of a traditional ICP-MS except that a collision/reaction cell with gas inlet is positioned just before the quadrupole mass analyzer. The cell consists of another quadrupole, hexapole, or octopole to which only RF-voltages are applied. When subjected to this field, incoming ions are focused and collide or react with the collision/reaction gas that is admitted through the cell gas inlet. The collisions and reactions that occur between the analyte ions and the gas molecules can eliminate problematic interferences as follows: (i) collisional deactivation where the energy of the collision gas exceeds the bond energy of the interfering polyatomic; (ii) the analyte reacts with the cell gas shifting its m/z; or (iii) energy discrimination by preferentially reducing the polyatomic ion energy over the analyte ion energy (because the polyatomic has a larger collision cross-section), followed by carefully adjusting the quadrupole bias voltage to admit only the more energetic analyte ions. Unfortunately, under these conditions rather complex secondary collisions and reactions can occur within the cell, leading to the generation of other interfering species. Such secondary interferences are rejected in different ways, depending on the multipole of the cell. Quadrupoles act through mass discrimination, whereas higher-order multipoles, such as hexapoles and octopoles, can discriminate analytes from interferences based on kinetic energy.[3] In particular, the concept of dynamic reaction cell (DRC) technology is based on the use of highly reactive gases (e.g., ammonia or methane) acting as catalysts for ion-molecule chemistry and the ions generated are discriminated in quadrupole.[43,47] Since hexapoles do not function as mass filters, only low reactivity gases (He, H_2, Xe) are used, thus limiting the formation of new ions. In this case, analyte ions can be distinguished from other ions by allowing the cell bias to be slightly less positive than the mass filter bias. This causes ions with the same energy as the cell bias to be rejected, whereas the analyte ions, which have energy higher than the cell bias, can be transmitted. Octopoles operate in a similar manner, but offer higher transmission characteristics, particularly at the lower end of the mass range.[3,46]

One of the main characteristics of mass spectrometry is the possibility of precise and accurate isotope ratio measurements. The isotopic dilution technique is based on the principle that most elements in nature possess fixed isotopic ratios. This natural ratio can be altered by spiking a sample with an analyte standard consisting of a different isotopic abundance. The change in the measured isotopic ratio can then be used to elucidate the original elemental composition of the sample. The only real requirements of this technique are that the analyte of interest has more than one stable isotope and that the spike standards are isotopically pure. Furthermore, isotope dilution has become widely recognized as a definitive technique that can be used to overcome many of the problems associated with instrumental drift and incomplete extraction of analyte from the sample.[48] In the same manner, isotope dilution can also be used to compensate for the poor ionization efficiency exhibited by a number of nonmetal elements. Over the past 40 years, isotope dilution mass spectrometry (IDMS) has proved to be a very effective method for the measurement of total element concentration and as applied to elemental speciation studies.[35,45] In particular, the quadrupole-based spectrometers with collision/reaction cells, high-resolution instruments, and those offering simultaneous monitoring of different ions are well suited for isotopic analysis. If the sector field mass analyzer is operated at low resolution ($R \sim 300$), the isotope ratios can be measured with a precision as high as 0.02% (RSD) and the detection limits are in the picograms per liter range.[35]

3 APPLICATIONS

Historically, most analytical applications of ICP-OES and ICP-MS have addressed total concentrations of elements in real-world matrices. It is now common knowledge that the mobility, bioavailability, retention, and specific biological function of an individual element depend on its physicochemical form. As approved by respective international union of pure and applied chemistry (IUPAC) commissions, ''chemical species'' is a specific and unique molecular, electronic, or nuclear structure of an element. The term ''speciation analysis'' refers to the measurement of the quantities of one or more individual chemical species in a sample.[49] Analytical results are helpful in studies on the mechanisms of element transport and/or degradation in the environment and also on the element pathways in living organisms. Other relevant topics include more efficient elimination and/or recovery of elements from industrial and mining effluents (Hg, As, Cd, etc.), refining of certain industrial processes (tanning with chromium salts, metal-based catalytic mixtures, etc.), development of new metal drugs (Pt, Ru, Ti), as well as promotion of necessary regulations for the commercial use of metal/metalloid based biocides (As, Sn). Different classifications have been proposed for possible elemental forms, depending on the selectivity of measurement (specific compounds versus operationally separated forms), the type of element bonding (chemical bonds versus weak interactions, covalent versus coordination bonds, etc.), molecular structure (inorganic salts, organic and biometals, or biometalloid compounds), and also molecular size (small molecules vs biomolecules).[50–53] A consensus seems to exist in regarding ''large molecules'' as those with molecular weight >5 kDa. In this section, ''small molecules'' are limited to inorganic salts, organometals, and organometalloids with molecular weights <5 kDa.

3.1 Total Concentrations of Elements

The primary application field of ICP-MS and ICP-OES in routine analysis is semiquantitative and quantitative determination of metals and metalloids in a wide range of materials that can be of either natural or anthropogenic origin.

As already discussed, the detection limits of ICP-OES are generally poorer than those of ICP-MS (Table 1), which limits specific applications of this technique. Generally speaking, it can be used for practically all metallic elements in liquid, dissolved, or suspended samples. It is an important tool in geochemistry, providing precise and accurate results for trace, minor, and major elements. This technique is also suitable for the analysis of biological materials, natural, and waste waters, fuels, and lubricating fluids. The industrial applications include process control, evaluation, and quality control of final products in metallurgy, refinery, ceramics, glass, polymer production, as well as catalyst evaluation. The detailed information on these applications can be found in atomic spectrometry updates on environmental, industrial, food, and beverage analysis, which are published annually in the *Journal of Analytical Atomic Spectrometry*.

In principle, the applications of ICP-MS resemble those listed for OES. This technique however is required for samples containing sub-part per billion concentrations of elements. Quantitative information of nonmetals such as P, S, I, B, Br can be obtained. Since atomic mass spectra are much simpler and easier to interpret compared to optical emission spectra, ICP-MS affords superior resolution in the determination of rare earth elements. It is widely used for the control of high-purity materials in semiconductor and electronics industries. The applications also cover the analysis of clinical samples, the use of stable isotopes for metabolic studies, and the determination of radioactive and transuranic elements. In addition to outstanding analytical features for one or a few elements, this technique provides quantitative information on more than 70 elements present from low part-per-trillion to part-per-million concentration range in a single run and within less than 3 min (after sample preparation and calibration). Comprehensive reviews on ICP-MS applications in total element determinations are available.[54–59]

3.2 Speciation of Small Molecules

Speciation studies have been focused on relatively few elements, mainly aluminum, antimony, arsenic, chromium, lead, mercury, selenium, and tin.[60,61] The primary species of these elements studied with ICP-MS detection are presented in Table 3 and they include different oxidation states, alkylated metal and/or metalloid compounds, selenoaminoacids, and selenopeptides. In addition, applications in studies of the pharmacokinetics of metal-based drugs (Pt, V, Au), metalloporphyrins (Ni, V, Fe, etc.), heavy metals in phytochelatins (Cd, Cu, Zn, Hg, etc.) and in humic substances should be mentioned.

A common speciation scheme after sample preparation involves a fractionation step followed by the quantification of element in the obtained fractions. A clear trend exists toward using the techniques that combine separation and detection steps into one operating online system. In these procedures, the selectivity is achieved by application of powerful separation modes (different chromatographic or electrophoretic methods), while the use of atomic spectrometric techniques assures high sensitivity of detection. The number and variety of combinations have been continuously increasing and almost every possible instrumental coupling has been examined. Among element-specific detectors, ICP-MS has become a primary tool in speciation analysis because of its unique features such as (i) monitoring effluents for their elemental composition with high sensitivity, (ii) determination of the target element with the selectivity over coeluting elements, (iii) compensation of incomplete chromatographic resolution from complex matrices, isotope ratio, and isotope dilution capabilities, and (iv) detection of a number of elements virtually simultaneously.[60] On the other hand it should be stressed that hyphenated techniques with atomic spectrometry detection do not provide structural information for the species. If the appropriate standards are available, the assignation of chromatographic peaks can be accomplished by spiking experiments. On the other hand, the identification of unknown forms and/or ultimate confirmation of unexpected compounds observed in the sample require the use of complementary techniques (molecular mass spectrometry or NMR (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Inorganic/Organometallic Molecules***)).

The selection of a suitable separation technique is always dictated by the analyte(s) properties (volatility, stability, polarity, electrical charge, etc.) as well as the sample composition. In speciation of small molecules, different chromatographic and electrophoretic modes have been explored. It should be stressed that, owing to high sensitivity, ICP-MS is especially suitable for low-flow and low-volume chromatographic methods (microbore LC columns or capillary electrophoresis (CE)). The advantages of such coupling include outstanding resolution power, low sample loading, minute amount of column effluent entering plasma, and hence better transport efficiency and enhanced analytical performance of the plasma.

The great majority of small elemental forms are polar or ionic compounds, and thus the first separation technique of choice to address speciation analysis is LC. Of special importance for small molecules are reversed phase, ion-pairing, micellar, and ion exchange techniques that have been reviewed elsewhere.[11,12,18] The optimum separation conditions may not always be used in speciation studies. Compromises are sometimes necessary to avoid possible changes in natural species distribution due to their interaction with stationary and mobile phases (pH conditions, complexing agents, organic modifiers).[61]

Table 3 Elements and their species of low molecular mass analyzed with ICP-OES and ICP-AES detection

Element	"Small molecules" of interest	Importance	Typical samples
Al	Organic complexes with citric, lactic, malonic acids, etc., Al-desferroxiamine	Studies on Al toxicity and detoxification routes	Clinical materials
As	Stable oxidation states: As(III) and As(V)	Higher toxicity of As(III) vs As(V), detoxification routes	Environmental, biological, and clinical samples
	Monomethylarsonic acid (MMAs(V)) Monomethylarsonous acid (MMAs(III)) Dimethylarsinic acid (DMAs(V)) Dimethylarsinous acid (DMAs(III)) Trimethilarsineoxide (TMAsO) Tetramethylarsonium ion (TETRA) Arsenocholine (AsC) Arsenobetaine (AsB) Arsenosugars (AsS)	Biomethylation pathways	
Cr	Stable oxidation states: Cr(III) and Cr(VI)	Toxicity of Cr(VI) versus essentiality of Cr(III)	Natural and waste waters, biological fluids
Hg	Inorganic (Hg(II))	Biomethylation with formation of toxic organomercuric compounds	Sea water, natural and waste waters, sediments, food products, fish tissues, biological fluids
	Mono- and dimethylmercury (MMHg, DMHg) Mono- and diethylmercury (MEHg, DEHg) Monophenylmercury (MPhHg)		
Pb	Inorganic and alkyllead:	Toxicity and persistence of lead species in the environment	Air, sea water, natural waters, biological materials
	$R'_nR''_mPb^{(4-m-n)+}$ (R′-methyl, R″-ethyl)		
Pt	Anticancer drugs and their metabolites:	Pharmacokinetics and toxicological studies	Drug formulations,
	Cisplatin, carboplatin, oxaplatin, lobaplatin, nedaplatin, JM216		Clinical materials
Sb	Oxidation states: Sb(III) and Sb(V)	Higher toxicity of Sb(III) vs Sb(V), possible biomethylation processes	Different types of water, fermentation gases, headspace over microorganism cultures
	Mono-, di- and trimethylated Sb compounds		
Se	Stable oxidation states: Se(IV) and Se(VI)	Elucidation of biological pathways and specific role of Se species, phytoremediation	Environmental samples, yeast, plants from allium family and Se-accumulating plants, clinical samples
	Organic selenium species: Mono- and dimethylselenide (MMSe; DMSe) Mono- and diethylselenide (MESe, DESe) Trimethylselonium ion (TMSe) Selenomethionine (Se-Met) Methylselenomethionine (Me-Se-Met) Selenocysteine (Se-Cys or oxidized Se-Cis) Methylselenocysteine (Me-Se-Cys) Selenohomocystine (Se-Hcy) Selenoethionine (Se-Et) Adenosylselenomethionine (AdoSe-Met) Adenosylselenohomocysteine (AdoSe-Hcy) γ-Glutamyl-methylselenocysteine		
Sn	Inorganic forms (Sn(IV)/Sn(II))	Harmful effects of organotin pesticides, antifouling paints, and their degradation products	Sea water, natural waters, sediments, soils, marine organisms
	Organotin compounds: $R_nSn^{(4-n)+}$ ($1 < n < 4$; R-methyl, ethyl, butyl or phenyl)		

Volatile compounds that present thermal stability, monomeric form, neutrality, relatively low molecular weight, coordinative saturation, and shielding of the metal/metalloid atom by bulky and inert organic functional groups can be separated by GC.[51] The direct applications of GC with ICP-MS detection in speciation analysis are limited to relatively few volatile organometals (Hg, Pb, Sn, Bi) and organometalloid compounds (Se, As). Different precolumn derivatizations can be used to improve and/or expand GC potential. The most common procedures include (i) conversion of inorganic and small organometallic ions into volatile covalent compounds (hydrides, fully ethylated or propylated species) in aqueous media, (ii) conversion of larger alkylated cations with Grignard reagents to saturated nonpolar species, and (iii) conversion of ionic species to volatile chelates (dithiocarbamate, trifluoroacetone, etc.).[62,63] In the separation of small elemental species, low-temperature GC should also be mentioned. In this mode, the gaseous species are cryogenically trapped on the column (Pb, Sb, Hg, As) and then separated during the controlled column heating, according to their boiling points.[64,65] Owing to the sharpness of chromatographic peaks, the speed of data acquisition by the mass analyzer is of vital importance. Within this context, the time of flight analyzer offers better detection conditions with respect to the quadrupole.[66] Virtually simultaneous extraction of all m/z ions in time of flight mass spectrometry (TOFMS) enables the measurements of multiple isotopic ratios (species-specific isotope dilution and multielemental speciation); however the loss of sensitivity in the single ion mode is still a limitation.

Supercritical fluid chromatography (SFC) combines the high diffusion coefficient of GC and the solubility properties of LC and this separation mode has also been coupled with atomic spectrometric detection.[67–69]

Performing electrophoretic separations in capillaries allowed the possibility of automated analytical equipment, fast analysis times, and online detection of the separated peaks. The separation of species in CE is controlled by two phenomena: the electrophoretic mobility and the electroosmotic flow. With careful selection of separation conditions (type and concentration of the electrolyte solution, complexing reagents, pH, etc.), the combined effect of these two forces can be controlled, resulting in the high-speed resolution of a large number of cations, anions, small metal ions, metal–organic ligand complexes, and organometallic molecules in a single run. Moreover, the technique has been successfully used for the separation of relatively labile complexes and to study the kinetics of complex formation. Owing to the small sample volume (in the range of nanoliter) introduced to a narrow capillary (internal diameter 20–100 μm), the lack of sensitivity is a general limitation, almost independent of the detection systems used. One approach for improving the detection limits is to increase loading of the CE system. This can be achieved by preseparation cleanup or preconcentration procedures, electrokinetic sample introduction, application of electrostacking effect, or isotachophoresis. On the other hand, coupling of CE to highly sensitive and specific ICP-MS detection seems to be an attractive speciation tool.[9,70] As the amount of capillary effluent entering the plasma is very low, its chemical composition does not affect the performance of the plasma and the optimum separation conditions can be used. However, the applications of CE in real-world samples have been limited, because the effect of sample matrix and/or chemical conditions applied during separation on the speciation results is difficult to control. CE-ICP-MS has been used in the analysis of stable oxidation states (As, Cr, Se), metal complexes (Au, Cd, Co, Pt, Sb), and small organic compounds (As, Se, Hg).

3.2.1 Aluminum and Antimony

These two elements have a variety of important chemical forms and provide a number of very interesting speciation applications, but to discuss these here would exceed the limitations of this article. The reader is referred to Table 3 and selected references.[64,69,71]

3.2.2 Arsenic

In addition to the natural abundance of arsenic forms, various compounds have been extensively used in processes, such as arsenic-based pigments, biocides, and so on. The arsenicals emitted into the environment can be degraded and/or biotransformed, resulting in a variety of chemical forms (Table 3). Owing to the species-dependent toxicity, the environmental materials, foods, and biological and clinical samples have been analyzed.[12,61,72] In particular, elemental speciation in marine organisms that accumulate and metabolize arsenic have often been addressed. LC hyphenated with ICP-MS is suitable for the common small molecules (As(III), As(V), MMAs(V), DMAs(V), and arsenobetaine (AsB)). Depending on the pH conditions, these species can be cationic, anionic, or uncharged (pK_{a1} respectively, 9.3, 2.3, 2.6, 6.2, and 2.2),[72] which makes the separation by anion exchange, ion-pairing, and, to a lesser extent, cation-exchange chromatographic modes possible. In the applications of anion-exchange LC, good resolution has been achieved at pH ranges from 5 to 11, usually with the elution order AsB, As(III), DMAs(V), MMAs(V), As(V) and separation times between 7 and 30 min. Cation-exchange separations, requiring lower pH values (pH < 4) have been preferred for the analysis of AsC, tetramethylarsonium ion (TETRA), and/or trimethylarsineoxide (TMAsO).[73] Several applications of ion-pairing separation have been proposed, based on the use of tetrabutylammonium ion (pH 6–11) and different alkylsulfonates (pH 2.7–4.5).[10] The separation of larger amount of species has been addressed. For more detailed information, recent reviews can be consulted.[12,36,74,75] The particular interest in the intermediate products of arsenic methylation (MMAs(III) and DMAs(III)) is worth mentioning. As these species are highly toxic, the detoxification effectiveness of arsenic biomethylation is uncertain. Pergantis

et al. reported the speciation procedure of As(III), DMAs(V), MMAs(III), and MMAs(V) by anion-exchange LC coupled with ICP-MS, which was applied to study the mechanism of nonenzymatic methylation of arsenic.[76]

The separation of As species (As(III), As(V), MMAs(V), DMAs(V), AsB, AsC) has also been accomplished by CE (electrolyte in the pH range 5.6–11.2; phosphate, triethanolamine or borate buffers), but only in simple aqueous matrices.[9] Online hydride generation in capillary effluent has been proposed to increase transport efficiency.[77] SFC has been used only for nonpolar As compounds, like trimethyl-, triphenylarsine, and triphenylarsine oxide.[69]

3.2.3 Chromium

Various industrial processes, like plating, tanning, paint, and pigment production, and so on, involve the use of chromium. The hexavalent form of this element represents a considerable health hazard, related to the easy permeation through biological membranes and high oxidation potential. The challenge for analytical speciation is to discriminate between two stable oxidation states and to perform their quantification in environmental and clinical materials. The difficulty is increased, because the Cr(III)/Cr(VI) equilibria are highly pH dependent, the two forms have opposite electrical charge and different Cr(III) species can be formed in the aqueous medium (mono- and polynuclear complexes presenting different electrical charge and considerable lability). A great number of speciation schemes and procedures have been described, both for the specific determination of one form and for simultaneous speciation of the two forms.[78] The most common hyphenated techniques involve liquid chromatographic separation; ethylenediaminetetraacetic acid (EDTA) has often been used for stabilization of Cr(III) and the separation was accomplished on anion-exchange columns.[75] Increased detection power was obtained with the use of a microbore column and DIN (detection limit (DL) 3 pg for each species, as compared to 44 pg with the application of conventional analytical column).[79] The application of ion-pairing LC with tetrabutylammonium ion has also been reported.[68] In addition to the valence states, hydrolytic polymerization products of Cr(III) were investigated by CE.[9,80] Several organic complexes of Cr(III) were analyzed by SFC–ICP-MS.[69]

3.2.4 Lead

The main anthropogenic sources of lead include lead-based paints, solder, and metallurgy. Even though utilization of the alkyllead compounds such as gasoline additives has already been regulated, the persistence of various lead forms in the environment is still an issue (Table 3). ICP-MS detection of lead has been used in hyphenation of GC, ion exchange, ion-pairing LC, and, to a lesser extent, SFC.[69,75] The gas chromatographic approach usually involves the extraction with diethyldithiocarbamate (DDTC) followed by the reaction with Grignard reagent (butylmagnesium chloride) to form volatile butylated organolead species. Alternatively, tetraalkylborates (ethyl- or propyl-) have been used, allowing for the derivatization of lead species directly in aqueous solutions. Different mono- to trimethylated and ethylated lead species have been analyzed in water samples, airborne particles, fuel, and naphtha.[12,81] Capillary columns have been preferentially used because of better resolution and lower plasma loading with solvents, as compared to the packed columns. Owing to the reduced sample volume, the high sensitivity of ICP-MS detection becomes essential.[20,75] The detection limits for organolead species obtained with a quadrupole mass analyzer were around 50 and 500 $pg\,L^{-1}$ in ICP-TOFMS.[82,83] In the latter case, substantial improvement (DL 3 $pg\,L^{-1}$) has been achieved after preconcentration of trimethyllead, dimethyllead, and triethyllead complexes with DDTC on C_{60} (fullerene).[81] In liquid chromatographic separations, different alkylsulfonate ion-pairing reagents have been used for inorganic lead and the charged alkyllead compounds in aquatic and urine samples. Even though gradient elution enhances the speed of separation, isocratic conditions have been preferred to maintain the same sensitivity of ICP-MS quantification over the whole chromatogram.[68,84]

3.2.5 Mercury

Mercury has been extensively used in different anthropogenic activities and the forms released to the environment include elemental Hg, inorganic salts, as well as organic species. Furthermore, naturally occurring biomethylation processes contribute in species interconversion. The accumulation of toxic methylmercury in different living organisms (in particular aquatic) is well documented. Other forms of organomercury are listed in Table 3. For risk assessment, accurate speciation analysis is needed with emphasis on natural and sea water, marine organisms (fish and mussels), soils, sediments, and biological fluids. The important part of the analytical procedure is the efficient extraction of different mercury species from the original sample. According to a recent review, distillation of methylmercury from soils and microwave-assisted alkaline digestion of fish tissue with tetramethylammonium hydroxide assured recoveries in the range 95–105%.[85] Practically every possible hyphenation technique with ICP-MS detection has been explored for mercury. In GC, the reactions with Grignard reagents or with tetraalkylborates yield volatile, thermally stable covalent derivatives.[20] Purge and trap, cryogenic trapping, and solid phase microextraction techniques for the recovery and/or preconcentration of these compounds have been used.[20,86] Relatively poor resolution on the packed columns was observed (undesirable interaction of mercury species with packing material) and capillary columns have been used in the majority of applications. Absolute detection limits reported recently in the analysis of biological

tissues ranged between 100 and 200 fg (as Hg mass) for methylmercury and between 500 and 600 fg for inorganic mercury using a 1 μL injection.[87] Isotopically enriched inorganic mercury and methylmercury have been used for species-specific isotope dilution.[20,54,88] A detailed review on mercury speciation by high performance LC is available.[85] In brief, the majority of procedures reported involve reversed phase columns (silica-bonded phases) and the mobile phases containing a chelating (sodium pyrrolidinedithiocarbamate, cysteine, 2-mercaptoethanol) or ion-pairing (ammonium pentanesulfonate or acetate) reagent. ICP-MS detection has gained popularity relatively recently. With the use of HHPN or DIN, the detection limits for monomethyl-, monoethyl-, and monophenylmercury (MMHg, MEHg and MPhHg, respectively) were in the range of a few picograms (as Hg). Similar results were reported with online cold-vapor generation prior to ICP-MS detection.[85,86] There have been several reports on CE–ICP-MS for mercury speciation; cysteine was used for species chelation and separation carried out with borate or carbonate buffers.[9] Typical detection limits for MMHg, MEHg, and MPhHg were in the range of a few picograms (as Hg).[77] Similar absolute detection limits have been reported for diethylmercury (DEHg) and inorganic mercury by SFC.[69]

3.2.6 *Platinum*

Cisplatin has become one of the most widely used chemotherapy drugs. The mechanism of action relies on the ability of the drug to modify the DNA structure in cancer cells, hence causing their apoptosis. However, it presents severe toxicity and its anticancer activity is limited to a small group of tumor cell types. In further development, several other platinum complexes (mainly oxaliplatin, carboplatin, satraplatin, JM-216, ZD0473) have been synthesized and tested for their possible anticancer activity.[89–93] The challenge is to obtain drugs active against a broad spectrum of tumor cells, to minimize their toxicity and to avoid development of resistance mechanisms in target cells.[94]

After intravenous or oral administration of the drug, it undergoes several biotransformations that activate its toxicity (tumor cells as well as nephro- and neurotoxicity). A number of speciation studies that focused on characterization and quantification of parent drug and its possible metabolites in vitro and in vivo have been reported. Element-specific ICP-MS detection has been applied after LC separation of platinum compounds.[89,91,92,95–101] In Figure 6, the LC–ICP-MS chromatogram is presented, and this was obtained for the mixture of cancerostatic platinum compounds.[91]

3.2.7 *Selenium*

The growing interest in selenium speciation is due to its toxic and/or essential properties that depend on the actual physicochemical form of the element. Strong evidence exists on the adverse health effects related to selenium deficiency. It was also demonstrated that supplementation with different selenium forms might help to remove the symptoms of deficit.[102] Selenium has been found in the active site of different antioxidant enzymes, protecting cells against the action of free radicals. The species-dependent cancer-preventive properties are well documented, yet the specific biological functions have not been ultimately elucidated. The list of small selenium compounds includes inorganic forms (two stable valence states), volatile alkylated species, and

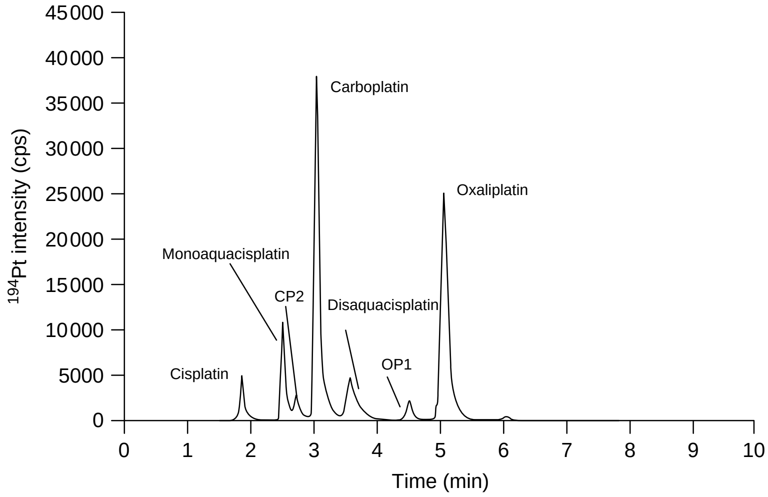

Figure 6 LC–ICP-MS chromatogram obtained from a 24-h mixture of cisplatin ($Rt = 1.9$ min), carboplatin ($Rt = 3.1$ min), and oxaliplatin ($Rt = 5.1$ min) in subboiled water using pentafluorophenylpropyl-functionalized silica as stationary phase. In addition to the parent drugs, the chromatogram shows the major degradation products of cisplatin (monoaquacisplatin, $Rt = 2.5$ min; diaquacisplatin ($Rt = 3.6$ min)), the product of carboplatin (CP2, $Rt = 2.7$ min) and the product of oxaliplatin (OP1, $Rt = 4.5$ min). (Reproduced with permission Hann, Stefanka, Lenz and Stingeder[91] © 2005, Springer Science & Business Media)

nonvolatile organoselenium compounds (Table 3). Speciation studies focus on the analysis of environmental materials, food (vegetables from the Allium family, wheat sprouts, crops and nuts), nutritional supplements (Se-enriched yeast), as well as clinical samples (serum, urine). Element speciation in selenium-accumulating plants (*Brassica juncea*, *Astragalus praleongus*) has also been addressed.[103] The reliability of speciation results in biological materials strongly depends on sample pretreatment. The homogenization of the initial material (for yeast–the rupture of cell walls), fractionation protocol to separate large molecules from low molecular weight compounds, extraction of lipids, and protein hydrolysis yielding selenoaminoacids are key steps in any speciation procedure.[61,104–106] For urine analysis, the cleanup and preconcentration steps are important.[104,107]

LC coupled to ICP-MS is preferentially used for nonvolatile species. Two inorganic forms (Se(IV) and Se(VI)) predominating in aquatic samples, are usually separated on strong anion-exchange columns. Anion-exchange separations have also been performed on mixtures of inorganic and organic compounds (Se-Met, Me-Se-Cys, Se-Cis, TMSe); however poor resolution has often been observed.[108] The applications to real-world samples include vegetable and yeast extracts, bacteria, as well as urine samples.[61,104,109] Different organic selenium compounds (selenoaminoacids, peptides, TMSe, etc.) are cations, or can be easily converted to cationic species by lowering the pH of the solution, thus enabling separation by a cation-exchange mechanism. Up to eight selenium compounds (Se(IV), Se(VI), Se-Cys, Se-Hcy, Se-Met, Se-Et, TMSe, dimethyl selenium propionate) have been resolved with different mobile phases at pH 2–5.7 (pyridine, ammonium formate, etc.).[10,110] Cation-exchange columns have been used for selenium speciation in urine.[104] Ion-pairing LC is a common separation technique in the analysis of yeast, garlic, onion extracts, and urine. Different perfluorinated carboxylic acids have been examined and the feasibility for separation of a large number of species demonstrated (pH 2.5–4.5).[12,111] The alkylsulfonic acids have been successfully used as counterions in the speciation analysis carried out on nuts, yeast, and urine.[10] The identification of selenium-containing compounds observed by LC–ICP-MS is not always straightforward. The lack of commercially available standards and often unknown selenium pathways in the studied system are the main problems. The characterization of a number of species (AdoSe-Hcy in yeast, γ-glutamyl-methylselenocysteine in garlic, Se-methyl-N-acetylselenohexosamine in rat urine, etc.) has been obtained by complementary electrospray ionization mass spectrometry experiments.[12]

Owing to the different biological activities of D and L enantiomers of selenoaminoacids, chiral separation of these compounds has been undertaken. Both, chiral stationary phase (crown ether) and chiral derivatization prior to reversed phase LC were used.[10]

GC–ICP-MS is suitable for the determination of volatile selenium species. Figure 7 shows the chromatogram obtained by GC–ICP-MS measuring Se and S (m/z 77 and 33, respectively) from the *Brassica juncea* seedlings grown in the presence of sodium selenate. The main Se species found were dimethylselenide and dimethyldiselenide as labeled in the chromatogram.[103] GC separation of volatile, chiral derivatives of Se-Met enantiomers has also been reported.[10]

The applications of CE–ICP-MS to selenium speciation has been reviewed.[9] This technique allows the separation of two inorganic forms of the element and several organic compounds in a short time. Different alkaline electrolytes have been reported in the pH range 9–11.5. Detection limits of 10 to 50 $\mu g\,L^{-1}$ have often been obtained. The majority of studies have dealt with standard mixture

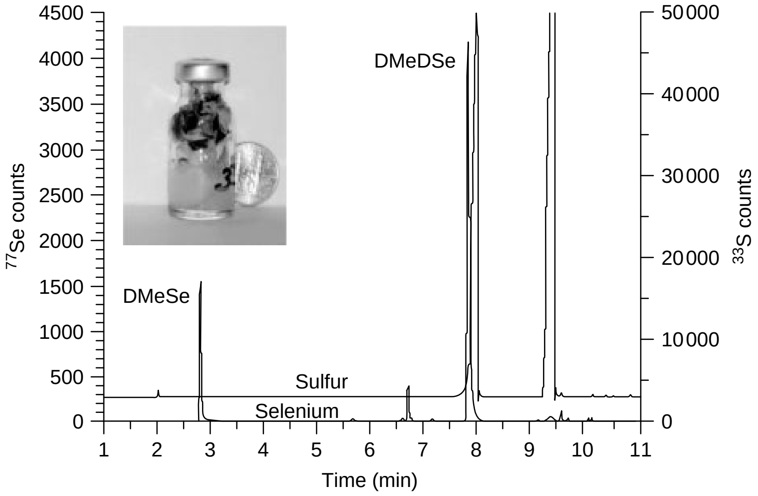

Figure 7 GC - ICP-MS chromatogram of Se and S in Brassica juncea headspace after solid phase microextraction. The photograph shows Brassica plant grown for the experiments. (Montes-Bayon, Grant, Meija and Caruso.[103] Reproduced by permission of The Royal Society of Chemistry)

solutions, and the analysis of milk and serum samples was reported only by Michalke *et al*.[112]

3.2.8 Tin

The main toxicological and ecotoxicological aspects of tin are related to the extensive use of organotin antifouling boat bottom paints. There is a need for speciation analysis in sea water, natural waters, soils, sediments, and marine organisms. The efficient extraction of tin compounds from solid matrices is a challenge. Certain complexing agents (tropolone or DDTC) were shown to favor the extraction of monobutyltin and, to a lesser extent, other cationic species. On the other hand, accelerated solvent extraction, supercritical fluid extraction, and microwave-assisted leaching techniques have been explored.[12,113] The small tin molecules of interest are summarized in Table 3; among them, tributyltin and triphenyltin have received major attention, followed by mono- and disubstituted species and inorganic forms. GC is the most common approach; it allows the separation of many different groups of organotin compounds in a single analysis. The derivatization of mono-, di-, and triorganotins to form thermally stable volatile species is necessary. This has been achieved with Grignard reagents and also by ethylation or propylation in an aqueous medium.[20,63] Conventional solvent extraction, solid phase microextraction, stir bar sorptive extraction (SBSE), and cryotrapping prior to capillary GC have been used. The majority of detection limits have been in the range of parts per trillion (picogram per liter); however with the preconcentration approach (SBSE, capillary cryofocusing) these values could be lowered by about 1 order of magnitude.[20] Multicapillary technology is a recent addition to the well-established GC, aiming for miniaturization of the GC unit and solute resolution in short time.[20]

Liquid chromatographic methods and detection techniques have been reviewed.[113,114] Elimination of the need for derivatization is a strong point for LC; however, the number of Sn species that can be analyzed in a single run is generally lower, the resolution poorer, and the transport to plasma less efficient than in GC. The separation of cationic butylated species has been achieved on cation-exchange columns using methanol–water mobile phases containing ammonium acetate or citrate. Ion-pairing chromatography with ammonium heptanesulfonate enabled the separation of cationic butylated, phenylated, propylated, ethylated, and methylated species. The capability of reversed phase LC for separation of butyltin and phenyltin species has been demonstrated with the addition of complexing agent tropolone to aqueous methanol or acetonitrile mobile phase. In a few studies, micellar mobile phases have been used with the aim of improving the separation.[113] The resolution of six species was reported (di- and trimethylated, -butylated and -phenylated Sn); however the elevated concentrations of surfactants increased the clogging of plasma torch. Similar absolute detection limits have been obtained for different separation modes; however, the lower values were reported with the use of DIN (1.8–2.5 pg of Sn in mono-, di-, and tributyltin). Post-column hydride generation has also been proposed.[113]

Isotopically labeled mono-, di-, and tributyltin have been obtained, allowing the use of species-specific isotope dilution techniques both in GC and LC separations. A comparative study revealed that the separation mode had no significant effect on mass fractions determined in the sediment sample; however GC–ICP-MS analysis yielded about 2 orders of magnitude better absolute detection limit (0.03 pg Sn as tributyltin) with respect to reversed phase LC–ICP-MS.[115]

Several applications of SFC–ICP-MS in organotin have been reported. The SFC mode is particularly suitable for tri- and tetraorganotin species and this technique enables better sensitivity when compared with LC (better transport efficiency to plasma). A comprehensive review is available.[69]

3.3 Element-Specific Detection in Metallobiomolecules

Different metals and/or metalloids, while present at low concentrations, play an important role in the biological activity of ''large'' molecules. It has been estimated that around 40% of all proteins and enzymes contain metal ions in their structures. Metal-binding proteins and metalloproteins are responsible for many metabolic processes, such as biological energy conversion in photosynthesis and respiration, as well as for signaling processes, which govern gene expression and regulation. Metal sites in protein structures also command other processes such as catalysts action, substrate binding and activation, transportation, and storage.[41,116] Atomic spectrometry techniques have been introduced in studies of metallobiomolecules relatively recently. In particular, ICP-MS and, to a lesser extent, ICP-OES are used as element-specific detectors in chromatographic and electrophoretic separations.[117–120] To assess the patterns of element distributions in molecular mass fractions, size exclusion chromatography is typically used.[3,41,121–123] As an example, the elution profiles of Fe, S, P in protein liver extract was obtained and polyatomic interferences typically observed on most abundant isotopes, were removed using a magnetic sector mass analyzer at medium spectral resolution.[124] In other work, the speciation of zinc and copper binding with proteins in human serum was studied.[125] The concentrations of α2-macroglobulin-zinc, ceruloplasmin-copper, and the element species with albumin were estimated. Metal binding to proteins has also been investigated in cancerous and healthy human thyroid samples.[126] For the protein extract of Brazil nuts, SEC–ICP-MS was carried out in the presence and in the absence of reducing agent (β-mercaptoethanol) to distinguish between selenium firmly and weakly bound to proteins.[106] This technique has also been used for studying the distribution of metals and metalloids in molecular mass fractions of different mushrooms.[127,128]

Another separation technique suitable in nondenaturing conditions is ion exchange chromatography and it has

been frequently coupled with ICP-MS. A post-column isotope dilution analysis was used for the quantitative speciation of Fe, Cu, and Zn in human serum.[129] A similar separation system with high-resolution ICP-MS was applied to multielemental speciation.[130] The use of variable resolution allowed the detection of Ca, Sr, Fe, Cu, Zn, Se, Mn, Cr, Pb, Al, and Sn in different serum samples.

A common practice in the fractionation of proteins is the use of sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE). The feasibility of ICP-MS as a detection tool in the measurements of heteroatom stoichiometry in a biomolecule isolated as a spot in two-dimensional gel electrophoresis has been demonstrated.[41,118,131] As an example, ETV–ICP-MS was applied for the detection and quantification of selenium in proteins directly from the bands of a stained gel.[132] The method was optimized by using glutathione peroxidase and then applied to the determination of selenium in proteins fractionated from a selenium–yeast candidate reference material. In another study, Lustig *et al.* used two-dimensional electrophoretic separation (isoelectric focusing and native PAGE) combined with sector field ICP-MS for the speciation of Cr, Ga, In, Pt, and V in human and rabbit sera.[133] Laser ablation of PAGE gels for sample introduction to ICP-MS has become a fast growing application area in the analysis of biomolecules.[41,118,134]

3.3.1 *Metallothioneins*

Element-specific detection by ICP-MS has been widely used in the characterization of metallothioneins (MTs). The biological importance of these proteins is due to their role in homeostatic regulation of essential heavy metals like Cu and Zn. On the other hand, MT protects the cells from harmful chemicals, like nonessential and excessive essential heavy metals, reactive oxygen species, radicals, and alkylating agents.[135] Fararello *et al.*[136] reviewed different chromatographic approaches with ICP-MS detection for the multielemental speciation in MTs and MT-like proteins.

3.3.2 *Metal binding to transferrin*

Several papers have focused on elements binding to transferrin (Tf). As to the possible biological significance, the identification of this iron-transporting glycoprotein as a target for other elements could contribute to better understanding the pharmacokinetics of these elements in the human body. It should be stressed that the application of a highly sensitive ICP-MS detection system allowed the determination of element speciation in unspiked clinical samples.[137] The chemical forms of Al and Fe bound to human serum Tf were investigated by anion-exchange HPLC coupled to high-resolution (HR) ICP-MS.[138] The levels of ^{27}Al, ^{56}Fe, and ^{32}S, which are interfered with by polyatomic ions such as $^{13}C^{14}N^+$, $^{12}C^{15}N^+$ and $^{12}C^{14}N^1H^+$, $^{40}Ar^{16}O^+$ and $^{40}Ca^{16}O^+$, and $^{16}O_2{}^+$, when using a quadrupole mass analyzer, were monitored simultaneously by HR-ICP-MS at a resolution of $m/\Delta m = 3000$. Monitoring ^{32}S helped to assess the protein levels in the HPLC eluate. In the following study, the same analytical system was used to investigate the effect of structural changes in Tf on the affinity of Al and Fe to this protein.[139] The binding patterns of V(III), V(IV), and V(V) to human serum Tf were also investigated.[140] The observed affinity decreased from the lowest to the highest oxidation state of the element in the presence of bicarbonate. This order was altered in the absence of bicarbonate, which is generally required for metal binding to Tf. Another element of interest is bismuth, which is widely used in clinical treatment of different gastrointestinal ulcers. Fast protein LC–ICP-MS was the analytical tool for studying competitive binding of Bi to human albumin and transferrin.[141] It was found that over 70% of bismuth binds to Tf even in the presence of a large excess of albumin (albumin/transferrin = 13:1).

3.3.3 *Metalloenzymes*

A few reports on metal ion characterization in metalloenzymes by hyphenated techniques with ICP-MS detection should also be mentioned. Inhibition, reactivation, and determination of metal ions in membrane metalloproteases of bacterial origin was studied by Leopold *et al.*[142] The results obtained by SEC–ICP-MS and the results of enzymological methods indicated that two different membrane proteases from *Bacillus cereus* and *Pseudomonas aeruginosa* were zinc metalloproteases. In another study, ICP-MS measurements helped in the characterization of a fibrinolytic metalloprotease from the fruiting bodies of an edible mushroom.[143] Using HPLC–ICP-MS, Suzuki *et al.* detected a zinc-binding protein present specifically in the livers of male adult rats.[135]

3.4 Metallomics Approach

Metallomics is emerging as an important application area of ICP-based atomic spectrometries. While there is no IUPAC definition of metallomics yet, the metallome has been defined as the complete complement of metals and metal moieties in a biological cell, tissue, or system. This definition is analogous to that of the genome (genes), proteome (proteins), and metabolome (metabolites). Metallomics, accordingly, is the study of metals and metal species, and their interactions, transformations, and functions in biological systems.[144–146] Metallomics differs from speciation and other related terms in that it considers the global role of all metals/metalloids in a given system.[145] Thus, multielement capabilities of ICP-MS and ICP-OES make these techniques especially well suited to meet present and future challenges of metallomics in different research fields.[119,147,148] Several papers reporting specific applications are available.[127,149–153]

4 ABBREVIATIONS AND ACRONYMS

AdoSe-Hcy = adenosylselenohomocysteine; AdoSe-Met = adenosylselenomethionine; AsB = Arsenobetaine; AsC = arsenocholine; CE = capillary electrophoresis; DDTC = diethyldithiocarbamate; DEHg = diethylmercury; DESe = diethylselenide; DIHEN = direct injection high-efficiency nebulizer; DIN = direct injection nebulizer; DL = detection limit; DMAs(III) = dimethylarsinous acid; DMAs(V) = dimethylarsinic acid; DMHg = dimethylmercury; DMSe = dimethylselenide; DPhHg = diphenylmercury; EDTA = ethylenediaminetetraacetic acid; EIE = Easily ionized elements; ETV = electrothermal vaporization; GC = gas chromatography; HEN = high-efficiency nebulizer; HHPN = hydraulic high pressure nebulizer; ICP = inductively coupled plasma; ICP-HRMS = inductively coupled plasma high-resolution mass spectrometry; ICP-MS = inductively coupled plasma mass spectrometry; ICP-OES = inductively coupled plasma optical emission spectrometry; IDMS = isotope dilution mass spectrometry; LC = liquid chromatography; MCN = microconcentric nebulizer; MEHg = monoethylmercury; MESe = monoethylselenide; Me-Se-Cys = methylselenocysteine; Me-Se-Met = methylselenomethionine; MMSe = monomethylselenide; MMHg = monomethylmercury; MPhHg = monophenylmercury; MTs = metallothioneins; NMR = nuclear magnetic resonance; pKa = negative logarithm of acid dissociation constant; PMT = photomultiplier tube; QITMS = quadrupole ion trap mass spectrometry; SBSE = stir bar sorptive extraction; SDS-PAGE = sodium dodecylsulfate polyacrylamide gel electrophoresis; Se-Cis = selenocystine; Se-Cys = selenocysteine; Se-Et = selenoethionine; Se-Hcy = selenohomocysteine; Se-Met = selenomethionine; SFC = supercritical fluid chromatography; TBT = tributyltin; TETRA = tetramethylarsonium ion; Tf = transferrin; TMAsO = trimethylarsineoxide; TMSe = trimethylselonium ion; TOFMS = time of flight mass spectrometry; USN = ultrasonic nebulizer.

4	Case Studies	6
5	Abbreviations and Acronyms	14
6	References	14

METHOD SUMMARY

Acronyms, Synonyms
- Fourier Transform Microwave Spectroscopy.
- Microwave Spectroscopy.
- Rotational Spectroscopy.

Measured physical quantities
- rotational transition frequencies; fine and hyperfine structure splittings.

Information available
- rotational constants, A, B, C
- centrifugal distortion constants, for example, Δ_J, Δ_{JK}, Δ_K, δ_J, δ_K
- nuclear quadrupole coupling constants, χ
- nuclear spin rotation (C) and nuclear spin−spin interaction (S) constants
- electron spin rotation and electron spin−spin interaction constants
- tunneling splittings
- electric dipole moment components, μ.

Information not available, limitations
- The molecule needs to have nonzero electric dipole moment.

Examples of questions that can be answered
- What are the symmetry, geometry, and structure of the molecule?
- How high is the inversion or internal rotation barrier?
- What is the nature of the bond of this atom with a quadrupolar nucleus?
- What are the (approximate) relative stabilities of the different conformers?

Major advantages
- accurate determination of bond lengths (±0.01 Å or better) and bond angles (±0.1° or better)
- exquisitely sensitive to small structural changes and small mass changes
- unambiguous identification of structural isomers and conformers
- applicable to the study of neutral molecules, ions, radicals, and noncovalently bound complexes and clusters.

Major disadvantages

- Complete structure determination requires investigation of several isotopically labelled compounds.
- Spectroscopic analysis and interpretation can be complex.
- Instrumentation is not commercially available.

Sample constraints

- The sample must be brought into the gas phase.

1 INTRODUCTION

Microwave spectroscopy in general is a method to investigate rotational transitions or low energy ro-vibrational transitions of small (two atoms) to medium sized (~40 atoms) molecules. For the purpose of this article, we can define the microwave wavelength range rather narrowly to be between 300 and 10 mm, corresponding to frequencies between 1 and 30 GHz. This region is bordered by the radio frequency range at lower, and the millimeter range at higher frequencies. The standard reference books for the area of microwave molecular spectroscopy are those by Gordy and Cook[1] and Townes and Schawlow.[2]

The molecules under investigation must possess a nonvanishing electric dipole moment to exhibit a (dipole-allowed) microwave rotational spectrum. Normally, the species of interest must be brought into the gas phase, at pressures of a few mTorr or in a molecular beam, for the spectroscopic investigation. The primary data obtained are rotational transition frequencies that correspond to energy differences between rotational energy levels. The observed rotational lines may be split into fine and hyperfine components as a result of large amplitude tunneling motions (e.g., the inversion splitting due to the umbrella motion in ammonia) and magnetic or electric interactions (e.g., nuclear quadrupole hyperfine structure due to the interaction of a nuclear electric quadrupole moment with the molecular electric field gradient at the site of the nucleus). Analyses of the spectra can then yield the corresponding spectroscopic constants, for example, rotational constants, which are inversely proportional to the molecular moments of inertia; centrifugal distortion constants, which are a measure of the change of moment of inertia due to centrifugal effects as the molecule rotates; barriers to internal motions; and nuclear quadrupole coupling constants, which are a measure of the molecular electric field gradient. The interpretation of these spectroscopic parameters can yield some of the most accurate structural information about gas phase molecules, and a detailed description of the electronic character of the molecular bonds.

From its inception, microwave rotational spectroscopy has contributed greatly to our knowledge about classical inorganic compounds. It all began with a low resolution recording of the ammonia inversion spectrum in 1934.[3] The first high resolution microwave spectra were recorded after the Second World War and resolved rotational structure of the ammonia inversion spectrum and later nitrogen nuclear quadrupole hyperfine structure. An account by Gordy of the early history of microwave spectroscopy can be found in Ref. 4. Since then, a myriad of small inorganic compounds has been studied and their structures and bonding characterized by rotational spectroscopy. This includes gas phase diatomic molecules, such as alkaline and alkaline earth halides and chalcogenides, essentially all diatomics involving C, Si, N, O, boron family (I) halides, basically any imaginable linear molecule, transition metal compounds, interhalogen compounds, species of atmospheric importance, including halogen-containing molecules, and reactive intermediates, and other types of molecules too many to be listed here. In most of these cases structural parameters of the highest accuracy were determined, and in many cases it was possible to extract information about the bonding character of these compounds.

Much of the microwave work up to the 70s or 80s had been done with waveguide based absorption spectrometers. Waveguides are round or rectangular metal tubes up to several meters in length that serve both to propagate the microwave radiation and as sample cell. The cross-sectional inside area of a waveguide depends on the wavelength and is, for example, $0.900'' \times 0.400''$ for a so-called X-band waveguide with frequency range from 8.2 to 12.2 GHz (*see* ***Electron Paramagnetic Resonance (EPR) Spectroscopy***). For a 2 m cell, this corresponds to a sample volume of not quite 0.5 L. These spectrometers typically employ a modulation scheme for sensitivity enhancement. In the case of Stark modulation, the molecular absorption is modulated by a square wave electric field that is introduced using an electrode that runs through the entire length of the waveguide. The detected signal is then processed with a phase sensitive detector. Flygare introduced Fourier transform techniques into microwave spectroscopy,[5,6] analogously to pulsed nuclear magnetic resonance (NMR) spectroscopy (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Inorganic/Organometallic Molecules***). Here, a relatively high power (up to 20 W) microwave pulse is used to excite the molecular sample. After the excitation pulse has dissipated, the subsequent molecular emission signal is detected, digitized in the time domain, averaged, and finally Fourier transformed to obtain the spectrum in the frequency domain. This technique has been used in the Dreizler[7,8] laboratory in Kiel, Germany,

and in the Bauder[9] laboratory at the eidgenössische technische hochschule (ETH) in Zürich, Switzerland. In combination with waveguides and static gas samples, this technique was used to characterize many molecular systems. Numerous technical improvements were implemented by these research groups. The Fourier transform microwave (FTMW) technique is now most commonly used in combination with a molecular beam and a microwave resonator, or cavity, as a sample cell designed originally by Flygare.[10] Since, in our opinion, pulsed molecular beam cavity FTMW spectroscopy is the most sensitive and most versatile method, we will restrict our discussions from now on mainly to this technique.

The pulsed molecular beam technique provides a wide open playing field for sample preparation. The pulsed nozzle can be combined with an electric discharge or a laser ablation source to generate and to stabilize reactive species, weakly bound complexes and clusters,[11] and compounds that cannot be made otherwise. The molecular beam technique allows us to ‘‘synthesize’’ inorganic and organometallic compounds that are of interest to modern inorganic chemistry and to bring them into the gas phase for high resolution spectroscopic investigation and characterization. Very recent examples include the discovery of the long elusive molecule AuF,[12] detection of covalent bonding involving the noble gas argon,[13] and structure elucidation of organometallic compounds.

2 TECHNICAL BACKGROUND

In the 1970s, a commercial microwave spectrometer employing Stark modulation and a waveguide sample cell was developed and sold by Hewlett Packard[14] and used in a number of research laboratories. Twenty years later, there were a number of attempts to commercialize a trace gas sensor based on a cavity FTMW spectrometer. It turned out that the complexity of the rotational spectra, the difficulties associated with the spectroscopic analyses, and the problems with intensity calibration, amongst other issues, foiled these attempts to transform microwave spectroscopy into a routine analytical tool. However, microwave Fourier transform spectroscopy as a research tool continues to contribute significantly to our understanding of geometry, electronic structure, and dynamics of small to medium sized molecules and molecular associations. We estimate that there are today about 25 to 30 research groups worldwide that operate cavity FTMW spectrometers, and essentially all are in use for research applications. Since this type of instrument is not commercially available, it is appropriate to give a brief overview of instrument design and operation. More details about the instrument design and literature references can be found in a recent review on rotational spectra of weakly bound complexes.[11] We also note the recent development of a broadband FTMW spectrometer[15] that overcomes the narrow bandwidth problems of the current general design (see succeeding text).

2.1 Instrument Design and Operation

A schematic diagram of a typical FTMW spectrometer is given in Figure 1. The heart of the instrument is a microwave cavity which serves as the sample cell. In our case, the cavity consists of two aluminum mirrors each with a diameter of 25 cm and radius of curvature of 30 cm. This microwave cavity is housed in a vacuum chamber which is evacuated by a diffusion pump/forepump combination to reach background pressures in the sub-mTorr range. The gaseous sample is introduced into the microwave cavity as a pulsed molecular expansion that is generated using a pulsed nozzle mounted near the center of one of the cavity mirrors. A microwave synthesizer serves as the radiation source. The microwave single sideband modulator generates a frequency sideband, for example, 20 MHz above the original frequency, to simplify detection of the molecular signal. A pin diode switch can generate microwave pulses of a few microseconds duration and this excitation pulse is fed into the microwave cavity through a simple wire-hook antenna. The molecular signal is picked up by an antenna in the other mirror and fed into the detection microwave circuit. This consists of a low-noise microwave amplifier, followed by an image rejection mixer which is used to down-convert the molecular emission signal from the microwave range to frequencies around 20 MHz. Signals in this radio frequency regime can be conveniently amplified, filtered, and finally sampled and analog-to-digital converted.

In general it is necessary to average the time domain signals of successive experiments to increase the signal-to-noise ratio of the observed transitions. To

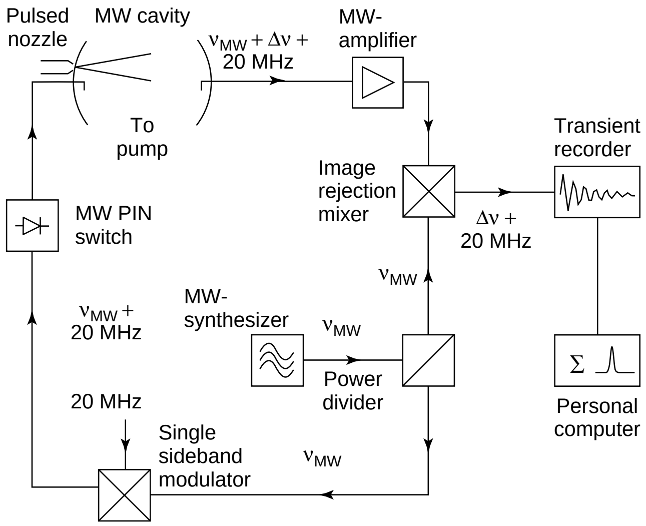

Figure 1 Simplified block diagram of a FTMW spectrometer

achieve this, it is essential to ensure phase coherent coaddition of the time domain signals, which is achieved by deriving mixing and sampling frequencies from a 10 MHz frequency standard and by tying all timing pulses to this standard.

The useful bandwidth of a single FTMW experiment is limited by both the length of the microwave excitation pulse (several μs) and by the quality factor of the microwave cavity ($Q \approx 10\,000-100\,000$). Useful ranges are typically 100 to 500 kHz in a single experiment. It is often necessary to conduct relatively wide frequency range searches for transitions of new compounds. FTMW spectrometers have therefore been automated and frequency stepping, tuning of the cavity into resonance with the external microwave radiation, and data accumulation can be done intervention-free over GHz ranges.

The molecular expansion travels parallel to the microwave cavity axis and, as a result, the observed transitions are split into Doppler doublets at sufficient resolution. Typical linewidths are 10 kHz and depend on the observation time, that is, the time required for the beam to travel from the nozzle to the opposite mirror. This in turn depends on the mirror separation and the backing gas (typically He, Ne, or Ar) used.

2.2 Sample Preparation

The molecular beam expansion into the microwave cavity is formed using a pulsed nozzle with circular orifice. The nozzle sample system by itself can be used to bring any compound with sufficient vapor pressure into the molecular expansion and also to synthesize complexes and clusters for spectroscopic study. The sample mixture typically consists of a few percent of sample molecules in a backing gas, often helium, neon, or argon, at pressures from 1 to 100 atmospheres. The combination of the pulsed nozzle with an electric discharge, a laser ablation source, or a miniature heating element extends its use significantly to bring low vapor pressure substances into the gas phase or to produce highly labile species that can further react with other precursors that are entrained in the backing gas or can be investigated directly. A typical laser ablation setup has a rod of the material to be evaporated mounted near the nozzle orifice. In some of the studies described in Section 3.1, for example, a copper rod was used to produce Cu atoms that then react with Cl_2 molecules in the expanding sample gas to form CuCl. CuCl can then react further with argon in the sample gas to form ArCuCl, a compound with significant covalent Ar−Cu bond character. Similarly, an electric discharge through the sample gas within the nozzle orifice can be used to generate, for example, fluorine atoms from SF_6 for further reaction with an additional precursor molecule in the sample gas.

3 MEASURED QUANTITIES AND DERIVED INFORMATION

The primary measured quantities are the frequencies of the recorded spectroscopic transitions of the species under investigation. Often, these frequencies correspond to energy differences between rotational energy levels or between fine or hyperfine components of the rotational levels. Typically, a good number of transitions need to be measured to assign their quantum numbers confidently. The frequencies can then be used in a fitting procedure to determine the spectroscopic parameters of a model effective Hamiltonian, such as rotational constants, centrifugal distortion constants, nuclear quadrupole coupling constants, spin rotation coupling constants, spin−spin coupling constants, and barriers to internal motions. Although rotational transitions within excited vibrational states have been recorded in many instances, we restrict our discussions to the measurement and analyses of rotational transitions within the vibrational and electronic ground state. We discuss selected spectroscopic parameters below, which we feel are of most importance for the purpose of extracting information about the molecular system. For example, we neglect completely the interactions of molecules with external magnetic fields.

3.1 Mechanical Parameters: Rotational and Centrifugal Distortion Constants

The rotational constants are inversely proportional to the moments of inertia of the molecule in its principal inertial axis system, that is, the axis system in which the moment of inertia tensor is diagonal. They are thus a measure of the mass distribution within the molecule and can be used to derive structural information, that is, bond lengths and bond angles. For an asymmetric top molecule there are three rotational constants, A, B, and C, which can be used to determine at most three structural parameters. If more structural parameters are required, it is necessary to investigate the spectra of isotopically labeled species which can often be achieved using their natural abundances. All rotational constants can then be used to directly fit the structural parameters to obtain a so-called effective or r_o-structure, where r_o refers to the vibrational ground state. The r_o-structure differs from the equilibrium, r_e-structure because of the zero-point vibrational motions, and r_o-values are typically larger than r_e-values, depending on the ‘‘floppiness’’ of the bending or stretching vibration. The effects of the zero-point motions can partly be corrected for by the evaluation of a substitution, r_s-, structure using Kraitchman’s equations.[1] This procedure allows determining the position of an atom in the principal inertial axis system using the rotational constants of the parent molecule and of the species that is isotopically substituted at the atom in question. For a complete structure determination of a molecule with N atoms it is necessary to know the rotational constants of $(N-2)$ singly substituted species in the

case of a planar asymmetric top, and $(N-3)$ for a nonplanar asymmetric top. The remaining coordinates can be obtained using the moment of inertia equations and center of mass relations. A word of caution regarding the accuracy of derived structural parameters is warranted. Experimental rotational constants can be determined with sub-kHz accuracy at values of several GHz. A straightforward fitting procedure often results in very precise structural parameters, for example, bond lengths with errors in the 0.0001 Å range. These errors, however, do not take into account model inadequacies of the effective Hamiltonian or that the structural parameters represent some kind of average over zero-point motions that may be quite large in amplitude. Realistic errors are therefore often probably in the 0.001 to 0.01 Å range.

The centrifugal forces that occur during the rotation of a molecule lead to a slight deformation of the molecular structure and thus a slight change in molecular moments of inertia. The degree of bond stretching depends on the particular rotational state of the molecule. The centrifugal distortion constants are corrections to the rotational constants and account for this dependence. It is, therefore, possible to extract information about bond strengths, that is, force constants and vibrational frequencies from the centrifugal distortion constants. In a harmonic force field analysis, the force constants corresponding to, for example, the normal modes of vibration, are determined by fitting to the centrifugal distortion constants of one or more isotopomers. The vibrational frequencies can then be extracted using Wilson's GF matrix method.[16]

3.2 Nuclear Quadrupole Coupling Constants, Nuclear Spin-Rotation Constants, Nuclear Spin–Spin Interaction Constants

Some nuclei have a nonzero spin angular momentum **I** which can couple to the overall rotation of the molecule or to another spinning nucleus. If the nuclear spin quantum number $I > 1/2$, the nucleus has a nonzero electric quadrupole moment, Q, that can interact with the electric molecular field gradient, $q_{zz} = \delta^2 V/\delta z^2$, at the location of the nucleus to mediate the coupling between nuclear spin and molecular rotation (*see* ***Nuclear Quadrupole Resonance (NQR) Spectroscopy***). The result is a splitting of the rotational energy levels and the occurrence of a nuclear quadrupole hyperfine structure in the spectrum, where the number of hyperfine components depends on I and the rotational angular momentum quantum number J. The magnitude of the splitting depends on the nuclear quadrupole moment and the field gradient and can range from a few kHz for deuterium to several hundred MHz for iodine hyperfine structures. The analyses of the hyperfine structure yields the nuclear quadrupole coupling constants $\chi_{ij} = eQq_{ij}, (i, j = a, b, c)$, which are components of the nuclear quadrupole coupling tensor in the principal inertial axis frame of the molecule. Typically, the χ_{aa}, χ_{bb}, and χ_{cc} constants can be determined; sometimes one can obtain values for an off-diagonal constant, for example, χ_{ab}. In some cases, it is clear from the molecular symmetry that the principal axes of the quadrupole coupling tensor and of the inertial tensor coincide; in other cases, their relative orientation may be inferred from the geometry of the molecule or from χ_{ab}.

Since the electric quadrupole moments of many important nuclei are known, it is then possible to determine the electric field gradient tensor at the site of the nucleus, in particular, the field gradient components along the directions of the bonds involving the quadrupolar nucleus. Some of the dominant contributors to the field gradient are the electronic structure of the atom itself, the degree of hybridization of the bonding orbitals, the ionic character of the bond, π electron participation in the bond, and orbital overlap with the bonded atom. Townes and Daily[17] developed a method for the interpretation of nuclear quadrupole coupling constants in terms of the ionic character of the bond and hybridization, which takes into account only the valence electrons of the participating atoms. Consider the Cl nuclear quadrupole coupling constants in the cases of NaCl, with a rather ionic bond, and of ICl which has a substantial covalent bonding character. The Cl^- in NaCl has an essentially closed third electron shell and thus an essentially zero field gradient at the nucleus; the nuclear quadrupole coupling constant is therefore rather small, less than 1 MHz. In ICl, however, the singly occupied 3p orbital of Cl points along the bond axis, causing a substantial field gradient at the nucleus. The coupling constant χ_{Cl} is -82.5 MHz, whereas χ_{Cl} of the free Cl atom is -109.6 MHz. The discrepancy between χ_{Cl} in ICl and the Cl atom can be attributed to hybridization in ICl. Mixing of the doubly occupied 3s orbital with the bonding 3p orbital would reduce the electron deficiency along the bond axis and the magnitude of the nuclear quadrupole coupling constant decreases. In practice, one cannot differentiate between the effects of ionic bond character and hybridization, and one needs to, for example, estimate the ionic bond character based on electronegativity differences. A more detailed account regarding the interpretation of nuclear quadrupole coupling constants can be found in ***Nuclear Quadrupole Resonance (NQR) Spectroscopy***. Today, wavefunction-based and density functional ab initio methods are capable of calculating field gradients of at least second row elements and the Gaussian 03 program can calculate the actual nuclear quadrupole coupling constants.

Nuclei with nuclear spin quantum number $I \geq 1/2$ possess a nuclear magnetic moment that can interact with the magnetic field generated by the molecular rotation (spin rotation coupling) or with the magnetic field generated by another spinning nucleus (dipole–dipole or spin–spin interaction). The interpretation of spin rotation coupling constants, C, in terms of molecular properties is not straightforward. Bryce and Wasylishen have reviewed the relationships between microwave and NMR parameters involving spinning nuclei,[18] and point out the connection between spin rotation tensor and the chemical shift tensor, δ, an NMR observable (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Inorganic/Organometallic Molecules***). The

spin–spin interaction is described by two parameters, a second rank tensor parameter, S, and a scalar spin–spin constant. Their connection to the corresponding NMR parameters, that is, the direct dipolar coupling constant, R_{DD}, and the scalar coupling constant, J_{iso}, is also given in Ref. 18. The tensor spin–spin constant, S, provides information about the distance, r, between the interacting nuclei, and is proportional to $\langle 1/r^3 \rangle$, where the brackets indicate averaging over the corresponding wavefunction.

3.3 Electron Spin and Electron Orbital Angular Momentum Interactions

Electronic spin and orbital angular momenta in radicals and ions result in large magnetic moments that can interact with each other and with the rotational motion of the molecule.[19] The most important interactions are spin orbit coupling, spin–spin coupling, and spin rotation interaction. For molecules in Π electronic states, Λ-doubling effects are important. Nuclei with $I \geq 1/2$ possess a magnetic moment that leads to additional hyperfine structure through the interaction with the electronic angular momenta. These are the Fermi contact interaction and the dipole–dipole coupling term. The resulting spectroscopic parameters can be interpreted in terms of the molecular distribution of the electrons with nonzero angular momentum (see Section 4.3). However, the vast majority of microwave investigations involve molecules in $^1\Sigma$ states, and the reader is referred to Ref. 19 for a detailed description for the case of diatomic molecules.

3.4 Barriers to Internal Motions

Some molecules undergo large amplitude internal motions that interconvert equivalent configurations. Examples are the inversion umbrella motion in ammonia and methyl group internal rotations. These tunneling motions lead to splittings of the rotational energy levels that can manifest themselves as tunneling splittings in the observed spectra. In general, the higher the barrier to the internal motion, the smaller the tunneling splitting is. The splittings can be analyzed with an appropriate effective Hamiltonian to give parameters, such as the tunneling barrier, moment of inertia of the internal rotor, and orientation of the internal rotor axis within the molecular inertial axis frame.

3.5 Dipole Moments

The $(2J + 1)$-fold degeneracy of an energy level with rotational quantum number J can be partially lifted by placing the molecule in a static electric field. This so-called Stark effect can be utilized to measure the magnitudes of the dipole moment components, μ_a, μ_b, μ_c, in the principal inertial axis system of the molecule. For this purpose, Stark electrodes can be mounted outside the microwave cavity to generate a reasonably homogeneous electric field in the region of the molecular expansion. The observed rotational transition will split into several Stark components and the splittings can be used to fit values for the dipole moment components. It turns out that the splittings depend only on the magnitude of μ; the direction of the dipole moment must therefore be inferred from structural considerations or ab initio calculations.

3.6 Effects of Spin Statistics

If there are equivalent nuclei in the molecule, effects of spin statistics have to be taken into account.[20] In the case of two equivalent nuclei, such as for example, the two hydrogen nuclei in the water molecule, the total molecular wavefunction has to be antisymmetric under exchange of equivalent fermions (nuclei with half integer spin, e.g., the proton with $I = 1/2$) and symmetric under exchange of equivalent bosons (integer spin nuclei, e.g., the deuteron with $I = 1$). As a consequence, energy levels of different symmetries may have different spin statistical weights and certain levels may be completely missing. The observation of characteristic intensity ratios or the failure to observe transitions involving rotational levels of particular symmetry are thus good evidence for the existence of particular molecular symmetry elements.

4 CASE STUDIES

The following case studies are not meant to represent a comprehensive review, but are rather our narrow selection of some interesting cases that illustrate, in our view, the power and versatility of FTMW spectroscopy for the discovery and investigation of compounds that are of interest to inorganic and organometallic chemists.

4.1 Noble Gas–Metal Bonding in, and Structures of, Noble Gas–Noble Metal Halides

The first noble gas–metal halide investigated with the method of FTMW spectroscopy is Ar–NaCl.[21] The ^{23}Na and ^{35,37}Cl nuclear quadrupole coupling constants are changed by 1.3% to 17.3% from the respective NaCl monomer values. This is indicative of a slight change of the electronic structure of NaCl upon complex formation, although some of this effect must be attributed to vibrational averaging. The Ar–Na bond length ($r = 2.887$ Å) determined from the rotational constants and the relatively large centrifugal distortion constants are indicative of a true van der Waals bond in this linear complex. The small dissociation energy (660 cm^{-1}) and the low Ar–Na stretching frequency (76 cm^{-1}) obtained from ab initio calculations further support the notion of a true van der Waals bond. Some of the relevant parameters are listed in Table 1. Also given in Table 1 are columns with ‘‘covalent’’

Table 1 Derived spectroscopic and ab initio parameters of noble gas–metal halide systems[(a)]

	r_o/Å[(b)]	r_{vdW}/Å[(c)]	r_{cov}/Å[(d)]	D_o/ kHz	ω_e/cm^{-1}[(e)]	E_e/cm^{-1}[(f)]	ΔeQq/%[(g)]
Ar–NaCl	2.887	2.67		9.0874(59)	21	670	+1.8% (^{23}Na), −14.8% (^{35}Cl)
Ar–AgF	2.558			0.9533(15)	141	1470	N/A
Ar–AgCl	2.597	2.69	2.26	0.34651(49)	135	1360	−5.4% (^{35}Cl)
Ar–AgBr	2.639			0.11069(23)	124		−6.1% (^{79}Br)
Ar–CuF	2.219			0.9416(24)	224	3080	+73.3% (^{63}Cu)
Ar–CuCl	2.258	2.48	2.04	0.3435(14)	197	2300	+105.2% (^{63}Cu); −12.7% (^{35}Cl)
Ar–CuBr	2.296			0.12085(40)	170		+132.9% (^{63}Cu); −13.6% (^{79}Br)
Ar–AuF	2.391			0.5075(14)	221	4200	+507% (^{197}Au)
Ar–AuCl	2.469	2.65	2.25		198	3150	+2690% (^{197}Au), −12.8% (^{35}Cl)
Ar–AuBr	2.502			0.06506(39)	178		+582% (^{197}Au), −13.0% (^{79}Br)
Xe–AuF	2.548	2.95	2.57	0.06753(14)	169	8150	+891% (^{197}Au)

and ''van der Waals'' noble gas–metal bond lengths, which were obtained from the covalent noble gas and metal radii and from the van der Waals noble gas radius and ionic metal radius, respectively. Note that the Ar–NaCl bond length is actually larger than the ''van der Waals'' reference bond length.

The Gerry group began then to investigate coinage metal-containing systems, starting with ArAgX (X = F, Cl, Br).[23] Here, the Ar metal bond lengths range from 2.56 Å in ArAgF to 2.64 Å in ArAgBr, and are somewhat shorter than the reference van der Waals separation, r_{vdW} (see Table 1). Similarly, the centrifugal distortion constants, D_o, range from 0.9533 kHz in ArAgF to 0.11069 kHz in ArAgBr and are at least an order of magnitude smaller than those of typical van der Waals complexes. This implies that the ArAgX are more tightly bound than typical van der Waals complexes and that the Ar–Ag bonds may be classified as borderline between van der Waals and covalent bonds. It should be noted that the $^{35/37}$Cl and $^{79/81}$Br nuclear quadrupole coupling constants in the complexes are changed by only 5.3% to 6.1% from the monomer values. However, these coupling constants of the terminal halogen atoms are not very sensitive to the charge rearrangement upon complex formation that would involve mainly the Ar–Ag subunit. Unfortunately, there is no stable silver isotope with a nuclear quadrupole moment to probe this charge rearrangement more directly. Van der Waals stretching frequencies were determined from the rotational and centrifugal distortion constants, using $\omega_e = \left(4B_e^3/D_{J_e}\right)^{1/2}$ and approximating B_e and D_{Je} with the effective ground state constants B_o and D_o, respectively. Relatively large values of 141 cm^{-1} and 135 cm^{-1} were obtained for ArAgF and ArAgCl, respectively. For ArAgF and ArAgCl, ab initio dissociation energies of 1470 cm^{-1} (ArAgF) and 1360 cm^{-1} (ArAgCl) were determined.[22] These results are also supportive of some covalent bonding character of the Ar–Ag bond, as is the comparison of centrifugal distortion constant, Ar metal stretching frequency, and dissociation energy with the corresponding values of Ar–NaCl (see preceding text and Table 1).

Copper-containing noble gas–metal halides are predicted to have stronger noble gas–metal bonds compared to the silver analogues. Analyses of the microwave spectra of the ArCuX (X = F, Cl, Br) complexes[13] support this. The Ar–Cu bond lengths are rather short, ranging from 2.22 Å in ArCuF to 2.30 Å in ArCuBr. In fact the Ar–Cu bond lengths are about halfway between the reference van der Waals, r_{vdW}, and covalent, r_{cov}, bond distances in Ar–Cu (see Table 1). The centrifugal distortion constants are small, implying that the Ar–Cu bond is relatively rigid and can be classified as ''weakly covalent''. There is strong support for this view from the experimental nuclear quadrupole coupling constants, in particular, those of ^{63}Cu. The absolute values of these constants increase by 73% for ArCuF to 133% for ArCuBr compared to the respective copper halide monomers. This is a result of a significant charge redistribution upon complex formation. Second order Møller-Plesset calculations show significant overlap between the Cu 3d$_\sigma$ and Ar 3p$_\sigma$ orbitals in ArCuF, consistent with the large change in Cu nuclear quadrupole coupling constants.

The investigations continued with ArAuX (X = F,[24] Cl,[25] Br). In all instances, the Ar metal distances are now about halfway between the reference van der Waals, r_{vdW}, and covalent, r_{cov}, bond lengths (see Table 1). This is accompanied by dramatic changes in the ^{197}Au nuclear quadrupole coupling constants and large ab initio dissociation energies. Further evidence for real chemical bonds between Ar and Au comes

from molecular orbital ab initio calculations on the MP2 level of theory. In the cases of ArAuF and ArAuCl, there is significant overlap of Ar and Au orbitals in the 9σ, 6π and 11σ, 8π orbitals, respectively.

Gerry and co-workers have also investigated the corresponding compounds with krypton and xenon as noble gas atoms.[26–29] An example spectrum of the $J = 8-7$ rotational transition of XeCuCl is shown in Figure 2 to demonstrate the sensitivity and resolution that can be achieved with a FTMW spectrometer, and also indicates the complexity of the spectra if, for example, two quadrupolar nuclei are involved (^{65}Cu, $I = 3/2$; ^{35}Cl, $I = 3/2$) (J. M. Michaud, Private Communication). As expected, the degree of covalent bonding increases in going from argon to krypton to xenon. Of particular interest is that there are krypton and xenon isotopes with a nuclear quadrupole moment, that is, ^{83}Kr, $I = 9/2$ and ^{131}Xe, $I = 3/2$. In an isolated noble gas atom, the electric field gradient at the site of its nucleus is zero because of the spherical electronic charge distribution of the atom. The result is a nuclear quadrupole coupling constant of zero. There have been many cases reported of weakly bound complexes involving krypton and xenon atoms.[11] In all these cases, small, but nonzero, ^{83}Kr or ^{131}Xe nuclear quadrupole coupling constants provided evidence for a nonzero field gradient. This was attributed to the electric multipole moments (electric dipole moment, electric quadrupole moment) of the binding partners (a few MHz contribution to the nuclear quadrupole coupling constant at most) and to dispersion interactions (less than a MHz contribution). The ^{83}Kr and ^{131}Xe nuclear quadrupole coupling constants in Kr-, Xe-noble metal halide molecules are on the order of 100 MHz. These large values cannot be explained by the effect of charges external to the noble gas atom and with dispersion effects, but rather point to a significant participation of noble gas orbitals in a noble gas-noble metal chemical bond. It appears that the strongest such bond has been found in XeAuF (see Ref. 30, see Table 1). Note that the Xe–Au bond length in this compound is actually shorter than the reference covalent bond distance, r_{cov}. Most significant, however, remains the fact that this series of investigations provided some of the first evidence for covalent character of bonds involving the noble gas atom argon.

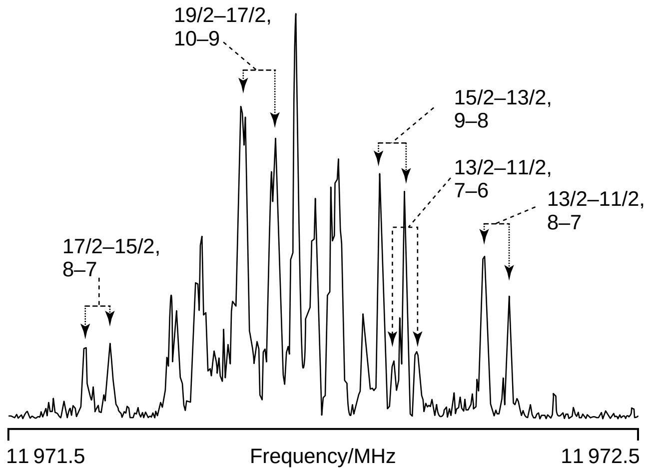

Figure 2 Spectrum of the $J = 8-7$ rotational transition of ^{132}Xe^{65}Cu^{35}Cl. The complicated hyperfine structure arises from nuclear quadrupole interactions of ^{65}Cu ($I_{Cu} = 3/2$) and ^{35}Cl ($I_{Cl} = 3/2$). All transitions are split into Doppler doublets as a result of the molecular expansion traveling parallel to the microwave cavity axis. For clarity of the picture, the quantum number assignments of only a few hyperfine components are given as $F_1'-F_1''$, $F'-F''$. The angular momentum coupling scheme $\mathbf{F}_1 = \mathbf{I}_{Cu} + \mathbf{J}$; $\mathbf{F} = \mathbf{F}_1 + \mathbf{I}_{Cl}$ was used. The compound was produced using laser ablation of a copper rod in a molecular expansion of a mixture of 0.1% Cl_2, 15% Xe, and 85% Ar. The particular isotopomer was measured in its natural abundance of 6.3%. This spectrum was recorded using 15 000 averaging cycles with a total accumulation time of about 3.5 h

High resolution spectroscopic measurements of the type described above often go hand in hand with highest level ab initio electronic structure calculations, to provide either help with the spectroscopic searches and quantum number assignments, or to aid in the interpretation of the spectroscopic information obtained. In the case of the larger noble gas atoms, xenon in particular, and the transition metals, ab initio calculations are still far away from even approaching spectroscopic accuracy. This has to do with the larger number of electrons involved and with the difficulties to account for relativistic effects. The ab initio computation of field gradients for atoms beyond the second row, for example, is exceedingly difficult.

4.2 Organometallic Compounds

Microwave spectroscopic studies of organometallic complexes began in the mid 90s, pioneered by the Kukolich group at the University of Arizona. One emphasis of these studies is to understand the relation between structure and reactivity of transition metal complexes. Very often the structures of these complexes were determined using X-ray diffraction in the solid state where ''crystal packing'' effects are present. These effects can distort the ''true structure'' of the molecule, and it is desirable to investigate these systems in the gas phase where these effects are absent. Using FTMW spectroscopy, the Kukolich group has measured rotational transitions of several transition metal complexes and determined the corresponding rotational constants, which have been utilized to derive structural information about these compounds. The transition metal complexes studied so far can loosely be grouped into four different types and some examples are discussed below.

4.2.1 Transition Metal Hydrides

One group of complexes studied are transition metal monohydrides such as the $C_5H_5Mo(CO)_3H$ and $C_5H_5W(CO)_3H$ complexes.[31] Transition metal monohydride complexes can serve as catalysts in acid–base synthetic

reactions. Some of their molecular derivatives have been explored as selective catalysts for hydrogenation reactions and protonation of aldehydes and ketones. Central to their catalytic activities is the metal hydrogen bond, which can function as a proton, hydrogen, and hydride donor under different conditions. Information about bonding and stability of the metal hydrogen bond is therefore essential in these studies. In general, X-ray diffraction experiments are the most common routes applied to probe the overall geometry of large organometallic complexes. However, the uncertainties in the hydrogen atom coordinates from X-ray data are very large. It has been recognized that the X–H distances thus obtained are often significantly shorter than the true X–H distances. This is because the X-ray measurements show electron density, and the density around hydrogen atoms is aspherically displaced toward the bonded atom. Neutron diffraction can help, but this is not always feasible (*see* ***Neutron Diffraction***). Microwave spectroscopic measurements, on the other hand, can overcome this limitation. The rotational spectra of both the naturally occurring isotopes of tungsten: ^{186}W, ^{184}W, ^{183}W, and ^{182}W, and the corresponding isotopically enriched deuterium isotopomers were measured and assigned. The W–H bond length was obtained using a Kraitchman analysis by comparing the sets of rotational constants for the isotopomers substituted at tungsten and hydrogen atoms. The W–H bond distance thus obtained is 1.79(4) Å. A similar analysis was also reported for the Mo–H bond distance in $C_5H_5Mo(CO)_3H$ and the value obtained is 1.80(1) Å. By studying species that are isotopically substituted at different atoms, a nearly complete gas phase structure of $C_5H_5W(CO)_3H$ was obtained from the microwave data and a slightly improved W–H bond distance of 1.79(2) Å was determined.

Microwave spectroscopy has also been applied to studies of transition metal complexes containing two hydrogen atoms. The unexpected discovery of the existence of dihydrogen complexes has attracted considerable attention. In these dihydrogen complexes, the H–H bond remains intact and the bond length is very similar to that of a free hydrogen molecule. Two systems studied so far are tetracarbonyldihydroosmium[32] and tetracarbonyldihydroiron.[33] Through the analyses of the microwave isotopoic data, important structural parameters were determined, for example, $r_{HH} = 2.40(2)$ Å, $r_{OsH} = 1.72(1)$ Å, $r_{OsC1} = 1.96(1)$ Å, and $r_{OsC3} = 1.97(2)$ Å. The H–H bond distance clearly indicates that tetracarbonyldihydroosmium is a classical ''dihydride'' rather than a ''dihydrogen'' complex. An analogous analysis was performed for tetracarbonyldihydroiron, showing a H–H bond distance of 2.2 Å, also indicating that this is also a dihydride complex.

4.2.2 Ferrocenes and Their Derivatives

The most extensively studied group of transition metal complexes using microwave spectroscopy are ferrocene-based systems[34–39]: the π bonding of the cyclopentadienyl (cp) radical to metals results in surprisingly stable complexes and many examples have been reported since the earliest discovery in the 1950s. A series of microwave spectroscopic studies were carried out with emphasis on providing ''true structures'' of these ferrocenes without the interference of, for example, crystal packing effects that are present in the solid phase. A complete set of gas phase structural parameters of ethynylferrocene was determined using rotational constants of eight isotopomers.[38] Both direct least squares fitting and Kraitchman analyses were performed and the structure parameters obtained with these two methods agree within their quoted uncertainties. Because of the extremely high resolution nature of pulsed molecular beam FTMW spectroscopy, it was also possible to detect the hyperfine splittings due to quadrupolar nuclei such as ^{35}Cl, ^{37}Cl, ^{79}Br, and ^{81}Br. The corresponding nuclear quadrupole coupling constants determined provide information about the electric field gradient at the particular nucleus and therefore the associated chemical bonding character.

One very exciting result obtained using microwave spectroscopy is the experimental discovery of the existence of two different structural isomers of 1,1′-dimethylferrocene (Figure 3). With the help of density functional theory (DFT) calculations, energies of five different geometries (Figure 4) were evaluated. These are associated with different dihedral angles ϕ between the two methyl groups on the cyclopentadienyl ligands, with ϕ fixed at 0° and four multiples of 36°. Three structures E0, E72 and E144 were identified theoretically as true minima, while S108 and S180 were identified as saddle points, that is, transition states. Other ϕ values were tried, but no new isomers could be located. Experimentally, only E0, an eclipsed synperiplanar isomer, and E72, an eclipsed synclinal

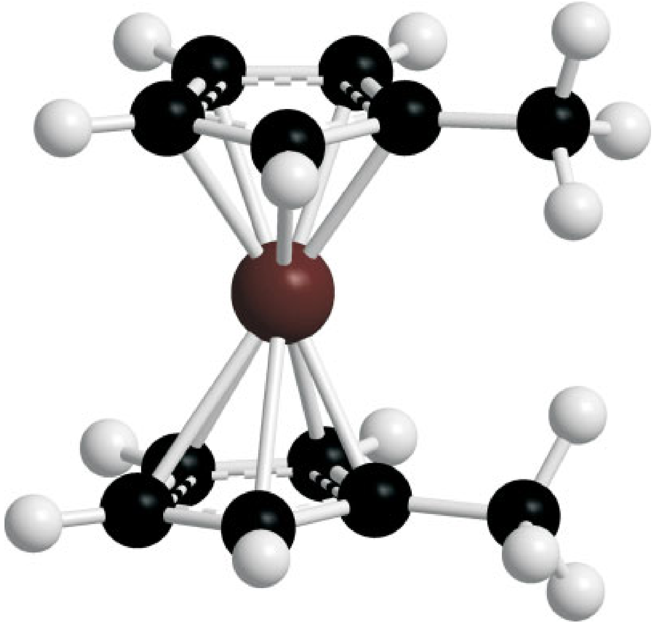

Figure 3 Structure of the eclipsed, synperiplanar (E0) conformer of 1,1′ -dimethylferrocene

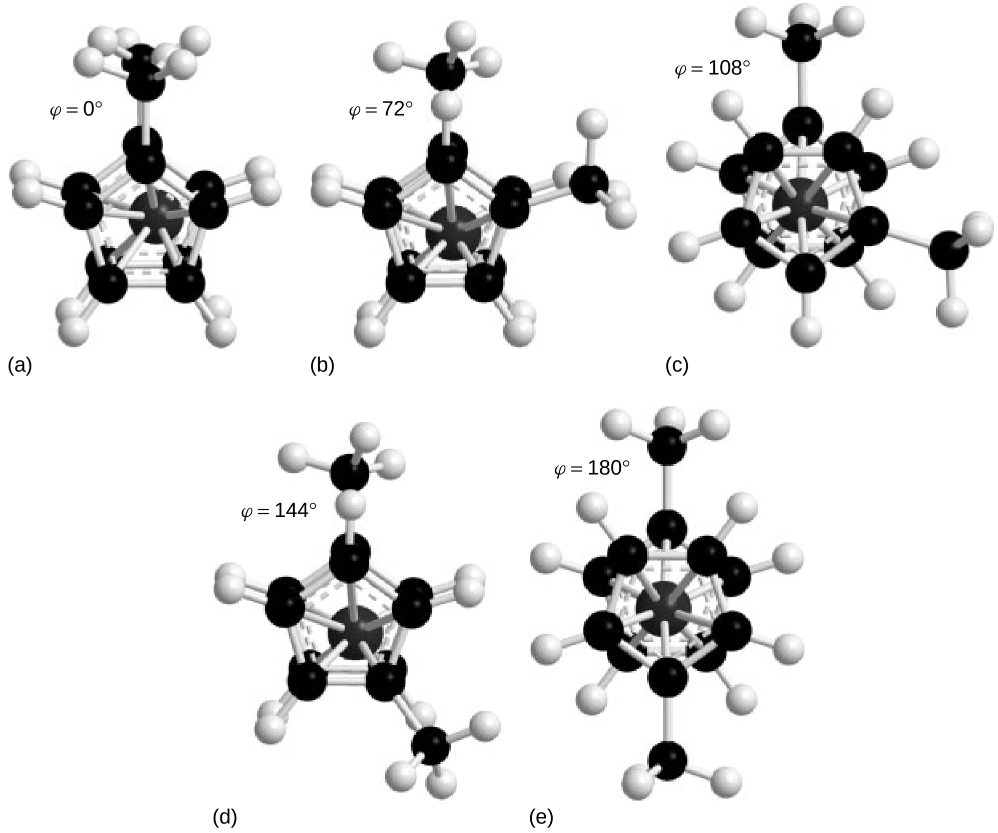

Figure 4 Five distinct structural conformers of 1,1′-dimethylferrocene: (a) eclipsed synperiplanar conformer E0 with $\phi = 0°$; (b) eclipsed synperiplanar conformer E72 with $\phi = 72°$; (c) staggered anticlinal conformer S108 with $\phi = 108°$; (d) eclipsed anticlinal conformer E144 with $\phi = 144°$; (e) staggered antiperiplanar conformer S180 with $\phi = 180°$

isomer, were detected. The assignment of the observed sets of rotational constants to these two isomers was achieved by comparing the experimental and the DFT rotational constants. The magnitudes of the centrifugal distortion constants indicate that E0 isomer is nearly rigid, while the E72 isomer exhibits fluxional behavior. For E72, the eclipsed synclinal isomer, some additional splittings were detected, providing further evidence of an internal tunneling motion. The E144 isomer could not be observed experimentally and this was attributed to the fairly small electric dipole moment predicted. The previous X-ray diffraction experiment showed only one isomer, E0, in the solid phase. The rotational constants determined from the X-ray structural parameters are somewhat larger than the experimental constants, evidence for possible effects of crystal packing forces.

From the microwave studies of different substituted ferrocene compounds, correlations between properties of the substituents and structural changes were established. It was noted that the carbon-iron bond distance in η5 C_5H_5-Fe is much more sensitive to substitution on the cyclopentadienyl ligand than the C–C bond distances of the C_5H_5 ring. This is summarized in Table 2. A linear correlation of the gas phase structural parameter r(Fe–Cp) and the electronegativity of the substituent group, represented by the Hammett substituent constant, $\sum \sigma_1$,[40] was established. In addition, a linear correlation was established between the r(Fe–Cp) structural parameter and the ferrocene/ferrocenium redox potential, $\Delta E°$,[41,42] at ambient temperatures relative to the ferrocene standard. The results of linear regression analyses are plotted in Figure 5. From the graphs, one can predict, for example, the r(Fe–Cp) gas phase value for unsubstituted ferrocene[43] to be 1.65(1) Å.

4.2.3 *Dinuclear Metal–Metal Carbonyl Complexes*

Metal–metal bonded dinuclear transition metal complexes are an important group of inorganic compounds and the research in this area has been reviewed recently.[44] Metal–metal carbonyl complexes are considered as building blocks for more specialized biological models and catalysts. One example of these simple metal–metal carbonyl complexes studied using the FTMW technique is $MnRe(CO)_{10}$. The Mn–Re bond distance obtained is 2.99 Å, in good agreement with the earlier solid phase value of 2.96 Å by Nesmeyanov *et al.*[45] but considerably longer than the 2.906 Å reported by Ridge *et al.*[46] Of interest is the determination of nuclear

Table 2 Structural parameters of different ferrocene compounds, $(C_5H_4\text{-}Y)\text{-}Fe\text{-}(C_5H_4\text{-}X)$, relative oxidation potentials at ambient temperatures, and Hammett substituent constants ($\sum \sigma_1$) for cp ligands

(b) The values for $\sum \sigma_1$ are from Ref. 40.

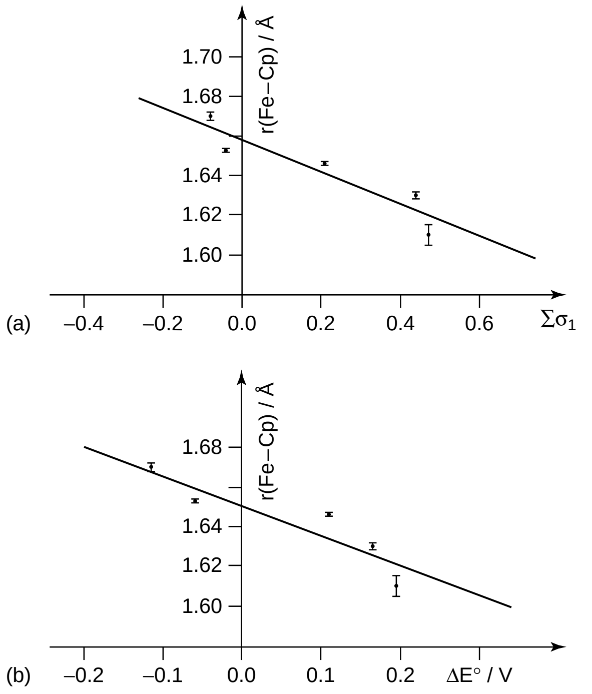

Figure 5 (a) The result of a linear regression analysis correlating the r(Fe−Cp) distance and $\Sigma\sigma_1$ of the substituent. This plot is governed by the equation r(Fe−Cp) $= -0.0821\Sigma\sigma_1 + 1.6585$ with a value of $r = 0.93$; (b) the result of a linear regression analysis between the r(Fe−Cp) distance and ΔE° of the substituent: r(Fe−Cp) $= -01499\Delta E^\circ + 1.6509$, with a value of $r = 0.91$

quadrupole coupling constants for ^{55}Mn, ^{185}Re, and ^{187}Re. The corresponding calculated ab initio values show very strong basis set dependent behavior and sometimes even the signs cannot be unambiguously determined. The experimental data here will be useful to guide and to test further theoretical developments in this respect.

4.3 Diatomic Transition Metal-containing Compounds

High resolution spectroscopic investigations of rotational spectra of transition metal compounds can contribute significantly to the characterization of the electronic structures of these compounds, which can often have high electronic spin and orbital angular momenta. The results are particularly important as a gauge for ab initio electronic structure calculations, which are still difficult for such heavy systems, partly because of the large number of low-lying electronic states. The method of FTMW spectroscopy in combination with a laser ablation/pulsed molecular expansion system is particularly suited for such investigations because of the high sensitivity and the high resolution achieved.

The National Institute of Standards and Technology (NIST) laboratory has studied rotational spectra of transition metal oxides, that is, YO, LaO, ZrO, and HfO.[47] Metal oxide molecules were entrained into the Ne backing gas expansion by laser ablation of the corresponding metal oxide rods near the nozzle orifice. ZrO and HfO have $^1\Sigma^+$ ground electronic states and their spectra are complicated by several naturally occurring isotopes of Zr and Hf, respectively. In addition, Hf has two nuclei with electric quadrupole moments (^{177}Hf, $I = 7/2$; ^{179}Hf, $I = 9/2$) leading to hyperfine structure in the spectra of the corresponding oxides. In both instances, the $J = 1\text{–}0$ rotational transitions were measured. The Stark effect of the $J = 1 - 0$ transitions was also investigated and dipole moments of 2.551 (11) D for ZrO and 3.431 (5) D for HfO could be determined. YO and LaO both have $^2\Sigma^+$ electronic ground states and both occur as only one naturally occurring isotopomer (^{89}Y, $I = 1/2$; ^{139}La, $I = 7/2$). The nuclear spins are coupled to the electron spin by a Fermi-contact interaction and there is additional nuclear quadrupole hyperfine structure in the spectra of LaO. The effect of Earth's magnetic field was canceled by the use of Helmholtz coils. Stark investigations gave dipole moments of 4.45 (8) D for YO and 3.207 (11) D for LaO. The dipole moment is a direct measure of the ionic character of the bond and the determined values agree with the expected trends. In general, the ionic bond character decreases in a row with increasing atomic number; an exception occurs between La and Hf, where the 4f shell is being filled.

Rotational spectra of copper iodide and silver iodide were investigated by the Legon group with a FTMW spectrometer.[48] The species were generated in a pulsed supersonic expansion in combination with a laser ablation

source. Cu or Ag atoms were produced by laser ablation of the corresponding metal rod. The metal atoms then reacted with methyl iodide contained in a pulse of argon backing gas, to abstract the iodine atom and to form the respective metal iodides. The hyperfine splittings of the rotational transitions were analyzed to give ^{107,109}Ag ($I = 1/2$), ^{63,65}Cu ($I = 3/2$), and ^{127}I ($I = 5/2$) nuclear quadrupole coupling constants. These constants were interpreted using the Townes-Daily model to evaluate the fractional ionic character, i_c, of the metal halide bonds to be 0.59 and 0.54 for CuI and AgI, respectively. The fractional ionic character of AgI can also be evaluated from its known dipole moment to be 0.53, in agreement with the value from the nuclear quadrupole coupling constants.

The FTMW spectrometer at the University of Tokyo was used to investigate rotational spectra of CrF and CrCl. Cr atoms were generated in a laser ablation source and reacted subsequently with chlorine or fluorine gas mixed into argon backing gas in the supersonic expansion to form the chromium halides. Both species have a $^6\Sigma^+$ electronic ground state. The electronic and nuclear spin angular momenta give rise to complex fine and hyperfine structures of the rotational transitions. Analyses of the spectra gave rotational and centrifugal distortion constants, electron spin–spin coupling parameters, λ, electron spin rotation coupling parameters, γ, magnetic hyperfine coupling constants that describe coupling of electron spin and nuclear spin of F or Cl, and, in the case of CrCl, a Cl nuclear quadrupole coupling constant. The electron configuration of CrF is (core) $(9\sigma)^1$ $(1\delta)^2$ $(4\pi)^2$. The magnetic hyperfine coupling constants are a measure of the contributions of the fluorine 2s orbital to the 9σ molecular orbitals and of the 2p (F) orbital to the 9σ and 4π orbitals. The former contribution was determined to be 0.19% and the latter to be 4.9%, implying that the 9σ and 4π molecular orbitals are mainly localized on the Cr atom. The 1δ orbital can be identified mainly with the 3d (Cr) orbital. The unpaired electrons are thus located at the Cr atom and the fluorine atom is essentially a closed shell F^- anion. The corresponding analysis of CrCl was complicated by effects of spin polarization. However, the ^{35}Cl nuclear quadrupole coupling constant $\chi = -17.4$ MHz allowed qualitative evaluation of the ionic character of the CrCl bond. If the bond is nearly ionic, such as in KCl, the Cl^- ion has a nearly spherically symmetric charge distribution and the value of the quadrupole coupling constant will be close to zero. In case of a nearly covalent bond, such as BrCl, the coupling constant is close to the atomic value, -109.74 MHz. A quantitative interpretation of χ will require support from high level ab initio calculations.

4.4 Species of Atmospheric and Astrophysical Interest

Microwave spectroscopy has been widely used to study small inorganic molecules and radicals that are of importance in atmospheric chemistry and astrophysics. One main driving force is the establishment of a spectroscopic database in the laboratory to aid the search and measurements of these species in the atmosphere and in interstellar and circumstellar environments.

Müller and Cohen have published a number of rotational spectroscopic studies on several important atmospheric molecules, such as $ClClO_2$,[49,50] which participate in catalytic ozone destruction. $ClClO_2$ was generated in situ by reacting $FClO_2$ with a volatile chloride. The products were then flowed through the absorption cell for spectroscopic investigation. The $ClClO_2$ molecule is an asymmetric prolate top and has four naturally occurring isotopomers due to the ^{35}Cl and ^{37}Cl isotopes. Extensive rotational data with quantum numbers $10 \leq J \leq 77$ and $0 \leq K_a \leq 34$ were collected in selected regions between 10 and 417 GHz, using a Stark-modulated absorption spectrometer. Analyses of the transition frequencies yielded rotational and centrifugal distortion constants with very high accuracy and the uncertainties of the fits are of a few kHz. It is therefore now possible to predict the frequencies of rotational transitions for future atmospheric measurements with very high confidence. The obtained rotational and centrifugal distortion constants were then used to derive the structural parameters and to refine the molecular harmonic force field. The quadrupole coupling constants for both Cl nuclei were determined and the molecular dipole moment was derived from low field Stark effect measurements. The experimental results were compared to theoretical predictions using ab initio and DFT methods with different levels of theory and basis sets. Such comparisons show that even with a fairly large basis set such as TZ2Pf at the MP2 level of theory, the dipole moment of the molecule is overestimated by 40%, while coupled cluster and density functional theories show good agreement for the dipole moment and its components in the principal inertial axis system.

Microwave spectra of small sulfur clusters and silicon clusters were reported by McCarthy, Thaddeus and co-workers.[51,52] Sulfur is one of the most cosmically abundant second row elements and 14 sulfur-containing molecules have been detected in a variety of galactic sources,[53] such as cold dense clouds and hot molecular cores, and some of them have been found in external galaxies. Despite extensive previous astronomical detection of small sulfur molecules, sulfur chemistry in space is still not well understood. In one of the laboratory studies, S_3 and S_4 were generated using a low-current DC discharge through argon flowing over a sulfur sample that was heated to 70 °C. Rotational transition lines of S_3 are typically four to five times more intense than those of S_4. These laboratory measurements of S_3 and S_4 provided accurate spectroscopic constants and relevant line frequencies to aid radio-astronomical searches for these new species in molecular clouds, circumstellar shells, Io, and comets. The ultimate aim is to identify the major sulfur reservoir in dense molecular clouds. A wide range of silicon bearing molecules has been observed in circumstellar envelopes, for example, SiO, SiS, SiC_2, SiC, SiC_4. This is in part due to extensive previous laboratory spectroscopic investigations which have provided accurate rest frequencies for these compounds. More

recently, pure silicon clusters, such as Si_3, were detected using a sensitive FTMW spectrometer.[52] Si_3 in its electronic ground state has an isosceles triangular structure with a dipole moment of 0.3 D.[54,55] Rotational transition frequencies of the main isotopomer, $^{28}Si_3$, and several of its rare isotopomeric species were measured to an accuracy of a few parts in 10^7. The frequencies of the most intense radio lines were calculated from the derived spectroscopic constants with an uncertainty of better than 3 km s^{-1} in equivalent radial velocity up to frequencies of 50 GHz. This is good enough for a search in the most promising astronomical sources for such species.

Small inorganic radicals have also been studied quite extensively in the microwave region. Some examples are metal-containing radicals such as $MgNH_2$,[56] $LiNH_2$,[57] and linear carbon chain radicals such as C_5H_2, C_6H_2,[58] C_5H, C_6H, and C_8H.[59] $LiNH_2$ can be used to deprotonate ketones, aldehydes, and other structurally related organic molecules and play an important role in organic synthesis. One challenge in carrying out gas phase measurements of alkali metal amides is that they tend to aggregate in the condensed phase and even in the gas phase. Rather than vaporizing monomeric $LiNH_2$ from a solid phase sample, Ziurys *et al.* produced it directly in the gas phase by the reaction of gaseous NH_3 and lithium vapor. In this way, they were able to generate enough monomeric $LiNH_2$ in the gas phase to study its rotational spectrum. From the microwave data, it was found that the molecule is planar with an Li−N distance of 1.736(3) Å, an N−H distance of 1.022(3) Å and an H−N−H angle of 106.9(1)°. Although there had been over 20 theoretical calculations reported for $LiNH_2$ and a substantial amount of experimental data for oligomeric solid phase samples, the question whether monomeric $LiNH_2$ is planar or not was not resolved before this study. These microwave results have provided the first direct experimental evidence for the planar structure of $LiNH_2$.

Linear hydrocarbon radicals have been the subject of intensive laboratory spectroscopic and radio-astronomical research since the early 1980s. In recent years, a considerable number of rotational spectroscopic studies of medium to longer hydrocarbon chains such as C_5H, C_6H, C_8H,[59] and $C_{14}H$[60] have been carried out using a pulsed molecular beam FTMW spectrometer. The high resolution offered by such a spectrometer allowed the detection of the hyperfine splitting of rotational transitions. These measurements improved fine and hyperfine coupling constants and provided rest frequencies with accuracies better than 0.30 km s^{-1} in equivalent radial velocity up to 50 GHz. Indeed, some of the small C_nH radicals with $n < 9$ have subsequently been detected in space, in molecular cloud cores, and in certain circumstellar shells. These hydrocarbon chains are among the most abundant reactive space molecules known.

An exciting recent development is the work by Endo *et al.* who reported the detection and analyses of the rotational spectrum of the water-hydroperoxy radical complex.[61] The self reaction of the hydroperoxy radical is a primary source of atmospheric hydrogen peroxide: $HO_2 + HO_2 \rightarrow H_2O_2 + O_2$.[62,63] This reaction is catalyzed by water. The $H_2O{-}HO_2$ radical complex was proposed to be the intermediate generated in the process.[62,63] The binding energy of the complex is fairly large, about 9.4 kcal mol^{-1}. It was hypothesized that this complex could act as a sink for the atmospheric HO_2 radical. Endo *et al.* produced the HO_2 radical by applying a high voltage electric discharge (1.5 kV) in a gas mixture of O_2 and Ar inside a pulse discharge nozzle. The radical entrained in the Ar flow was subsequently passed through a reservoir filled with pure water and then expanded into a vacuum chamber through the pulsed nozzle. The targeted radical complex was generated in the supersonic expansion. Pure rotational transitions with hyperfine splittings were measured and the frequencies were fitted to yield spectroscopic parameters. In addition to the rotational spectroscopic constants, the Fermi coupling constant, a_F, was also determined. This parameter is a direct measure of the unpaired electron density at each hydrogen nucleus and provides information about the unpaired electron distribution upon complex formation. In particular, this study shows that the a_F value for the HO_2 proton is −27.511(21) MHz, almost identical to that of free HO_2, while that of the H_2O protons is much smaller at −0.0395(62) MHz. This indicates that only a very small portion of the unpaired electron density is delocalized over the H_2O part. This result is somewhat surprising since substantial delocalization of the unpaired electrons was detected in other radical molecule complexes such as $H_2O{-}OH$[64] and NO−HF.[65] This is despite the fact that $H_2O{-}HO_2$ is much more strongly bound than $H_2O{-}OH$. The rotational spectroscopic study also shows that the radical complex forms a nearly planar five-membered ring with HO_2 acting as a proton donor and one hydrogen atom of water sticking out from the ring plane. The accurate transition frequencies obtained provide the data needed for remote sensing of this complex. Such work may further elucidate the potential roles of the water-hydroperoxy radical complex in atmospheric chemistry and provide a conclusive answer to the proposed hypothesis.

4.5 Weakly Bound Complexes

The method of FTMW spectroscopy has been used to study a large number of weakly bound complexes and clusters.[11,66] One main goal in these studies is to determine the structure and the intermolecular dynamics, that is, the degree of large amplitude vibrational motions, in these systems, and ultimately to characterize the intermolecular interaction potential as a function of separation and orientation. These are aspects of these studies that are of interest to the inorganic chemist.

As mentioned before, a nonzero electric molecular dipole moment is necessary for the observation of (dipole-allowed) rotational microwave transitions. That makes it impossible to study the rotational spectra of substances such as dinitrogen, N_2. Note, however, that microwave studies were

reported for isotopically labeled carbondioxide, $^{16}OC^{18}O$,[67] and for higher J transitions of methane[68] with a centrifugally induced dipole moment. Another possibility is to use a rare gas atom as a structureless probe to enable the spectroscopic investigation of otherwise nonpolar molecules. A molecular expansion of N_2 in neon backing gas can be used to produce Ne$-N_2$ van der Waals complexes. The binding energy is provided primarily by dispersion interactions, which also lead to a small, but nonvanishing, electric dipole moment. The rotational spectrum of the Ne$-N_2$ complex can then be investigated with a FTMW spectrometer.[69] This work has resulted in an accurate experimental determination of the ^{14}N nuclear quadrupole coupling constant in dinitrogen [$\chi = 5.372(2)$ MHz], which had thus far been unavailable. This procedure was validated by the microwave investigation of the Ar$-CO_2$ van der Waals complex.[70] In this case, the ^{17}O nuclear quadrupole coupling constant of the complexes could be determined. This constant was used to determine the corresponding constant in the carbon dioxide monomer, and was found to agree with the value obtained from the isotopic study.[67]

Another interesting aspect of the spectroscopy of van der Waals complexes is the investigation of species containing xenon atom. Hyperpolarized xenon is used in magnetic resonance imaging experiments to characterize void spaces, such as, for example, micropores in zeolites.[71] An interpretation of the measured chemical shifts in terms of the microscopic, molecular environment will require the availability of accurate Xe-surroundings interaction potentials and shielding surfaces. The microwave investigations of Xe-molecule systems are a first step to achieve this goal. Recent studies of the Xe$-H_2O$ and Xe$-(H_2O)_2$ complexes,[72,73] for example, can help to determine the effect of crystal water in zeolites on magnetic resonance parameters. It was possible in these studies to determine the ^{131}Xe nuclear quadrupole coupling constants. Their interpretation in terms of the electric multipole moments of water, together with ab initio calculations on the MP2 level, revealed that the two water molecules in Xe$-(H_2O)_2$ assume distinctly different orientations with respect to the xenon atom (Figure 6).

The xenon atom can therefore be used as a delicate probe to determine the number of surrounding water molecules and their orientations. These results demonstrate the sensitivity of the easily polarizable xenon electronic structure to the electrostatic properties of its surrounding and the great potential for achieving accurate interpretations of magnetic resonance parameters from imaging experiments with hyperpolarized xenon.

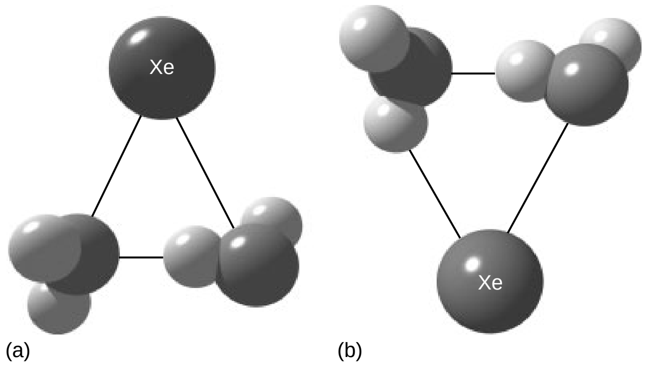

Figure 6 These two structures of the Xe$-(H_2O)_2$ complex correspond to the two minima found in ab initio calculations on the MP2 level for this system. An interpretation of the ^{131}Xe nuclear quadrupole coupling constants and comparison with the corresponding constant in Xe$-H_2O$ reveal that the structure in (a) is consistent with the data from the microwave spectrum

METHOD SUMMARY

Acronyms, Synonyms

- Neutron Radiation
- Crystallography
- Single-Crystal Neutron Diffraction.

Measured physical quantities

- diffraction of neutrons by the nuclei of atoms in a crystal.

Information available

- structural information including geometry and bond lengths, especially those involving light atoms like hydrogen;
- isotopic discrimination (most notably, distinguishing H from D).

Information not available, limitations

- not suitable for materials with a high content of neutron-absorbing elements such as boron or cadmium;
- heavy atom coordinates are usually required from an X-ray experiment to phase the single-crystal neutron diffraction data.

Examples of questions that can be answered

- What is the location of chemically interesting hydrogen atoms?
- What is the magnetic structure of the sample?
- Where has (H/D) isotopic exchange occurred?

Major advantages

- Hydrogen atoms can be located in a single crystal diffraction experiment.
- Information regarding magnetic structure can be obtained.
- The sample does not usually suffer any radiation damage.
- Metal−hydrogen and hydrogen−hydrogen distances can sometimes be measured to accuracies of ±0.005 Å or more in a single-crystal diffraction experiment.

Major disadvantages

- Neutron sources (a nuclear reactor or spallation source) are very limited in number.
- Large crystals (typically 1−5 mm^3) are required because neutron radiation is relatively weak (as compared to X-ray intensities).
- For single-crystal experiments, data collection times (1 day to 2 weeks) are several orders of magnitude longer than X-ray data collection times.
- Powder experiments are usually limited to compounds with smaller unit cells.

Sample constraints

- Large crystals in the range of 1 mm^3 or bigger are required for single-crystal neutron diffraction experiment.
- The sample must not contain, high amount of neutron absorbing element.

1 INTRODUCTION

Neutron diffraction is, for most practicing chemists, an underutilized and underappreciated tool. Nevertheless, it is rapidly gaining in popularity as newer (and more effective) instruments, as well as more intense neutron sources become available in the future. Thus, the main point of this article is to provide examples to show that neutron diffraction can offer additional valuable information in certain areas of chemistry where X-ray diffraction is either inadequate or inapplicable. As the focus of this article is on applications, the theory of neutron diffraction will not be discussed in detail, although we do refer the reader to a number of texts that cover this topic.[a][1,2] Nevertheless, to give the reader a ‘‘flavor’’ of what is ‘‘usually expected’’ in a neutron diffraction study, we will briefly describe the features of a few selected existing neutron facilities and instruments.

First of all, one should realize that, although the main focus of this article will be on *single-crystal* neutron diffraction,[3–7] it should be kept in mind that this only represents a small slice of all neutron scattering experiments. First and foremost, there is powder neutron scattering,[8–10] a field in which there are far more publications than those that feature single-crystal neutron studies. Then there are innumerable other applications that do not require the availability of crystalline samples, such as small-angle neutron scattering (SANS), inelastic neutron scattering (INS),[11] to name a few. Secondly *within single-crystal neutron diffraction itself* there are a number of subfields, such as (i) the location of small atoms (usually H or D) under conditions in which X-ray diffraction cannot provide an unambiguous answer, (ii) isotopic discrimination (usually experiments designed to tell the difference between H and D positions), (iii) studies of magnetic structure,[12,13] which take advantage of the fact that the neutron has a spin (unlike X rays, which as photons have no spin),[b] (iv) diffuse scattering,[14] in which the nature of *disorder* in a structure is studied, and (v) high-pressure studies in which the structure of crystalline materials when subjected to enormous pressures are probed. In this article we will mainly be focusing on topic (i), (also reviewed in references Refs. 3−7) which is starting to expand from the realm of small-molecule structure determination to the determination of H and D positions in macromolecules (proteins and oligonucleotides).[15–25]

2 SOME BASIC FACTS OF NEUTRON DIFFRACTION

In contrast to X rays, the scattering factors for neutrons are not proportional to atomic number. Whereas X rays

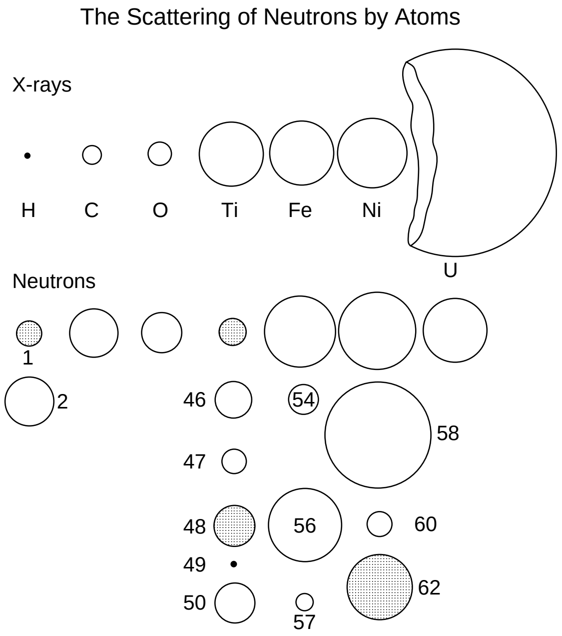

Figure 1 A comparison between the scattering of X rays and neutrons by the same seven atoms (H, C, O, Ti, Fe, Ni, and U). The numbers given in the bottom half of the figure are atomic weights, not atomic numbers. Shaded circles represent isotopes which appear as negative peaks in a neutron Fourier map. (From Bacon.[1] Permission of Oxford University Press)

are scattered from electrons, the point of diffraction for neutrons is the nucleus of an atom. Figure 1 schematically compares the scattering factors of some atoms for both X rays and neutrons. One can immediately notice that for the small atoms, like H and D, neutrons are scattered significantly better than X rays, while the opposite is true for heavier atoms. A second feature to note from Figure 1 is that neutrons have the ability to distinguish between some isotopes (notably H from D) since the scattering factor for hydrogen is negative (shaded in Figure 1). (Note: a positive scattering factor indicates that the neutron wave undergoes a phase inversion upon scattering, whereas a negative scattering factor corresponds to no phase change. This peculiar ''inverted'' convention was adopted deliberately in order to ensure that most nuclei would have positive scattering values.[1] In practice, this means that H appears as a negative peak in a neutron difference Fourier map, whereas a D-atom appears as a positive peak.)

To summarize what was pointed out earlier, this makes neutron diffraction invaluable for studies of metal hydrides, agostic interactions, and H/D exchange. Furthermore, since neutrons have an intrinsic spin (unlike X rays which are massless photons) they can interact with the electronic spin of the atoms in a sample and thereby provide information concerning the magnetic properties of the sample under study. Data collection at high scattering angles (back-scattering reflections) are often possible since the level of falloff of neutron intensity at high resolution is much less than that of X rays.[1] In addition, neutron radiation is nondestructive in nature which allows for the study of most materials that are sensitive to radiation damage.

3 DISADVANTAGES OF NEUTRON SCATTERING

The major disadvantages of neutron diffraction, from the viewpoint of most practicing chemists, are twofold: the requirement of a large crystal, and the limited availability of neutron sources. (i) Since the neutron flux from most existing neutron sources are several orders of magnitude weaker than photon fluxes from a typical X-ray tube, much larger crystals (originally in the range of 5–20 mm^3, more recently, vide infra, in the range of 1–2 mm^3) are needed for a neutron diffraction experiment. Any chemist who has gone through the trouble of growing diffraction-quality crystals for an X-ray study can appreciate the difficulty involved in growing ''neutron-sized'' crystals: that is, samples with 10–100 times the volume of ''X-ray-sized'' crystals. (ii) Another consequence of low neutron flux is data collection time: while modern X-ray diffractometers equipped with efficient charge-coupled device (CCD) detectors can typically collect a data set in several hours (and in tens of minutes or less in the case of X-ray synchrotron sources), most of the older ''traditional'' neutron diffractometers require data collection times of a week or so. Currently there are newer instruments[26,27] that can cut neutron data collection times to a day or two, and these will be discussed later in this article. The second disadvantage mentioned earlier is the fact that neutron *sources* are not as widely available as X-ray sources, with only a handful of facilities in the world capable of conducting neutron experiments. In the next section, we will give a little more background information and briefly describe the two major types of neutron sources that are used around the world today.

4 NEUTRON FACILITIES (REACTOR SOURCES AND SPALLATION SOURCES)

Neutron ''user'' facilities are scattered throughout the world. These neutron sources are of two types, (i) nuclear reactors which provide a steady beam of neutrons[1] and (ii) spallation sources which offer pulsed neutron beams.[2] Each type of facility offers its own advantages and a reader interested in pursuing this topic is referred to the description of each individual site[28–33] for further details. Reactor sources are based on the conventional ^{235}U fission process and therefore, are somewhat similar to conventional nuclear-powered electricity generators, with the major exception that the ^{235}U enrichment level of the nuclear fuel in a research reactor is much higher than that in a conventional electricity-generating nuclear power plant. Existing neutron sources of this type include the HFIR reactor in Oak Ridge,

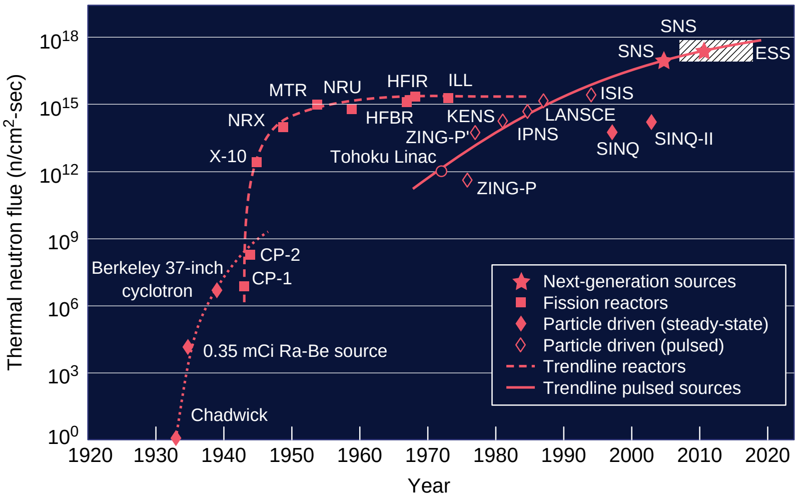

Figure 2 Improvement in Neutron Fluxes (vertical axis) over time (horizontal axis). Note the predominance of fission reactor sources from 1945 to 1980 (dashed line in the middle) and the steady drift toward more intense spallation sources in more recent years (solid line to the right). (Drawn from data in Skold & Price, 1986)

Tennessee,[28] the JRR-3 reactor in Tokai (Japan),[29] the Institut Laue-Langevin (ILL) reactor in Grenoble, France,[30] and, two more recent facilities, the new Opal reactor in Lucas Heights, Australia[31] and the FRM-II Reactor in Munich, Germany.[32] There are countless other less intense sources too numerous to mention in this brief review.[33] It is generally acknowledged that the ILL reactor currently has the highest flux of conventional nuclear sources (Figure 2).

Pulsed sources[2,34,35] operate under a completely different principle and basically are meant to produce neutrons without the use of a nuclear reactor. In brief, hydride ions (H^-) are accelerated down a linear accelerator (LINAC) to velocities approaching the speed of light. Then their electrons are stripped off, converting the H^- ions into H^+ (protons) which are then diverted into an accumulator ring in most sources, whose main function is to accumulate protons to produce short-, high-intensity pulses. Several times a second (typically, 10–60 s), these protons are directed onto a target (usually made of a high-melting, heavy-atom target such as tungsten, tantalum, or uranium), where they collide with the nuclei of the target and produce large amounts of neutrons through a process known as spallation.[2,34,35] Each collision of a proton with a heavy-atom nucleus produces between 10 and 30 neutrons. The main advantage of a pulsed source is that, in principle, all the thermal neutrons from each pulse are useful in a diffraction experiment (as opposed to those from a monochromatized steady-state nuclear reactor source, most of which are wasted). At a pulsed source, the more energetic neutrons arrive at the sample and the detector *earlier* than the slower and less energetic neutrons such that time-of-flight techniques are utilized to determine the wavelength of each detected neutron. Thus, one needs ‘‘three-dimensional’’ detectors (recording two spatial coordinates, x, y, and time), coupled to computers able to acquire and process enormous amounts of data. The first spallation source was ZING-P constructed by Jack Carpenter and his group at Argonne Laboratory,[34,35] subsequently replaced by ZING-P’ and now the intense pulsed neutron source (IPNS)[36] at Argonne. Other pulsed sources included the LANSCE spallation source at Los Alamos, New Mexico[37] and ISIS in Didcot, England.[38] Currently under construction are much more powerful spallation sources: spallation neutron source (SNS) in Oak Ridge, Tennessee[39] and J-PARC in Tokai, Japan.[40] The latter two facilities, whose single-crystal instruments will gradually become available in the years between 2008 and 2010, are expected to have neutron beams about 50–100 times more intense than those of existing spallation sources because of their intended use of liquid mercury as a heavy-metal target.[39,40] When operational, it is expected that they should cut down crystal-size requirements by at least an order of magnitude compared to current ‘‘neutron-sized’’ crystals, which should clearly be an advantage for practicing chemists (and biologists).

Figure 2 summarizes the historical development of neutron sources and the gradual drift toward spallation sources (and a concomitant increase in neutron flux) with the progress of time.

5 NEUTRON INSTRUMENTS (DIFFRACTOMETERS)

Historically, all the early neutron sources were of the conventional reactor type, and a large monochromating crystal was commonly employed (for single-crystal diffraction experiments) to select neutrons with a small wavelength spread in order to produce a monochromatic neutron beam.[1] The rest

of the neutrons (of different wavelengths) were discarded and hence the use of a monochromatic beam was intrinsically a wasteful process (in that only a small fraction of the neutrons was used in a diffraction experiment). In addition, the earliest single-crystal instruments were modeled after existing X ray diffractometers, meaning that in those early days reflections were collected one at a time, another inefficient technique by today's standards. During that period (from the 1950s to the 1970s), crystal size requirements were typically in the volume range 5–20 mm^3.

With time, improvements in instrumentation[26,27,33,41–45] were made which resulted in reduced sample size and/or data collection time. An especially significant step (following developments in X-ray data collection) involved the use of area detectors to collect dozens to hundreds or thousands of reflections simultaneously. The details of various area detectors used are too varied to warrant a detailed discussion here, and may not be of interest to many readers of this article. Suffice it to say that most detectors rely on efficient neutron-absorbing components (such as ^{3}He, ^{6}Li, ^{10}B, or ^{157}Gd), which then produce other particles (typically, photons or electrons) that are actually counted.

One noteworthy (relatively recent) event is the development of neutron-sensitive image plates that are relatively inexpensive and capable of high spatial resolution. A particularly successful example of this is a plastic film containing atoms of Gd, which act as neutron-capturing centers that subsequently emit detectable radiation.[41,42] The flexibility of this plastic-supported detector allows it to be fashioned into a cylindrical shape, which results in a much larger solid angle of reflections that can be collected, as compared to a flat detector. Examples of such cylindrical detectors include those presently used in the BIX-3 and BIX-4 diffractometers at JAEA in Tokai, Japan,[43] the LADI[44] and VIVALDI[26,27] diffractometers at ILL in Grenoble, France, and the soon-to-be-operational quasi-Laue diffractometer (KOALA) diffractometer at the open pool Australian light-water reactor (OPAL) reactor in Lucas Heights, Australia, which has a design similar to VIVALDI. Some of the above-mentioned instruments further take advantage of data collection using the quasi-Laue technique[46–48] (which employs a broader range of neutron wavelengths and allows for a greater neutron flux).[46–48] VIVALDI, in particular, is capable of handling samples as small as 0.5–1.0 mm^3, and with (in favorable cases) data collection times as short as 24 h.[26,27]

But arguably, the most exciting future development is the SNS, which is currently being built in Oak Ridge, Tennessee.[39] When fully completed (scheduled to take place around 2007–2008), this facility is estimated to provide neutron beams between 50 and 100 times the intensity of current pulsed neutron sources. As far as single-crystal neutron diffraction experiments are concerned, the instrument currently being built for medium-sized unit cells is TOPAZ[49] (Figure 3), which is scheduled to be available to users some time in 2009 and is planned to handle crystals having volumes as small as 0.1 mm^3 (i.e., ''X-ray-sized'' crystals) and/or data collection times as short as 6–12 h. Also in the planning stage is an instrument at SNS designed to handle protein crystals called *macromolecular neutron diffractometer* (MaNDi),[50] which should be ready about a year or so after TOPAZ. It should also be pointed out that, additionally, another instrument called BIX-P1[51] is also being planned for macromolecular crystallography in the analogous spallation source J-PARC[40] under construction in Tokai, Japan and an instrument called LMX[52] (large molecule crystal diffractometer) designed for crystals with large unit cells is planned for a second target station at ISIS[38] in Didcot, England.

6 POWDER DIFFRACTION

In cases where it is difficult to obtain large crystals, chemists may logically conclude that powder diffraction experiments offer a suitable alternative. However, powder diffraction experiments[8–10] are usually restricted to large samples of smaller unit cells than those commonly involved in a typical organometallic structure. In addition, because the nature of the diffraction data is one-dimensional (rather than three-dimensional in a single-crystal experiment), peak overlap is a serious problem. This difficulty is largely alleviated by the use of the Rietveld method,[53–57] in which the overall *profile* of the diffraction pattern is essentially scanned stepwise to yield hundreds of individual intensity measurements. Furthermore, deuteration is almost always necessary in a powder

diffraction experiment because, otherwise, background problems (arising from the incoherent scattering[1] from hydrogen atoms) would seriously compromise the results of the structural analysis. Finally, combined X-ray/neutron refinement, in which both X-ray and neutron data[58] are used in least-squares refinement of a structure, is much more commonly used in powder diffraction studies (*see* ***X-Ray Powder Diffraction***). Despite all these limitations, publications involving powder neutron studies far outnumber those involving single-crystal neutron investigations largely because of the previously mentioned difficulties in growing large single crystals.

7 MAGNETIC STUDIES

Another widely used application of neutron diffraction is in the study of magnetic structure.[59–61] We will not say much in this article because of space limitations, but in essence the technique takes advantage of the fact that neutrons, being intrinsic particles, have spins, while X rays do not. The *nuclear* spin of the neutrons can interact with the *electronic* spins in a magnetically active sample and, for example, can distinguish between parallel and antiparallel spins of pairs of atoms in a ferromagnetic or antiferromagnetic sample (e.g., Figure 4).

In favorable cases, even the spin density of a paramagnetic molecule can, in principle, be mapped out.[62–66] In some cases, polarized neutrons[67–70] are necessary in a magnetic structural study, in other cases, an unpolarized neutron beam is adequate. The subject matter of magnetic structure is discussed in Ref. 61 but for a more detailed discussion the reader is encouraged to consult more specialized texts regarding this subject.[59,60]

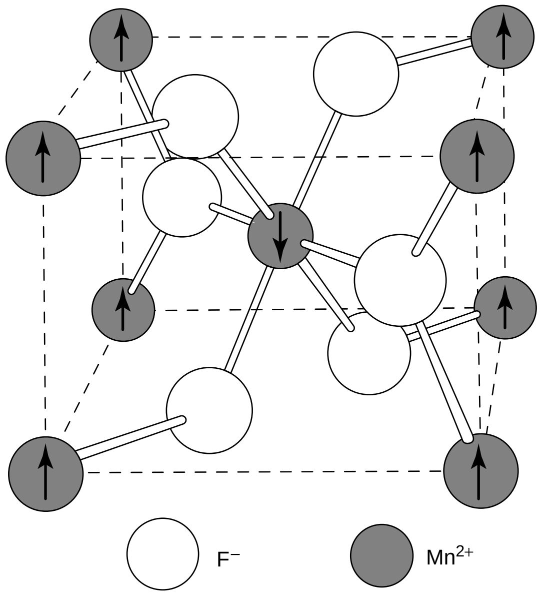

Figure 4 The magnetic structure of MnF_2 from a neutron diffraction study.[1] Note that the central Mn atom has its spin opposite to those at the corners in this antiferromagnetic arrangement. (From Bacon.[1] Permission of Oxford University Press)

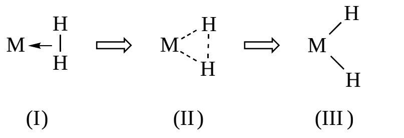
8 LOCATION OF HYDROGEN ATOMS

We now come to the main theme of the article, the part that is perhaps the most interesting to the average chemist (and biologist), and that is the accurate location of hydrogen atoms in a molecule. While it is true that the data from current CCD-based X ray diffractometers are good enough to enable the investigator to find most hydrogens (certainly hydrogens bonded to the light elements, or at times to a single atom of a first-row transition metal), there remain several areas in which neutron diffraction data can make a difference: (i) when ultra-accurate H atom positions are needed (e.g., in distinguishing between a symmetric and an almost-symmetric hydrogen bond);[71] (ii) when H atoms are bonded to extremely large atoms like Th or U,[72] or when H atoms are surrounded by several metal atoms in a cluster[73–76]; (iii) when H...H distances, such as those in nonclassical dihydrogen complexes[77–81] or ‘‘stretched’’ dihydrides,[82–89] need to be measured to a high-level of precision (vide infra); (iv) when H atoms are involved in agostic[90] interactions (again, this involves measuring C–H distances and M–C-H angles to a high-degree of accuracy); and finally (v) last but rapidly gaining in scientific interest, the location of H atoms near the active site of an enzyme.[15–25] Owing to limited space, we will not attempt to cover all of these areas but will selectively discuss a few.

The general strategy for a single-crystal neutron diffraction study is to first solve the crystal structure using X-ray diffraction, in order to acquire the coordinates of all the nonhydrogen atoms. Then, after a sample suitable for neutron diffraction has been grown and data collected, the atomic positions obtained from the earlier X-ray study are used to phase the neutron data. At this point, location of H atoms is done merely by searching for negative neutron peaks in the density map (or positive peaks in the case of D atoms). (The separate subject matter of H/D discrimination will be discussed later in this article.)

9 OXIDATIVE ADDITION TO A H–H BOND

Oxidative addition of H_2 to a metal has been well characterized only in recent years from a structural point of view using single-crystal neutron diffraction. Back in the mid-1980s, Kubas *et al.* made a landmark discovery when they first reported that H_2 can exist as a discrete ligand in the stable organometallic complex molecule $W(CO)_3(H_2)(P^iPr_3)_3$.[91] Subsequent structural characterization (using neutron diffraction)[92] showed that the H_2 ligand was bound to



Scheme 1 Oxidative addition of H_2 to a metal center

the metal in a sideways fashion (structure I in Scheme 1). If enough complexes could be analyzed similarly,[93] the process of oxidative addition of H_2 to a metal could be captured structurally in a series of ''stop-action'' photographs and characterized as a series of interactions (see Scheme 1 above).

We start from the first interaction (I in Scheme 1) in which the H_2 ligand (now called the nonclassical dihydrogen[77,78] ligand) is only loosely bound to the metal atom. Further insertion of the metal into the H_2 ligand activates the H–H bond (II) until it is cleaved, forming two terminal metal-hydride bonds (III). Many classical complexes of type (III) were already well known[94,95] and thoroughly characterized before Kubas made his seminal discovery, and similar ''reaction profiles'' of the type represented by Scheme 1 had already been well studied in organic systems (using X-ray structural results) by Bürgi and Dunitz.[96]

Figure 5 shows the results of a neutron diffraction study[91] of the original Kubas complex, which unambiguously showed that the hydrogen molecule interacts with the metal in a side-on fashion, a fact that had not been previously anticipated. But the H...H distance in that compound was very short [0.82(1) Å], almost as short as that of molecular H_2 itself (0.74 Å).[97] Subsequent papers published in following years, by Koetzle, Morris, Heinekey, Jensen, *et al.*,[79–81] all seemed to indicate H...H distances in the 0.8–0.9 Å range (top portion of Table 1). So for a while, it seemed like the process of oxidative addition of a M atom to a H–H bond, like that to a C–H bond (see Figure 5 in Ref. 98), was an ''all or nothing'' process as far as structural studies were concerned: in other words, either (I) or (III) (in Scheme 1) could be observed, with nothing in between.

The situation changed dramatically some years later in 1991, when Brammer, Koetzle, Howard, Spencer *et al.*[82] reported an unusual H...H distance of 1.357(7) Å amongst the seven hydrogens in the complex $ReH_7[P(p\text{-tolyl})_3]_2$ (Figure 6), which fit neither (I) nor (III). In other words, here was a H...H interaction which was neither ''single-bond-like'' (I) nor ''zero-bond-like'' (III). The authors rationalized from this study that they had discovered the first example of the intermediate state (II) between the nonclassical dihydrogen ligand and the classical hydride.

Since then, other complexes with intermediate H...H distances (now called ''stretched'' dihydrogen ligands) have been located[83–89] whose bond order seems ambiguous. They are listed in the middle two blocks of Table 1 and numerous theoretical studies have been published to explain their existence.[102–110] The results of experimental studies

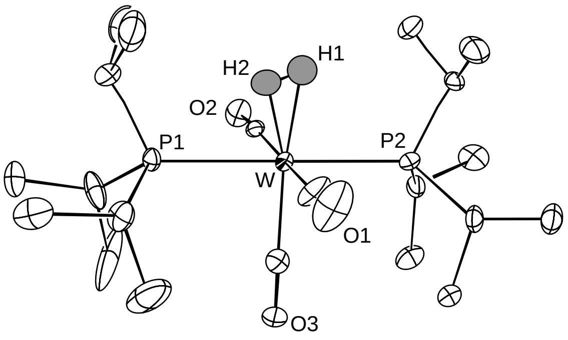


Figure 5 Molecular structure of $W(CO)_3(H_2)(P^iPr_3)_3$ from a neutron study. (Reprinted with permission from Kubas, Ryan, Swanson, Vergamini and Wasserman[91] © 1984 American Chemical Society)

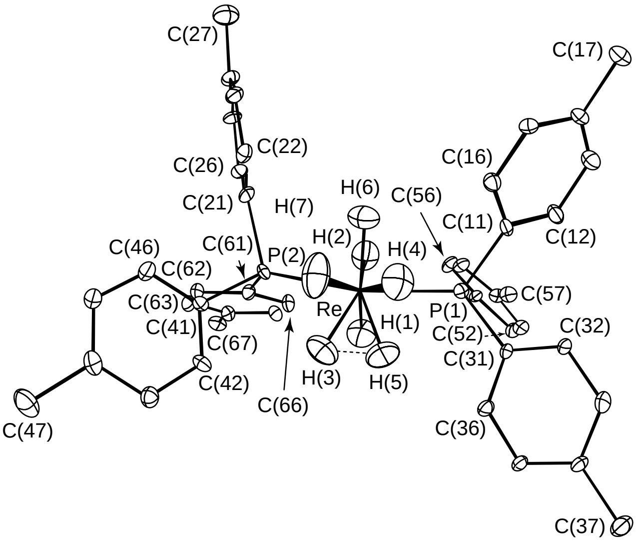

Figure 6 Structure of $ReH_7[P(p\text{-tolyl})_3]_2$ showing the ''stretched'' dihydrogen ligand [H(3)...H(5) = 1.357(7) Å]. (Brammer, Howard, Johnson, Koetzle, Spencer and Stringer[82] — Reproduced by permission of The Royal Society of Chemistry)

in this area, collected in Table 1, have allowed for a crude approximation of a ''reaction profile,'' the process of oxidative addition of a metal atom to an H–H bond (a unique analysis that could not have been achieved using X-ray diffraction, given the low precision of measuring a distance between *two* weakly scattering atoms). In this table, an attempt has been made to include all the available neutron diffraction data on H–H complexes, with the exception of the last category at the bottom of the table (''classical'' hydride complexes in which there are no H...H bonding interactions), for which neutron diffraction results are too numerous to be listed in full.

In Table 1, the first three columns, (i), (ii), and (iii), list the experimental H–H distances, H–M–H angles and M–H distances respectively, sorted in the order of increasing H–H distance. One can discern a very crude general trend of longer

Table 1 A selection of H. . .H distances in dihydrogen (η^2-H_2) and polyhydride $(H)_n$ complexes determined by neutron diffraction

	Compound	(i) H–H distance[a] (Å)	(ii) H–M–H angle (deg)	(iii) Avg M–H distance (Å)	(iv) ''Adjusted'' avg. M–H distance[a] (Å)	(v) M–X distance[b] (Å)	(vi) ''Adjusted'' M–X distance[a,b] (Å)

[a] The ''adjusted'' M–H and M–X distances were corrected for the differences in the atomic radii of the metal atoms, relative to the Fe radius as the ''standard'' (that is, the ''correction term'' for Fe was arbitrarily set to be zero) (atomic radii data from J. McMurray, R. C. Fay, *Chemistry 2nd Edition*, Prentice Hall, New Jersey, (1998)).
[b] M–X distances involved with the H_2 ligand where *X is the center of the H. . .H bond*.
[c] NA = not applicable. The position of ''*X*'' (the midpoint of the H. . .H bond) is not meaningful for classical hydrides, in which there are no H. . .H interactions.
[d] Please note that some H. . .H distances are corrected for libration (rotational effects) and some have not been corrected. Please refer to original publications for details.

H–H distances coupled with shorter M–H distances. However, one has to account for differences in metallic radii, and so in column (iv) the ''adjusted'' M–H distances are listed in which the differences in atomic radii are used as ''correction factors'', with the atomic radius of iron selected arbitrarily as a ''standard''. One can see that column (iv) is somewhat ''smoother'' than column (iii). Finally, recognizing that one should perhaps consider metal–*ligand* distances instead of metal–*hydrogen* distances, two extra columns have been included in which M–X distances are tabulated, where X is the midpoint of the H–H bond. Once again, the ''unadjusted'' and ''adjusted'' values [columns (v) and (vi) respectively] are listed, in which column (vi) contains the values ''corrected'' for differences in atomic radii.

Perhaps the most meaningful comparison in Table 1 is between column (i) [or column (ii)] and column (vi). Although there is obviously some scatter in the data, one can discern a definite trend, in which an increasing H–H distance appears to be correlated with decreasing metal–ligand distance: in other words, experimental evidence for the ''reaction profile'' depicted in Scheme 1. Schultz *et al.* have also recently written an authoritative article about this subject.[93]

10 HYDROGEN ATOMS IN METAL CLUSTERS

Hydrogen atoms can often occupy the interstitial sites of metal lattices. These materials are of potential use in areas of hydrogen storage applications, but normally they are not available in single-crystal form.[111,112] A somewhat related area is the chemisorption of hydrogen atoms on metal surfaces, which again often involve H atoms located on the surface as well as in interstitial sites. These can be studied with surface diffraction techniques,[113–116] but this work is usually carried out with X rays (*see* ***X-Ray Powder Diffraction***) and gives only limited information as far as truly embedded bulk interstitial H atoms are concerned. Perhaps, the best way to study the geometry of interstitial hydrides is to examine

the structures of *molecular* metal cluster complexes, with their covalent-like behavior (such as solubility in organic solvents). Covalent ligand-surrounded metal clusters are often obtainable as single crystals.[117–120] This is precisely one of the cases discussed in the introduction in which the *accurate* location of hydrogen atoms with X-rays diffraction is difficult because of the large number of metals involved (in other words, the signal-to-noise problem of finding one electron in the presence of three or more metals is a difficult problem with X rays). The tendency for H atoms to occupy vacant sites in metal clusters has led to unusually high coordination numbers (e.g., 4, 5, and 6) of hydrogen in these compounds. The method of choice to study these interactions is obviously neutron diffraction.

The existence of six-coordinate hydrogen (μ^6-H) in the metal cluster anions $[HCo_6(CO)_{15}]^-$ and $[HRu_6(CO)_{18}]^-$ was established[121–123] using neutron diffraction. The results from this neutron diffraction study were analyzed along with several other neutron studies involving cobalt clusters and there appears to be a relationship between the number of metal atoms surrounding a hydrogen atom and its corresponding M–H distance. In a series of cobalt compounds containing the following bonds: Co–H (terminal), $Co_2(\mu_2$-H), $Co_3(\mu_3$-H), $Co_6(\mu_6$-H), one can observe a gradual increase in Co–H distance (1.56, 1.64, 1.73, and 1.82 Å) along the above series.[121,122,124] This may reflect a decrease in Co–H bond order as the coordination number of hydrogen increases (Table 2).

Neutron analysis of a five-coordinate H (μ^5-H) atom has also been reported, located in two square pyramidal positions of the $[H_2Rh_{13}(CO)_{24}]^{3-}$ metal cluster anion.[124] As in the case of the Co–H series, a similar trend was noticed in Rh–H distances increasing as a function of the number of metal atoms around the H atom.

Recently, a four-coordinate H atom[125,126] has been unambiguously located by single-crystal neutron diffraction in the center of the tetrahedral metal complex $Y_4H_8(Cp'')_4$(THF) [$Cp'' = C_5Me_4(SiMe_3)$]. The core of the molecule consists of a tetranuclear cluster with one interstitial, one face-bridging, and six edge-bridging hydride ligands (Figure 7). The four individual Y–H distances to the unique interstitial hydride ligand are 2.184(16), 2.189(16), 2.221(13), and 2.168(12) Å.

The existence of four-coordinate hydrogen completed the series of high-connectivity hydride ligands (e.g., four, five, and six) located in the interstitial cavities of molecular cluster complexes. Other features that exist (more commonly than interstitial hydrides) in metal clusters include edge-bridging (two-coordinate H) and face-bridging hydride ligands (three-coordinate H).[94,95,127]

Table 2 Variation of Co–H distance with H coordination number

Compound	H coord no	Co–H dist(Å)
$CoH(CO)_4$	1	1.558(18)
$Co_2(\mu_2\text{-H})_3(\eta^5\text{-Cp}^{(a)})_2$	2	1.641(6)
$Co_3Fe(\mu_3\text{-H})(CO)_9[P(OMe)_3]_3$	3	1.734(4)
$[Co_6(\mu_6\text{-H})(CO)_{15}]^-$	6	1.823(13)

[(a)]For the original version of this table, complete with literature citations. (Data from Ref. 124)

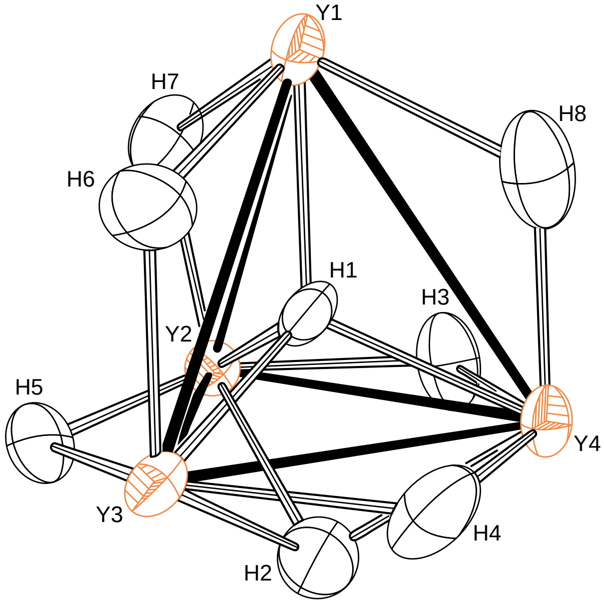

Figure 7 ORTEP plot of core of $[Cp''YH_2]_4$(THF). (Published in Yousufuddin, Baldamus, Tardif, Hou, Mason, McIntyre and Bau,[126] © Elsevier 2006)

The structure of $Y_4H_8(Cp'')_4$(THF) (Figure 7) [$Cp'' = C_5Me_4(SiMe_3)$] allows us (uniquely) to compare the three different types of linkages *in the same compound*: (μ_2-H), (μ_3-H), and (μ_4-H) metal–hydrogen bonds. Curiously, one does not observe exactly the same trends as those featured for Co–H bonds in Table 2. Although there is the usual (expected) increase as one goes from $Y_2(\mu_2$-H) [2.171(11) Å], to $Y_3(\mu_3$-H) [2.350(11) Å], the Y–H distance actually decreases in the next step, from $Y_3(\mu_3$-H) [(2.350(11) Å] to $Y_4(\mu_4$-H) [2.200(10) Å]. The relative shortness of the $Y_4(\mu_4$-H) distance probably reflects the tightness of a tetrahedral cavity, and the ability of the H atom to be four-coordinate may be attributed to the stabilizing effect of the other H atoms in the cluster.

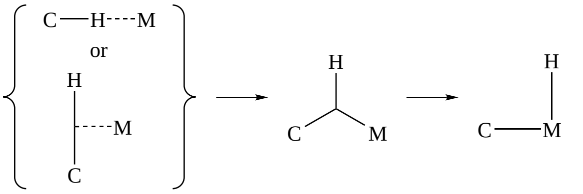
In contrast, for an octahedral interstitial site it is well known that there is more than enough space to allow the H atom to ‘‘rattle around’’ inside the cavity. In $[HCo_6(CO)_{15}]^-$[121,122] and $[HRu_6(CO)_{18}]^-$[123] the H atom is in the center of the octahedron, while in $[HNi_{12}(CO)_{21}]^{3-}$ and $[H_2Ni_{12}(CO)_{21}]^{2-}$[128] the H atoms are significantly off-centered (by 0.48 Å in the case of $[HNi_{12}(CO)_{21}]^{3-}$).[128] Additionally, inelastic neutron scattering[129,130] and low-temperature vibrational studies[131] on the Cs^+, K^+, and $[(Ph_3P)_2N]^+$ salts of $[HCo_6(CO)_{15}]^-$ suggest that, for *octahedral* interstitial cavities, there could be enough room for the H atom to ‘‘rattle around’’ inside the octahedral cage.

Some solid-state metal hydrides are commercially (and in some cases potentially) very important because they are a safe and efficient way to store highly flammable hydrogen gas (for example, in nickel-metal hydride (NiMH) batteries). However, from a structural and theoretical point of view many aspects of metal–hydrogen bonding are still not well understood, and it is hoped that the accurate analysis of H positions in the various interstitial sites of the previously described *covalent, molecular* metal hydride cluster complexes will serve as models for H atoms in binary or more complex solid state hydride systems. For example, we can speculate that the octahedral cavities are more spacious in which H atoms can ''rattle around'', while tetrahedral sites have less space and may even have to experience some ''expansion'' to accommodate a H atom.

11 AGOSTIC INTERACTIONS

In cases where a metal center is electron deficient, C–H bonds from a coordinated ligand can, in some cases, interact with the metal forming an agostic[90] C–H...M interaction. Structural studies of agostic interactions contribute to our understanding of the role of a metal atom in oxidative addition or reductive elimination processes involving a C–H bond (Scheme 2), in an obvious analogy with our earlier discussion of metal insertion into an H–H bond (Scheme 1).

Originally suspected to exist in certain molecules via X-ray studies,[132,133] agostic interactions are characterized structurally (as depicted in the left portion of Scheme 2) either (i) by a significantly shorter H...M distance[93,134–136] than those predicted by the van der Waals' radii of the M and H atoms, or (ii) by unusual distortions of M–C–H angles (i.e., smaller than expected M–C–H angles that suggest significant M...H attractive interactions that ''pull'' the H and M closer together than normal).[137,138] The former is represented by the neutron diffraction analysis of $\{Fe[P(OCH_3)_3]_3(\eta^3\text{-}C_8H_{13})\}^+[BF_4]^-$ (Figure 8), by Brown, Williams, Ittel *et al.*,[134,135] as well as by Williams, Schultz, Brookhart *et al.* on $Mn(CO)_3(C_7H_{11})$.[136] The agostic interaction in $\{Fe[P(OCH_3)_3]_3(\eta^3\text{-}C_8H_{13})\}^+[BF_4]^-$ (Figure 8) is characterized by an extra-short Fe–H(1A) distance of 1.879(9) Å, which is well below the sum of the covalent radii of H and Fe.



Scheme 2 Oxidative addition of a metal atom (M) to a C–H bond

The second characteristic of an agostic C–H...M interaction, as discussed before, is the existence of an unnaturally distorted C–H–M bond angle. An example is given by the alkylidene complex t-Bu–CH = $TaCl_4(PMe_3)$ (Figure 9), in which the normally sp^2 hybridized middle atom, C(1) of the C–CH = Ta linkage shows a significant compression from the normal sp^2 value of 120 degrees to the actually observed H(1)–C(1)–Ta value of 84.8 degrees shown in the figure.

A more recent example is represented by $Zr(9\text{-}BBN)_4$ [9-BBN = $(\mu\text{-}H)_2BC_8H_{14}$] (Figure 10), in which *three* different C–H...Zr agostic interactions were found associated with the electron-deficient zirconium atom.[139]

In the case of the analogous Si–H...M systems, the only two *bona fide* cases of known agostic interactions are neutron structure determinations carried out by Schubert *et al.* in 1982,[140] and by Mork *et al.* in 2004.[141] However, in recent years Nikonov *et al.* have been introducing an alternative concept, that of interligand hypervalent interactions (IHIs), to describe related systems.[142]

12 ABSOLUTE CONFIGURATION OF CHIRAL MOLECULES OF THE TYPE CHDRR*

The difference in scattering amplitudes between hydrogen (−3.74 fm) and deuterium (+6.67 fm) allows these atoms to be distinguished in a neutron diffraction study. In practice, as pointed out earlier in this article, this makes H atoms appear as negative peaks in a neutron Fourier map, while D atoms (like most other atoms) appear as positive peaks. Therefore, molecules that are chiral by virtue of a stereospecific isotopic substitution (such as molecules of the type CHDRR*) can have, in principle, their absolute configurations determined by neutron diffraction. This fact was first exploited in 1965 by C.K. Johnson *et al.*[143] for determining the absolute configuration of a deuterated glycolate ion $[(OH)\text{–}(CHD)\text{–}(COO)]^-$. In that experiment, the fact that the neutron scattering of ^6Li is anomalous[1] was used to determine the absolute stereochemistry of enzymatically produced $^6Li^+[(OH)\text{–}(CHD)\text{–}(COO)]^-$. However, this particular approach has a severe disadvantage due to the fact that anomalously scattering isotopes (^6Li, ^{10}B, ^{113}Cd, ^{149}Sm, ^{151}Eu, and ^{157}Gd) are also, by definition, efficient absorbers of neutrons, making a neutron diffraction study involving these atoms somewhat problematic (in other words, one needs a big crystal for a neutron-scattering experiment, but if the target molecule contains too much of a neutron absorber, then one runs into substantial absorption problems that make the measurement of neutron diffraction intensities difficult). To our knowledge, the only successful *single-crystal* neutron analysis of a boron compound with a high-boron content, is a $B_{10}D_{14}$ sample in which the B atoms were almost entirely replaced by the weakly neutron-absorbing isotope ^{11}B.[144]

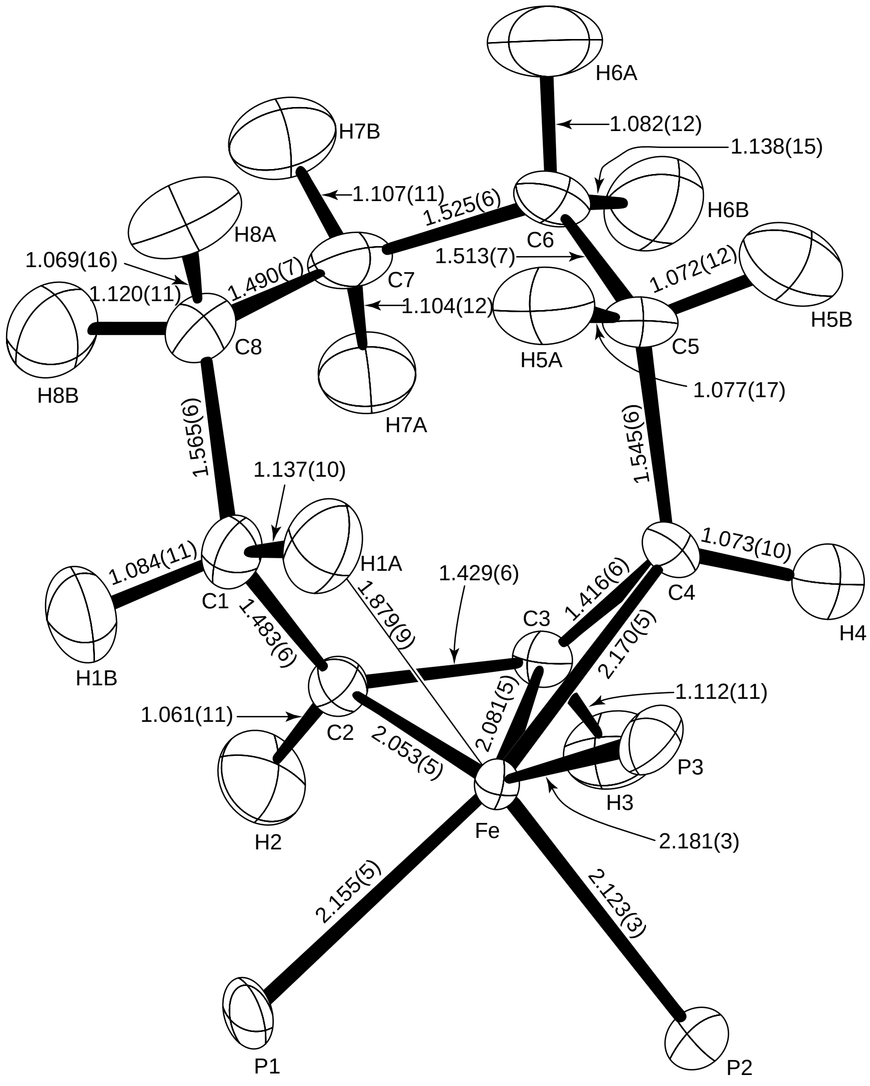


Figure 8 Neutron structure of $\{Fe[P(OCH_3)_3]_3(\eta^3\text{-}C_8H_{13})\}^+[BF_4]^-$. (Reprinted with permission from Williams, Brown, Schultz, Stucky and Ittel.[134] © 1978 American Chemical Society)

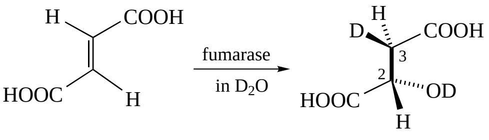
A more practical way to get around the problem of absorption is to incorporate into the target crystal a reference fragment having a known absolute configuration. This reference group can either be covalently attached to the chiral CHD group being studied, or be in the form of a counterion. To our knowledge, there are only a handful of studies[145–150] that make use of this approach. Two of these will be discussed here. One simple example (Scheme 3) is the study of the absolute stereochemistry of the addition of D_2O across the double bond of fumaric acid (I) to form malic acid (II), a process carried out naturally by the enzyme fumarase.

In principle the reaction could conceivably proceed four ways: two different ways of cis addition of D and OD, and two ways of transaddition, leading to four potential products. The results of our neutron analysis, which was carried out



(I) (II)

Scheme 3 Addition of D_2O to fumaric acid to form malic acid

using the known absolute configuration of the chiral cation [(+)](R) phenylethylammonium as a reference, is that the enzymatic reaction only produces the one product[145] shown in Figure 11, corresponding to a stereospecific transaddition of D_2O.

Another pair of studies involved investigating the absolute stereochemistry of the conversion of aldehydes

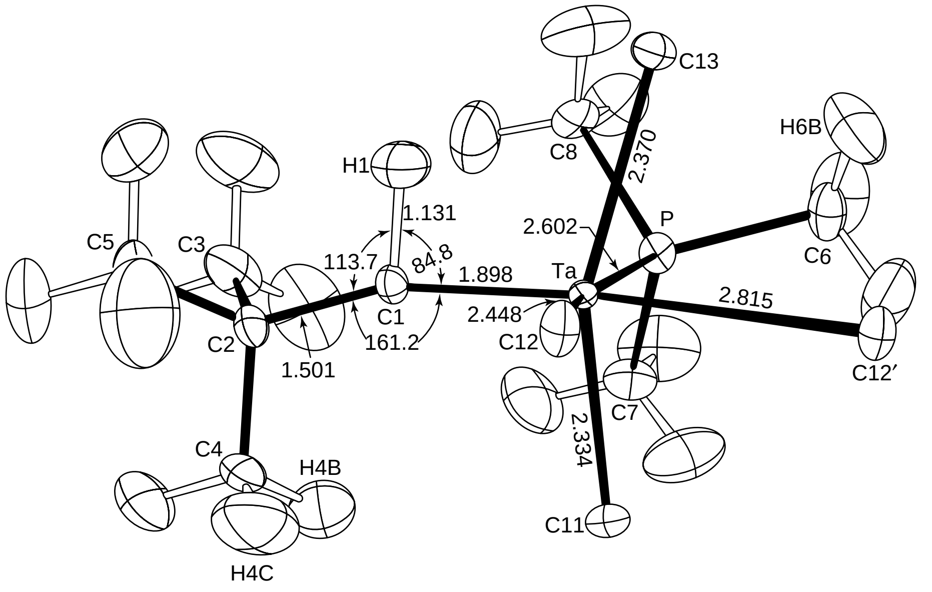


Figure 9 Neutron structure of t-Bu–CH=$TaCl_4(PMe_3)$. (Reprinted with permission from Schultz, Williams, Schrock, Rupprecht and Fellmann.[137] © 1979 American Chemical Society)

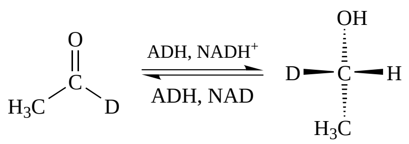
to alcohols by the enzyme yeast alcohol dehydrogenase (Scheme 4), carried out in collaboration with Prof. Harry Mosher of Stanford University.



Scheme 4 Conversion of aldehyde to alcohol

Studies were carried out both with chiral ethanol[146] and chiral neopentanol.[147] Figure 12 shows the anionic phthalate half-ester of (+)-neopentyl-1-*d* alcohol crystallized as its strychnine salt. In this study the absolute configuration of the –O–CHD–$C(CH_3)_3$ group was determined to be (S) (Figure 12).

These studies, in particular the one concerning chiral ethanol,[146] are completely consistent with the protein crystallographic results showing the active site of the zinc metalloenzyme alcohol dehydrogenase.[151]

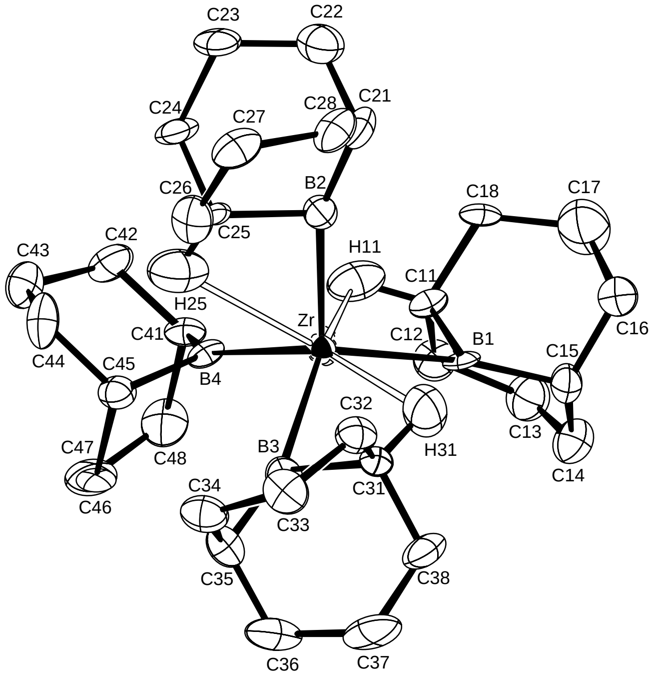


Figure 10 Neutron structure of $Zr(9\text{-}BBN)_4$ [9-BBN = $(\mu\text{-H})_2BC_8H_{14}$]. The three Zr…H agostic interactions are indicated by hollow bonds. (Reprinted with permission from Ding, Du, Meyers, Shore, Yousufuddin, Bau and McIntyre.[139] © 2005 American Chemical Society)

13 NEUTRON DIFFRACTION STUDIES ON PROTEINS

Publications of single-crystal neutron studies of macromolecules are comparatively underrepresented, but activity in this area has been increasing significantly in recent years. A survey of the Protein Data Bank[152] at the time this article was written reveals only 19 protein structures determined by neutron diffraction. However, the technique has actually been available for decades: in fact, two books have been published highlighting achievements in this area.[15,16]

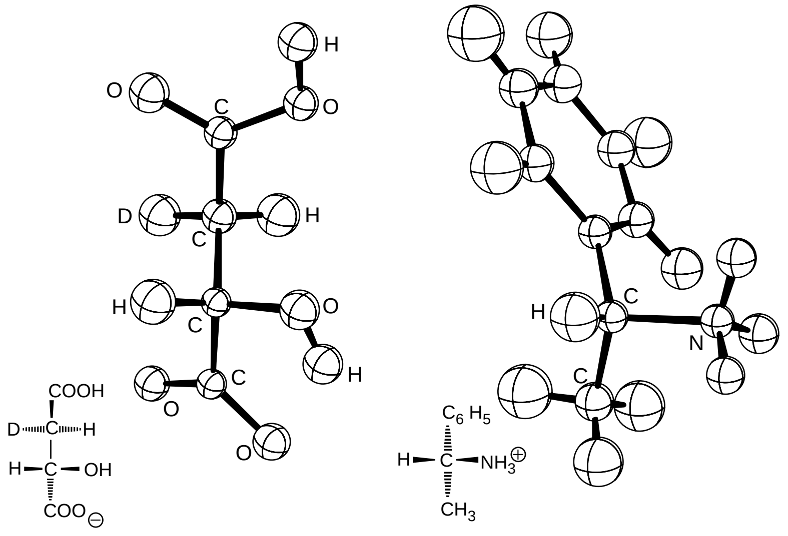

Figure 11 The neutron diffraction results of the enzymatic reaction of Scheme 3. The known absolute configuration of the (+)(R)α-phenylethylammonium cation (a) showed that the product malate anion, produced enzymatically by the enzyme fumarase (b), had the absolute configuration (−)(2S,3R), meaning that the enzymatic addition of D_2O was stereospecifically trans. (Published in Bau, Brewer, Chiang, Fujita, Hoffman, Watkins and Koetzle,[145] © Elsevier 1983)

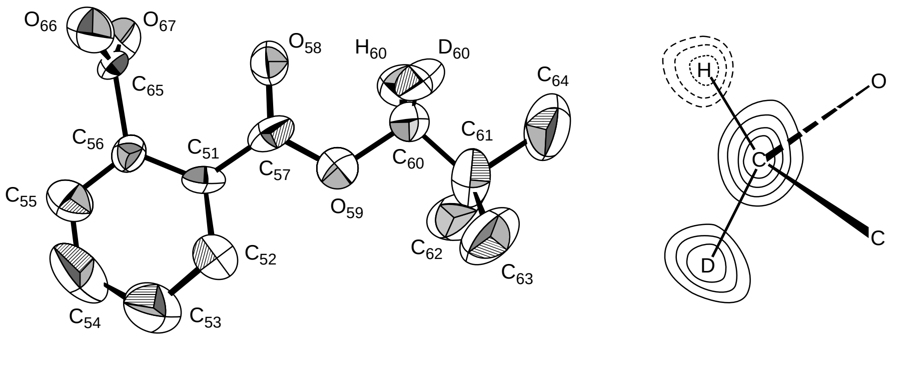

Figure 12 Neutron structure of the phthalate anion of (+)-neopentyl-1-*d* alcohol (a) crystallized with a strychnine cation (not shown). The corresponding neutron Fourier map of the key portion (b) shows the absolute configuration at the chiral CHD center. Dashed lines indicate the negative H peak and positive contours indicate the position of the D atom. (H.S.H. Yuan, R.C. Stevens, S.Fujita, R. Bau, H.S. Mosher and T.F. Koetzle (1994) *Proc. Nat. Acad. Sci. USA.*, **91**: 12872)

Lately, improvements in neutron sources and (especially) in instrumentation have led to dramatic changes, and these have been reflected in more recent review articles.[19–25] A description of current and future neutron *instruments* capable of studying macromolecules was discussed earlier in this article (end of Section 5) and described in Refs. 49–52. In this section we will simply discuss a few representative experimental results.

In proteins, neutrons can offer a wealth of scientific information often not obtainable from X rays alone. The principal applications of neutron studies, besides the location of H atoms near the active site of a protein, are the study of (i) the protonation sites of particular residues like glutamate (Glu), apartate (Asp), histidine (His), and lysine (Lys) residues; (ii) the O–H bonds in tyrosine (Tyr), serine (Ser), and threonine (Thr) residues; (iii) the orientation of amide groups in glutamine (Gln) and aparagine (Asn); (iv) the conformation of methyl groups in hydrophobic residues; (v) the H-bonding patterns in the core of a protein; and (vi) the detailed water structure inside and outside a protein molecule.

An early example of a neutron study of a protein is represented by a 1981 study of oxymyoglobin by Phillips and Schoenborn[153] in which the authors were able to show the existence of a rather unusual hydrogen bond involving the N–D group of a histidine residue and a coordinated O_2 ligand (Figure 13).

Another notable early example involves the investigation of the digestive enzyme trypsin (a member of the serine protease family) by Kossiakoff and Spencer in 1980.[154,155] This class of enzymes contains an Asp–His–Ser triad essential

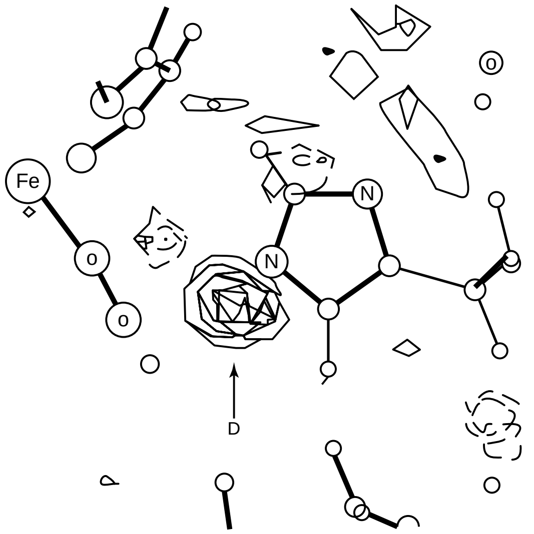

Figure 13 Neutron diffraction map of oxymyoglobin showing the presence of an unusual N–D...O_2 hydrogen bond involving the deuterated N(ε) atom (left) of a histidine group and the coordinated dioxygen ligand. Note that the other nitrogen atom of the imidazole ring, N(δ) (right), is seen to be unprotonated. (Reprinted by permission from Macmillan Publishers Ltd: Phillips and Schoenborn.[153] © 1981)

for catalytic activity. The mechanism of this class of proteases is generally acknowledged to involve a base-catalyzed nucleophilic attack, in which the O–H group of serine is deprotonated by the imidazole ring of the histidine residue (Scheme 5). As a result, the level of activity of the Ser residue is dramatically increased with the presence of the newly generated alkoxide-like transient O^- atom now available for nucleophilic attack of a carbonyl group of the target peptide bond. The central issue left unresolved was whether the histidine residue acts as an intermediate (Step 1 in Scheme 5) or rather as the actual base in the hydrolysis reaction (Step 2 in Scheme 5).

Kossiakoff and Spencer (Figure 14) unambiguously showed the histidine residue in its diprotonated form, consistent with mechanism 2 of Scheme 5.

A more recent example is represented by endothiapepsin, a member of the aspartate protease family of protein-cleaving enzymes. A neutron diffraction study by Cooper, Myles *et al.*[156,157] on this protein complexed with a transition state analog conclusively showed that the two catalytic aspartate residues are in different protonation states in the active enzyme. The results demonstrated that Asp215 crystallized in the neutral (protonated) state unlike Asp32 (Figure 15). This finding supported a proposed mechanism involving a tetrahedral intermediate stabilized by neutral and negatively charge Asp residues.

Oligonucletides have also been studied by neutron diffraction lately. The structure of large single crystals of

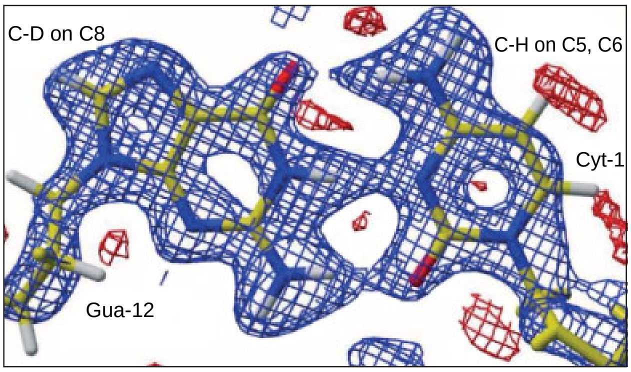

Figure 16 A view of one of the C–G base pairs of the hexameric Z-DNA oligomeric duplex, showing the C–H group at the #8 position of guanine12 (the yellow-to-white bond labeled ''C–D on C8'') being deuterated [blue (positive) contours], while the other C–H groups (the two yellow-to-white bonds of cytosine-1 labeled ''C–H on C5, C6'') are undeuterated [red (negative) contours, indicating the presence of unexchanged hydrogens]. (From Chatake, Tanaka, Umino, Arai and Niimura.[159] Reproduced by permission of International Union of Crystallography)

a double-stranded B-DNA decamer, d(CCATTAATGG)$_2$,[158] and a Z-DNA hexamer, d(CGCGCG)$_2$,[159] have been reported by the Niimura group. In the case of d(CCATTAATGG)$_2$, it was found that the ''spine'' of water molecules of hydration in the minor groove of this DNA oligomeric duplex were largely ordered but arranged in a complicated H-bonding pattern, while most of the water molecules in the major groove were less ordered and mostly ill-defined. Another interesting result is that in the case of d(CGCGCG)$_2$, it was found that the C–H groups of guanine, unlike virtually all other C–H groups in proteins and oligonucleotides, are kinetically labile and participate in H/D exchange (Figure 16). The only other example of a kinetically labile C–H bond in macromolecules that participates in H/D exchange is the central C–H group of the five-membered ring of histidine, an exchange which was shown to take place by the neutron analysis of insulin.[160] In both the imidazole case in proteins and the guanine case in nucleic acids, the common feature is that both kinetically labile C–H groups are in a five-membered ring situated between two N atoms.

Finally, one important development is the demonstration of the usefulness of complete deuteration of a protein for a neutron study, first demonstrated by Schoenborn *et al.*[161] and further developed recently by Podjarny *et al.*,[162] who were able to carry out a single-crystal neutron diffraction study of aldose reductase on a crystal as small as 0.15 mm^3, which is an order of magnitude smaller than a typical ''neutron-sized'' crystal. Deuteration is particularly advantageous because (as was pointed out earlier) hydrogen has a large incoherent scattering component, which gives rise to an undesirably high background level. A sample in which all H atoms have been replaced by D produces much better data (i.e., a much higher signal-to-noise ratio), and thus several laboratories[163] (D. Myles and F. Meilleur, Private Communication; B. Schoenborn and P. Langan, Private Communication; N. Niimura, Private Communication) have invested a significant amount of effort in developing complete deuteration facilities for single crystal protein crystallographic analysis, or are in the process of doing so.

14 CONCLUSION

Neutron diffraction has been shown to provide essential chemical information in a wide range of systems. We have selected a number of examples for which the technique is particularly well suited. Modern techniques have enabled improvements in instrumentation and data collection that allow for lower sample requirements and more sophisticated sample environments. In particular, the high-intensity spallation sources[39,40] currently under construction should be especially appealing not only to chemists,[49] but also biologists,[50–52] for which shorter data collection times and (more importantly) smaller crystal sizes are of paramount importance.

15 ACKNOWLEDGMENTS

We would like to thank many of my neutron diffraction colleagues who have collaborated with me and my group in the many decades of this work, in particular Tom Koetzle *et al.*, the late Dick McMullan and Wim Klooster. More recently, we have benefited greatly through interactions

with Art Schultz, Sax Mason, Garry McIntyre, Nobuo Niimura, and his group, Benno Schoenborn, Paul Langan, Dean Myles, and their colleagues, and most recently Matthias Gutmann. Without their ability, expertise, and help, much of the work described in this article would not have taken place. This work was largely supported over the years by the US National Science Foundation, the American Chemical Society and the US Department of Energy.

16 END NOTES

[a] Although virtually all spallation sources (described in the text) are pulsed sources, one exception is SINQ in Switzerland, which is almost a continuous spallation source.

[b] Although technically photons have no spin, there is a very small magnetic scattering cross section for X rays, which has been exploited in magnetic X-ray scattering experiments at synchrotron sources. Some investigators believe the effect can be enhanced by working near an absorption edge, e.g., for lanthanides.

17 ABBREVIATIONS AND ACRONYMS

CCD = charge-coupled device; IHIs = interligand hypervalent interactions; ILL = Institut Laue-Langevin; INS = inelastic neutron scattering; IPNS = intense pulsed neutron source; LINAC = linear accelerator; MaNDi = macromolecular neutron diffractometer; NiMH = nickel-metal; OPAL = open pool Australian light-water reactor; hydride; SANS = small-angle neutron scattering; SNS = spallation neutron source.

METHOD SUMMARY

Acronyms, Synonyms

- Neutron Diffraction
- Elastic Neutron Scattering
- Inelastic Neutron Scattering
- Inelastic Neutron Spectroscopy
- Neutron Spectroscopy
- Neutron Vibrational/Rotational Spectroscopy
- Quasi-elastic Neutron Scattering

Measured physical quantities

- Elastic Scattering (Diffraction)
- number of scattered neutrons of a particular wavelength (monochromatic) or by time-of-flight (white beam)
- Inelastic Scattering
- change (either gain or loss) in energy/momentum by incident neutron beam (of known energy)
- Quasi-elastic Scattering
- broadening of an elastic scattered neutron peak.

Information available

- characterize the atomic arrangement in crystalline and amorphous solids and liquids (magnetic materials in particular) via diffraction;
- microscopic dynamics: lattice vibrations, molecular motion and diffusion (both rotational and translational).

Information not available, limitations

- Some elements do not scatter well or have large neutron capture cross sections making them hard to study.
- The intensity of neutron beams are of orders of magnitude lower than X rays — structural determination is generally not as accurate for heavy — element containing materials.

Examples of questions that can be answered

- What is the structure of this material? In particular, what is the structure of light element-containing materials and magnetic materials?

- What are the vibrational/rotational modes of the material?
- What type of diffusion takes place within the system (rotational, translation, or both)?

Major advantages

- wavelengths and energies comparable to interatomic spacings and fluctuations within most condensed matter
- does not induce chemistry or physical change
- can vary sample environments greatly (high or low pressure, temperature)
- sees light elements well and has no selection rules for vibrational states
- highly penetrative; samples may be held in metal cans
- weak interactions with matter; pointlike scattering facilitates data analysis
- isotopic sensitivity enables contrast variation
- neutron magnetic moment couples to magnetic fields; unpaired electron spins characterized
- nonionizing radiation.

Major disadvantages

- measurements can take days for statistics
- low flux of neutrons on sample; which means low signals and large amounts of sample needed
- weak interaction with matter
- some elements (e.g., boron, rare earths, cadmium) absorb strongly
- limited number of worldwide neutron sources; hence production costly.

Sample constraints

- temperatures between ∼25 mK and 2000 K
- pressures between 10^{-5} Pa and 25 GPa
- magnetic fields below 30 T
- large sample (size depends on elemental content).

1 INTRODUCTION

The enormous opportunities that neutron scattering studies provide for probing the structure and dynamics of condensed matter have been the driving force behind continued interest in the development of new sources around the world. In fact, a soon to be released report from a workshop, ‘‘X-Rays and Neutrons: Essential Tools for Nanoscience Research’’ as part of the National Nanotechnology Initiative, indicates that ‘‘*for more than 50 years, x-ray- and neutron-based tools have opened new vistas at the (often intersecting) frontiers of materials science, biology, medicine, physics, chemistry, engineering, and geology.*’’ The initiation of operations at the Spallation Neutron Source (SNS) on the Oak Ridge National Laboratory facility, and recent operations in Germany and Australia, as well as plans in Japan, China, and Europe to develop new, more powerful sources clearly underscores how valuable these sources are. In this section, the two main methods of generating thermal neutrons for research purposes will be discussed in brief, namely, nuclear fission and spallation. While details concerning power level, core configuration for the fission sources, and accelerator design for the specific sources may vary, the production in generic terms will be discussed, and then, when specific examples are necessary, the Institute Laue Langevin (ILL) and the ISIS spallation sources will be used as the typical ‘‘best in class’’ examples of a reactor and accelerator source, respectively.

2 TECHNICAL BACKGROUND

2.1 Neutron Sources

2.1.1 Reactor-Based Sources

The very first nuclear reactor built, where the main objective was to perform condensed matter research, was the High Flux Beam Reactor (HFBR) at Brookhaven National Laboratory, Upton, NY. The first self-sustaining chain reaction at the HFBR took place on Halloween, 1965. For over 30 years, the HFBR was one of the premier beam reactors in the world, matched only by the ILL reactor in Grenoble, France. These reactor-based sources have been a continuous and reliable source of thermal neutrons for research in a wide range of different scientific fields from physics, chemistry, materials science, and biology to engineering and isotope enrichment. The instrumentation that is in place at these sources has seen steady improvement from the days when Nobel laureates, Brockhouse and Shull, performed their pioneering work at these facilities.

Nuclear reactors operate using the fission chain reaction process wherein heavy nuclei like uranium are used, for which the number of neutrons exceeds the number of protons by a large fraction. In the case of ^{235}U, when a neutron is absorbed, a significant amount of energy is transferred into the system, and an excited ^{236}U nucleus is created. As more energy is absorbed, this excited ^{236}U nucleus oscillates with increasingly larger amplitude until the repelling Coulomb force drives it into separation. Each of these fission reaction steps liberates two or three free neutrons leading to the ''chain'' reaction. A free neutron is necessary to sustain the chain reaction, that is, to trigger the generation of additional free neutrons. The energy of the fissioning nucleus is about 200 MeV, hence the quantity of neutrons produced in a nuclear reactor scales with the thermal energy produced. For a 60 Mwatt reactor like High Flux Reactor (HFR) at the ILL there are $\sim 1.8 \times 10^{18}$ fission events per second which results in about 7.5×10^{16} neutrons produced per MW. The research reactor is designed to generate as many neutrons as possible for use in research purposes; hence the reactor core design and the HFBR tangential beam tube concept, along with sophisticated neutron optical design components, are arranged to maximize the flux of neutrons at the sample position of the specific instrument. The main requirement is a high power density at the neutron core along with attendant reflectors to minimize the number of escaping neutrons at the core.

The most common configurations of research reactor vessels are the pool and tank coretypes (see Figure 1). Within the core of such reactors is an assembly composed of an organized collection of U fuel elements or rods (the collection known as *the core*), suspended in a large pool of light (H_2O) or heavy ($D_2O = {}^2H_2O$) water. In order to ''control'' the fission process, moveable rods of neutron-absorbing material like boron or cadmium are distributed among the fuel rods in such a way that they can be raised or lowered into the fuel element package in order to slow down or quench the reaction rate. The *water* moderates (or decelerates) the neutrons and cools the reactor core, while reflector materials like graphite or beryllium are used to bounce the neutrons back into the core region. As noted above, beam tubes (Figure 1) are inserted from the wall of the pool or tank vessel and are used to extract the neutrons from the core region to the instrumental research area (Figure 2).

Neutrons generated within the reactor have a broad energy distribution, ranging from below 1 meV to above 10 MeV. They can be subdivided into three subgroups, those with energies >500 keV or *fast neutrons* with a spectral distribution $N(E)$ given approximately by $N(E) \sim e^{-E} \sinh \sqrt{(2E)}$; those whose energies lie between 200 meV and 500 keV called *epithermal neutrons* (where the neutron spectrum is largely determined by the collisions they make with nuclei in the moderators)—here the spectral distribution, $N(E) \sim 1/N$; and thirdly, the *thermal neutrons* whose energies lie below 200 meV, whose spectral range looks like that of a gas in thermal equilibrium with the moderator nuclei (i.e., Maxwellian) or such that $N(E) \sim E/(kT)e^{-E/kT}$ where k is Boltzmann's constant. These thermal neutrons resulting from the interaction with a water moderator at room temperature have an average energy of about 25 meV or a wavelength of about 0.18 nm. The absolute flux within these three ranges depends on the reactor design, the reactor power level, and the location and type of moderator. Even

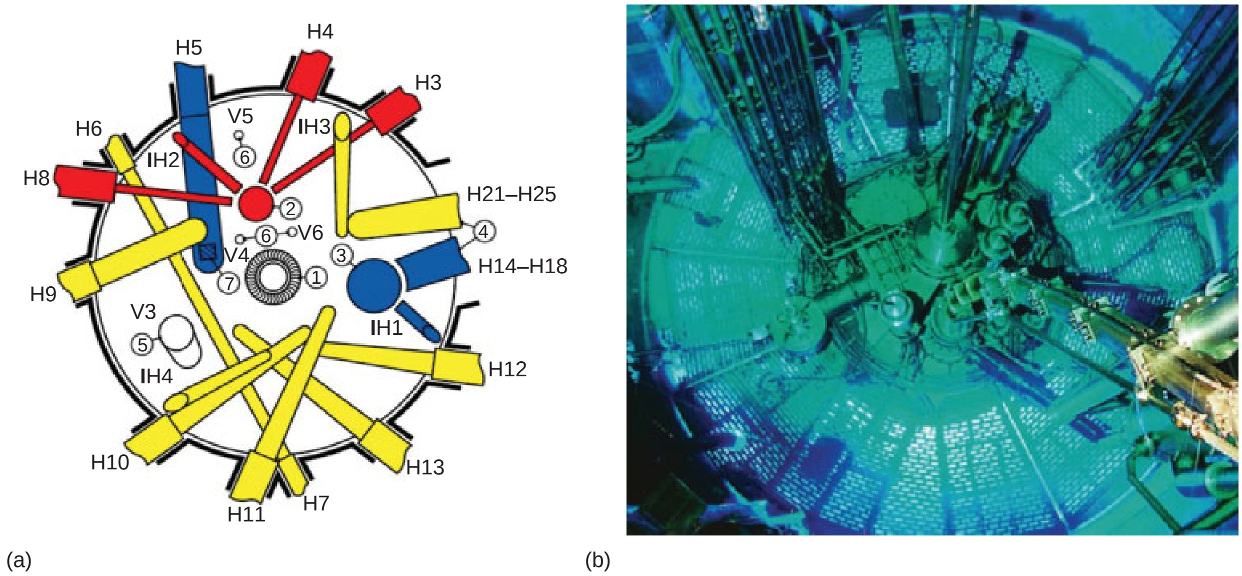

Figure 1 The figure (a) shows the beam tube arrangement for the High Flux Reactor at the ILL. The figure (b) is a photograph of the reactor core at the ILL. The blue glow is an excellent example of the Cherenkov radiation (i.e., electromagnetic radiation emitted when a charged particle passes through an insulator at a speed greater than the speed of light in that medium)

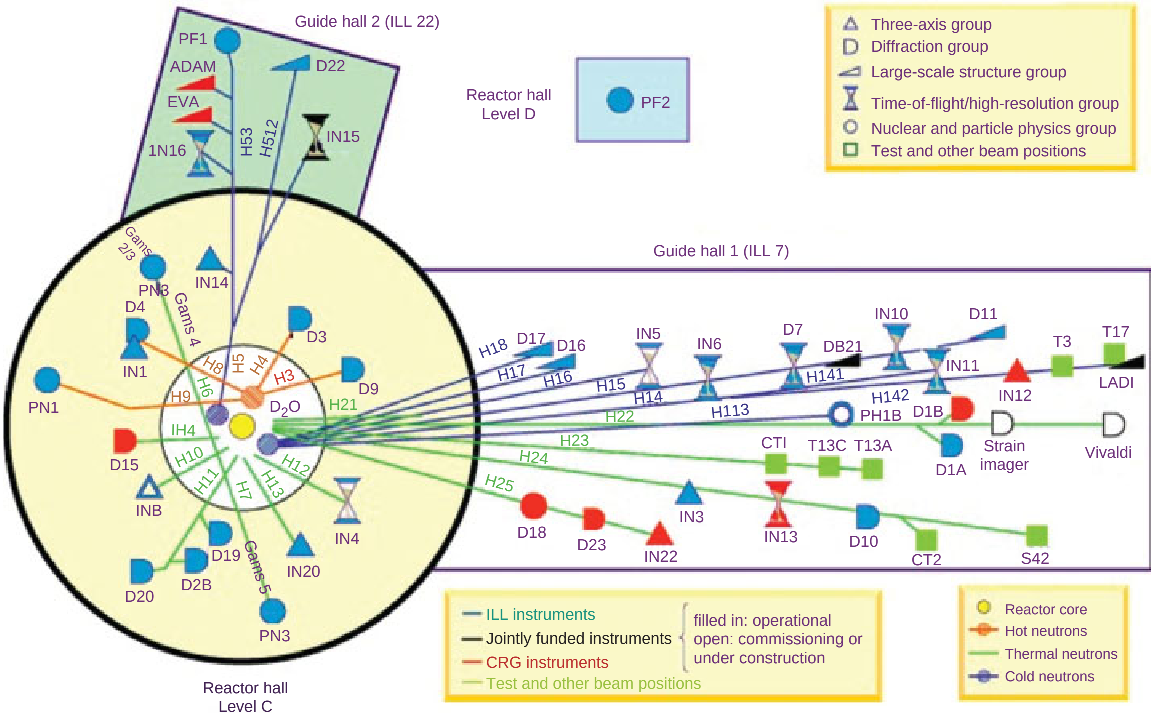

Figure 2 Layout of the Institute Laue Langevin (Grenoble, France) Research Reactor Instrumentation including two cold neutron guide halls

longer wavelength, or lower energy, neutrons are desired at times for examining large scale structures or probing slow motions. The lowest energy thermal neutrons (typically of wavelengths 0.5 nm or longer) are often called ''cold'' neutrons and are generated by using moderators filled with liquid cryogens (usually hydrogen or methane). Since neutrons are such a unique tool to study the microscopic structure and dynamics of condensed matter, it is not surprising that neutron scattering plays a major role in the experimental methods used at research reactors. Neutrons are electrically neutral and therefore don't scatter from the electron clouds but penetrate deep within matter (i.e., scatter from the nucleus). Furthermore, neutrons can be used to study bulk materials or those contained within pressure vessels, high or low temperature equipment or within magnetic fields (Table 1). Figure 2 shows the multitude of different instruments available for use at the ILL in Grenoble. An excellent description of the capabilities and applicability of each of these instruments at the ILL can be found in the ILL ''*Yellow Book*'',[1] located at http://www.ill.fr/YellowBookCDrom/index.htm.

Table 1 Physical properties of a neutron[2]

Particle and wave properties of neutrons			
Mass: $m_n = 1.675 \times 10^{-27}$ kg			
Charge = 0			
Spin = 1/2			
Nuclear magneton: $\mu_N = 5.051 \times 10^{-27}$ J T^{-1}			
Magnetic dipole moment: $\mu_n = 1.913\,\mu_N$			
Approximate values for ranges of energy			
	Energy (E/meV)	Temp (T/K)	Wavelength (λ/Å)
Cold	0.1–10	1–120	30–3
Thermal	5–100	60–1000	4–1
Hot	100–500	1000–6000	1–0.4
Relationships between neutron properties			
$E = 1/2 m_n v^2 = \boldsymbol{k}_b T = (h\boldsymbol{k}/2\pi)^2/(2m_n) = (h^2k^2)(2m_n)$			
Wavevector $\boldsymbol{k} = 2\pi/\lambda = m_n v/(h/2\pi) = m_n v/h$			
Units: E(meV); $\boldsymbol{k}$(Å^{-1}); λ(Å); v(m sec^{-1}); T(K)			

2.1.2 *Spallation Sources*

As opposed to the nuclear reactor-based production of neutrons, the SNS is usually accelerator based. Hydrogen ions, either H^+ or H^-, are produced by an ion source, accelerated in vacuum to speeds that exceed 80% of the speed of light, then directed at a heavy metal, for example, uranium (ISIS); tungsten (Los Alamos Neutron Science Center (LANSCE)); or mercury (Spallation Neutron Source (SNS)) target. A linear accelerator raises the velocity of the ions in stages by using a standing electric wave radiofrequency (RF) cavity. The nodes of the electric field are positioned such that the ions don't change their location (or decelerate) in these ''drift tubes''. In the region between these drift tubes, the ions gain energy and increase their velocity such that the gaps between and the drift tubes themselves increase in length. The efficiency of operation is increased because when the RF field reverses,

ions of opposite charge are accelerated in the gap. Magnetic fields serve to bunch and focus the ions at the ends of the drift tubes. Another type of accelerator is the synchrotron. Both of these types may be used in combination. Stripper foils are used to remove the electrons from the H^- ions. In most cases, once the ions are stripped of their negative charge, they are injected into a storage ring which converts the pulse of H^- ions that was ~650 μs long and accumulates the protons into a short ~100 ns bunch of protons that is then directed onto the spallation target. Proton currents are on the order of ~125 μA at LANSCE and ~300 μA at ISIS (after 2007 upgrade); these are two of the brightest spallation sources currently operating. Hence bursts of protons are released to the targets once every 1/20 of a second at LANSCE or once every 1/50 of a second at ISIS. When the protons hit the target nuclei, neutrons are spalled (knocked out) of the target. For example, when a pulse of energetic protons hits a tungsten target, each proton that collides with a tungsten nucleus causes the nucleus to release ~20 neutrons with different energies. These spalled neutrons, after passing through a moderator, travel along a beam line. The resulting pulse of neutrons is very short, but as the pulse travels down the beam line, neutrons with the higher energy travel down the beam pipe faster, and hence the pulse stretches out in space, much like cars that start out in a small group but are traveling at slightly different speeds; as they travel down the highway they start to move apart in space. In fact, the arrival times of the neutrons serve to identify their energies and wavelengths (by a time-of-flight (TOF) method). Neutrons generated by spallation in the targets are adjusted by the moderator-reflector configuration. For example, beryllium has a large neutron scattering cross section with negligible absorption and is used as a neutron reflector. Moderators slow down the spallation neutrons and can take various shapes and configurations. These moderators are typically filled with ambient temperature water, liquid methane or liquid parahydrogen, and are used to adjust the mean energy of the neutrons within the individual pulse (Figure 3). The sources at ISIS (Figure 4) and LANSCE produce neutron fluxes on the order of 10^{16} neutrons $cm^{-2}\,s^{-1}$.

When compared to reactor-based sources, SNSs appear to have the advantage that the proton current is virtually unlimited and thus the neutron flux could increase without physical limit. Naturally, this is not the case, since dissipation of heat and recrystallization of the heavy metal target and shock wave issues associated with the huge energy density of the beam ultimately constrain the designs. At reactor-based sources, it is not possible to increase the power without bounds due to reactor safety. Furthermore, SNSs are, due to the time structure of the neutron flux, ideal for TOF measurements. The SNS at Oak Ridge National Laboratory (Figure 5) is designed for proton currents of 2 mA at 1 GeV proton energy directed toward a liquid mercury target at a repetition rate of 60 Hz, resulting in a peak neutron flux on the order of 10^{17} neutrons $cm^{-2}\,s^{-1}$.[3] The KENS SNS[4] under construction at Tokai, Japan, is designed for a 333 μA current of 3 GeV proton energy, using a liquid mercury target and generating a peak neutron flux on the order of 10^{17} neutrons $cm^{-2}\,s^{-1}$. The US and Japanese SNSs are scheduled to become available to users in late 2007.

2.2 General Remarks

At any finite temperature, all matter is composed of atoms that are in constant motion, not just sitting in a fixed position in a crystal lattice. For example, at the atomic level, molecular solids exhibit vibrational, oscillatory and small excursions around their equilibrium position, as a result of thermal energy, even at low temperatures. In a crystalline solid, these movements are centered on the lattice position in the crystal and from the standpoint of diffraction, Bragg, or elastic scattering (*see* ***Neutron Diffraction***), these atoms (or scattering centers) contribute constructively to the diffraction signal only when they are at the *exact* lattice point. The more time that the atoms spend away from this lattice position, the smaller the diffraction signal becomes. If the diffraction signal is used to determine the arrangement of atoms in the crystal structure, the magnitude of these thermal departures can be determined from the distribution of the scattering. In many systems, these departures from the equilibrium lattice position are not uniform in every direction in the crystal. This anisotropy of the motion is signaled by a nonuniform distribution of the elastically scattered intensity. This can signal the onset of a phase transformation or the anisotropy of the elastic response of a system to some physical parameter (i.e., uniaxial pressure). In addition to the observation that the elastic (or Bragg) scattering has decreased thanks to thermal motion, other neutron scattering methods can be effectively used to identify the dynamics of these atoms. So-called *inelastic neutron scattering* (INS) techniques can be effectively used to monitor and quantify these atomic

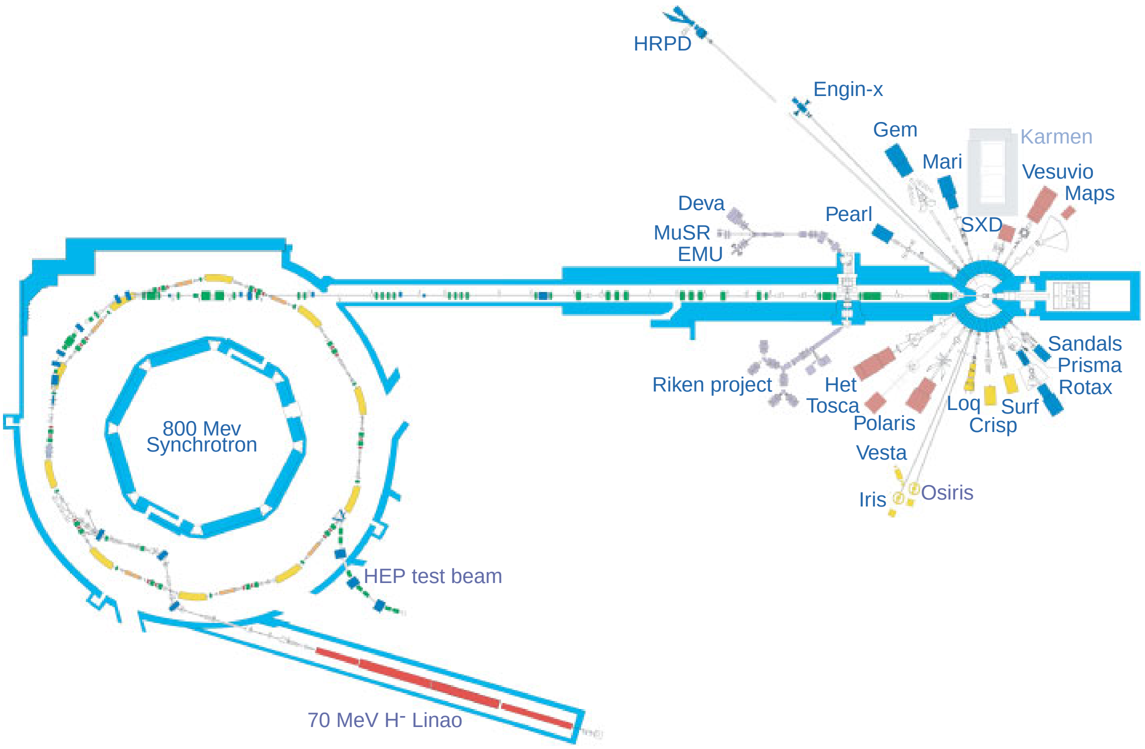

Figure 4 Layout of the ISIS Spallation Neutron facility in Chilton England including linear accelerator, 800 MeV synchrotron, target and instrument hall

Figure 5 Aerial view of the SNS on the Chestnut ridge site at the Oak Ridge National Laboratory operated by the University of Tennessee–Battelle

movements within the solid. As noted in the introduction, neutrons can be used to determine the thermal motion of the atoms that compose molecules or crystalline lattices and this property underlies the other great strengths of using neutrons to study condensed matter and inorganic systems. These motions or response to thermal (or other) forms of energy can be realized by monitoring the changes in the neutron energy after the neutron scatters off of the system. A net increase (or decrease) in the neutron energy can take place when the neutron interacts with the system under study and thus the neutron moves away at a faster (or slower) speed. This is analogous to the Doppler effect that causes the stationary listener to hear the whistle on an approaching and passing train to first raise and then lower in pitch. These changes in neutron energy can either be transferred to or from a crystal lattice, or to or from molecules in a liquid, or at an interface.

The dynamics of the sample can either be of a random nature, like translational or rotational diffusion, or of a collective type that has a propagating wavelike property. The latter collective type wave propagation in the crystal lattice is known as a *phonon* and these coordinated thermal motions of the crystal take place at discrete quantized phonon frequencies (hence energies) given by $h\nu$. These frequencies are usually dependent on the propagation direction in the crystal, the specific crystal structure, and its atomic composition. Rotational, vibrational, and librational motions can also be effectively studied with neutrons. Finally, using high surface-to-volume materials, neutrons can be employed to investigate surface phenomena. In the following sections, some of the mathematical formalism of the neutron scattering technique will be used and several examples that are aimed at illustrating the power of the technique, with the goal of stimulating additional interest and further

reading in more advanced and specialized monographs and journals.

2.3 Neutron Scattering Formalism

In a typical neutron scattering experiment, the intensity of the neutrons scattered from a beam incident on a sample is recorded. Usually, the scattering process will involve a deflection of the incident neutrons identified by a change in the wave vector, $\boldsymbol{k}$, of the beam, and denoted by the scattering vector $\mathbf{Q} = \boldsymbol{k}_i - \boldsymbol{k}_f$, where the subscripts i and f denote the incident and final directions, respectively. In addition to the change in wave vector, the scattering can also involve a change in the energy, E, of the neutrons. The magnitude of this energy change is usually associated with some dynamic process in the sample and hence we can represent that as an angular frequency, ω, such that $E = h\omega$. The scattered intensity measured in a neutron experiment is proportional to the dynamical structure factor, $S(\mathbf{Q}, \omega)$ and hence is a function of both $\mathbf{Q}$ and ω. $S(\mathbf{Q}, \omega)$ represents the Fourier transform of the temporal and spatial fluctuations of the atomic (spin) density in a normal (magnetic) neutron scattering process. There are many comprehensive discussions of neutron scattering formalism and the reader is directed to such monographs written by Marshall and Lovesey,[5] Lovesey,[6] Bacon[7] and Squires[8] for a much more thorough treatment.

What appears below is a brief discussion of neutron scattering formalism (for an in depth exposition see, for example, the classic paper by van Hove).[9] We assume the scattering is from point particles, which is reasonable, because thermal neutron scattering involves wavelengths on the order of 1 Å and the length scale of the interaction between an atomic nucleus and the neutron is around five orders of magnitude smaller. If we consider an individual particle j at position $\mathbf{r}_j$ at time t, the number density can be expressed as

$$r_j(\mathbf{r}, t) = \delta(\mathbf{r} - r_j(t)) \qquad (1)$$

where δ is the Dirac delta function. The Fourier transform of the spatial component of the number density is given by

$$\rho_j(\mathbf{Q}, t) = \int \rho_j \mathrm{e}^{i\mathbf{Q}\bullet r}\,\mathrm{d}r = \mathrm{e}^{i\mathbf{Q}\bullet r_j(t)} \qquad (2)$$

We can now express fluctuations in time by using the cross-correlation function.

$$f_{jk}(\mathbf{Q}, t) = \langle \rho_j(\mathbf{Q}, t)\rho_k(-\mathbf{Q}, 0)\rangle \qquad (3)$$

The angular brackets denote an average over all initial times. Because most materials are composed of a collection of different elements, the neutron scattering process represents the contribution of each atomic nucleus to the scattering process, weighted by the scattering length, b_j, of the individual nucleus j. The scattering length corresponds to the strength of the interaction between the jth nucleus and the neutron. As a result, each contribution to the scattering must be weighted accordingly, and taking into consideration the fluctuations of the whole sample, we can express the neutron scattering for N atoms in the form:

$$\begin{aligned} F(\mathbf{Q}, t) &= \frac{1}{N}\sum_{j,k}\langle b_j b_k \rho_j(\mathbf{Q}, t)\rho_k(-\mathbf{Q}, 0)\rangle \\ &= \frac{1}{N}\sum_{j,k}\overline{b_j b_k}\langle \rho_j(\mathbf{Q}, t)\rho_k(-\mathbf{Q}, 0)\rangle \end{aligned} \qquad (4)$$

$F(\mathbf{Q}, t)$ is referred to as the *intermediate scattering function*, and the bars placed above the scattering length variables b_j and b_k in equation (4) represent the time average of the cross-correlation functions. These scattering lengths are time independent and thus can be separated out from the time variations in the nuclear density. With this in mind, the dynamical structure factor can be derived using the time Fourier transform of $F(\mathbf{Q}, t)$ as

$$\begin{aligned} S(\mathbf{Q}, \omega) &= \int f(\mathbf{Q}, t)\mathrm{e}^{i\omega t}\,\mathrm{d}t \\ &= \frac{1}{N}\int \sum_{j,k}\overline{b_j b_k}\langle \rho_j(\mathbf{Q}, t)\rho_k(-\mathbf{Q}, 0)\rangle \mathrm{e}^{i\omega t}\,\mathrm{d}t \end{aligned} \qquad (5)$$

In terms of energy, this expression can be cast in the following form

$$S(\mathbf{Q}, E) = \frac{1}{N}\int \sum_{j,k}\overline{b_j b_k}\langle \rho_j(\mathbf{Q}, t)\rho_k(-\mathbf{Q}, 0)\rangle \mathrm{e}^{i2\pi Et/h}\,\mathrm{d}t \qquad (6)$$

While the treatment appears to be mathematically complicated, it is instructive to consider several special cases that lead to some special methods for extracting unique information about the system under investigation. For example, we can separate the elastic from the inelastic scattering, as well as the coherent from the incoherent scattering. Furthermore, we can use methods to integrate over either energy or scattering vector. The fact that we are able to carry out the separation of different scattering processes leads to the versatility and the application of neutron scattering methods to a wide variety of topics as suggested in the introduction.

Having introduced the neutron scattering length, b, above it has been assumed that the scattering length is the same for all of the atoms of a particular element in the sample. This presumes that the scattering length is independent of the isotope number and nuclear spin state, but what this assumption effectively does is average out the variation of the scattering length with isotope and spin number. No significant error results for many elements since only one isotope occurs naturally in significant quantities. In the case of the isotopes of oxygen, the relative abundances for ^{16}O, ^{17}O and ^{18}O are 99.76%, 0.04%, and 0.2%, respectively, and the variation in scattering length is small (5.803, 5.78 and 5.84 fm,

respectively); hence, assuming that the scattering length is constant has negligible consequences. There are of course important exceptions. For example, the two most abundant isotopes of nickel are ^{58}Ni and ^{60}Ni with relative abundance of 68.27% and 26.1% and scattering lengths of 14.4 and 2.8 fm respectively. Neither of these two nuclei has a nonzero value of the spin. As noted above, the effects of nuclear spin can also be important. In the case of hydrogen (^{1}H) the spin dependence of the nucleus–neutron interaction is extremely important. The natural abundance of ^{1}H isotope is more than 99.9%. When the quantum mechanical interaction of the spin 1/2 entities (i.e., the neutron and the ^{1}H, nuclear proton) is taken into account, four different arrangements of the spins need to be considered. Three of these configurations yield a total spin of $S = 1$ with z components -1, 0 or $+1$ (i.e., parallel alignment), whereas the fourth is the antiparallel alignment and total spin of $S = 0$. Many elements exhibit a nuclear spin of zero where the spin-dependent components of the nucleus–neutron interaction are not present, and in most cases the nuclear spin effects are often relatively weak. The scattering lengths for parallel and antiparallel alignment are 10.4 and -47.4 fm, respectively, giving an average value of only -3.74 fm. Sodium is another nucleus with an incoherent scattering cross section that arises from the spin states; the incoherent scattering length, 3.59 fm, is close to the coherent scattering length, 3.63 fm. Vanadium is unusual in that the sum of the coherent contributions is almost zero, with only a significant incoherent cross section. We therefore need to consider how the neutron scattering function can be modified to account for these effects, and it will be found that there are considerable applications from this extended approach. The comparisons between values of the coherent and incoherent scattering cross sections are illustrated in Table 2. A compilation of scattering lengths and cross sections can be found on the National Institute of Standards and Technology (NIST) website at http://www.ncnr.nist.gov/resources/n-lengths/,[10] or the monographs noted above.

In order to account for different scattering lengths for atoms of the same type, we can separate the intermediate scattering factor described above into two components:

$F(\mathbf{Q}, t) = F_{\mathrm{coh}}(\mathbf{Q}, t) + F_{\mathrm{inc}}(\mathbf{Q}, t)$ where the *coherent* term can be expressed as

$$F_{\mathrm{coh}}(\mathbf{Q}, t) = \frac{1}{N}\int \sum_{j,k} \overline{b_j}\ \overline{b_k} \langle \rho_j(\mathbf{Q}, t)\rho_k(-\mathbf{Q}, 0)\rangle \qquad (7)$$

and the *incoherent* term as

$$F_{\mathrm{inc}}(\mathbf{Q}, t) = \frac{1}{N}\int \sum_{j,k} \left(\overline{b_j b_k} - \overline{b_j}\ \overline{b_k}\right) \langle \rho_j(\mathbf{Q}, t)\rho_k(-\mathbf{Q}, 0)\rangle \qquad (8)$$

The coherent term has an average value for the scattering length and involves correlations between the position of an

[a]In the *free state* nuclei upon neutron impact; cross sections related to atomic mass number (M) by $\sigma_{\mathrm{free}} = (A/A+1)^2\sigma_{\mathrm{bound}}$. For H, $\sigma_{\mathrm{free}} = 1/4\sigma_{\mathrm{bound}}$, with the difference between the two cross sections decreasing rapidly for heavier nuclei.

atom j at time zero and the position of a second atom k at time t. Although j and k can be the same atom, in general they are not the same because most samples contain a large number of nuclei, N. Coherent scattering, in essence, describes the interference of waves produced by the scattering of a single neutron from all the nuclei in a sample. The intensity for this type of scattering varies strongly with the scattering angle and contains the information about coherent (i.e., correlated) processes, such as Bragg (diffraction) and phonon scattering. In most cases, $F_{\text{coh}}(\mathbf{Q}, t)$ is expanded in terms of the instantaneous displacements of the atoms from their mean positions, which makes it easier to apply the formalism to the study of phonon dispersion curves and other dynamical processes that will be discussed below.

Some expansion and development of the incoherent term will help us cast it in a more useful form. It is important to note that it has been assumed that there is no correlation between the particular value of the neutron scattering length and the location of the scatterer within the sample. We can use this to write $\overline{b_j b_k} = \overline{b_j}\ \overline{b_k}$ for $j \neq k$ so that in equation (8) above, only the terms where $j = k$ survive leaving:

$$F_{\text{inc}}(\mathbf{Q}, t) = \frac{1}{N} \int \sum_{j,k} \left(\overline{b_j^2} - \overline{b_j}^2\right) \langle \rho_j(\mathbf{Q}, t) \rho_j(-\mathbf{Q}, 0) \rangle \tag{9}$$

It is convenient to define two scattering cross sections:

$$\begin{aligned} \sigma_j^{\text{coh}} &= 4\pi \overline{b_j}^2 \\ \sigma_j^{\text{inc}} &= 4\pi \left(\overline{b_j^2} - \overline{b_j}^2\right) \end{aligned} \tag{10}$$

Then the incoherent structure factor can be expanded as:

$$F_{\text{inc}}(\mathbf{Q}, t) = \frac{1}{4\pi N} \sum_j \sigma_j^{\text{inc}} \left\langle e^{i\mathbf{Q}\bullet[\mathbf{r}_j(t) - \mathbf{r}_j(0)]} \right\rangle \tag{11}$$

Because incoherent scattering involves correlations between the position of an atom j at time zero and the position of the *same* atom at time t, the scattered waves from different nuclei do not interfere with one another. In light of this, it is useful to introduce a probability distribution function, $G(\mathbf{r}(t), \mathbf{r}(0))$, which gives the probability of finding a particle at a position $\mathbf{r}(t)$ at time t if it had a position $\mathbf{r}(0)$ at time 0. Thus we can cast equation (11) in a new form:

$$F_{\text{inc}}(\mathbf{Q}, t) = \frac{1}{4\pi N} \sum_j \sigma_j^{\text{inc}} \int e^{i\mathbf{Q}\bullet[r_j(t) - r_j(0)]} G(\mathbf{r}(t), \mathbf{r}(0)) p(\mathbf{r})\, \mathrm{d}r(t)\, \mathrm{d}\mathbf{r}(0) \tag{12}$$

where $p(\mathbf{r})$ is the probability of finding the atom at position $\mathbf{r}$ at time $t = 0$. Writing the intermediate scattering function in this way makes it easy to express the time dependence of the atomic motions using rate equations that will govern the time dependence of $G(\mathbf{r}(t), \mathbf{r}(0))$. For this reason, incoherent scattering provides a good method of examining processes in which atoms diffuse. In most situations, the incoherently scattered intensity is isotropic, that is, independent of scattering angle. Hence it is often possible to ignore this incoherent contribution during studies of coherent scattering processes, because the incoherent effects just add intensity as a featureless background.

Having discussed how the coherent and incoherent components of the scattered neutrons can be treated, it is extremely important to extend the mathematical discussion to include the formalism used to separate the elastic and inelastic scattering processes. Elastic scattering arises from the time-independent (static) component of a sample. This sample could be a crystalline or amorphous solid (i.e., a glass), but not a fluid (which exhibits molecular diffusive motions), because we are considering the case where $\omega = 0$. However, the elastic scattering is not identical with $S(\mathbf{Q}, \omega = 0)$, as discussed below. The function $S(\mathbf{Q}, \omega = 0)$ can be written as $S(\mathbf{Q}, \omega = 0) = \int F(\mathbf{Q}, r)\, \mathrm{d}r$. We can use this to separate $F(\mathbf{Q}, t)$ into two components, a constant term and one that depends on time (the temporal behavior is such that it either tends to zero as $t \rightarrow \infty$ or oscillates about zero at large t). We can then write $F(\mathbf{Q}, t) = F(\mathbf{Q}, \infty) + F'(\mathbf{Q}, t)$, where the first term is the time-independent (constant) term while the second term contains all of the time dependence. Naturally, this is written in such a way that the Fourier transform of the constant term yields a delta function for $\omega = 0$ (i.e., $F(\mathbf{Q}, \infty)\delta(\omega) = \int F(\mathbf{Q}, \infty) e^{i\omega t}\, \mathrm{d}t$), and the Fourier transform of the time-dependent term produces the same energy spectrum as the full $F(\mathbf{Q}, t)$ when $\omega \neq 0$.

Using equation (4) above, the function $F(\mathbf{Q}, \infty)$ can be written as:

$$\begin{aligned} F(\mathbf{Q}, \infty) &= \frac{1}{N} \sum_{j,k} \left\langle b_j b_k \rho_j(\mathbf{Q}, \infty) \rho_k(-\mathbf{Q}, 0) \right\rangle \\ &= \frac{1}{N} \sum_{j,k} \overline{b_j b_k} \langle \rho_j(\mathbf{Q}) \rangle \langle \rho_k(-\mathbf{Q}) \rangle \end{aligned} \tag{13}$$

which includes the situation that at infinite times the random fluctuations in the density function are totally uncorrelated. Consideration of the coherent scattering leads to a simplification of equation (7) to the form:

$$F_{\text{coh}}(\mathbf{Q}, \infty) = \frac{1}{N} \left| \sum_j \overline{b_j} \langle \rho_j(\mathbf{Q}) \rangle \right|^2 \tag{14}$$

What has been presented here underscores the fact that the elastic scattering is the Fourier transform of the time-independent component of the intermediate scattering function. Naturally, the Fourier transform of a constant function produces a δ-function at $\omega = 0$, which is the elastic scattering, but this is not the same as the zero frequency component of the scattered intensity. If the time correlation function has a component that exhibits some time decay or relaxation, then the integral of the time dependant part of

$F(\mathbf{Q}, t)$ will have a contribution to $S(\mathbf{Q}, \omega)$ at zero frequency that is nonzero. This makes an additional contribution to $S(\mathbf{Q}, \omega)$ as part of a continuous function separate from and in addition to the δ-function (from the elastic scattering) discussed above.

2.3.1 Inelastic Scattering

The formalism can now be developed for the neutron scattering function in the case when atoms vibrate about their mean positions, as in a crystalline solid, in order to examine the mathematical treatment of inelastic coherent scattering (once again treatments described in the monographs above give a much more detailed mathematical account of this). Consider a sample consisting of N atoms where the instantaneous position of atom j is identified by $\mathbf{r}_j(t) = \mathbf{R}_j + \mathbf{u}_j(t)$ where $\mathbf{R}_j$ is the average position of the atom, and $\mathbf{u}_j(t)$ is the instantaneous displacement of the atom from its average position. The intermediate scattering function, equation (7), can then be expressed as:

$$F(\mathbf{Q}, t) = \frac{1}{N}\sum_{j,k}\overline{b}_j\overline{b}_k \mathrm{e}^{i\mathbf{Q}\bullet[\mathbf{R}_j-\mathbf{R}_k]}\left\langle \mathrm{e}^{i\mathbf{Q}\bullet[u_j(t)-u_k(0)]}\right\rangle \tag{15}$$

If the motion of the atom about its equilibrium position is harmonic, then one can find, in numerous places (including the monographs identified above) that the time average of the exponential function with the main displacements in the argument is

$$\begin{aligned}\left\langle \mathrm{e}^{i\mathbf{Q}\bullet[u_j(t)-u_k(0)]}\right\rangle &= \mathrm{e}^{-\frac{1}{2}\langle \mathbf{Q}\bullet[u_j(t)-u_k(0)]^2\rangle} \\ &= \mathrm{e}^{-\frac{1}{2}\left(\left\langle[\mathbf{Q}\bullet u_j(t)]^2\right\rangle - \langle[\mathbf{Q}\bullet u_k(0)]^2\rangle + 2\langle[\mathbf{Q}\bullet u_j(t)][\mathbf{Q}\bullet u_k(0)]\rangle\right)}\end{aligned} \tag{16}$$

The first two terms in the exponential argument correspond to the normal thermal factors $\mathrm{e}^{-\frac{1}{2}\langle[\mathbf{Q}\bullet u_j(0)]^2\rangle} = \mathrm{e}^{-W_j}$ and $\mathrm{e}^{-\frac{1}{2}\langle[\mathbf{Q}\bullet u_k(0)]^2\rangle} = \mathrm{e}^{-W_k}$. The third term can be expanded in a power series as:

$$\mathrm{e}^{-(\langle[\mathbf{Q}\bullet u_j(t)][\mathbf{Q}\bullet u_k(0)]\rangle)} = \sum_{l=0}^{\infty}\frac{1}{m!}\left\langle[\mathbf{Q}\bullet u_j(t)]\,[\mathbf{Q}\bullet u_k(0)]\right\rangle^m \tag{17}$$

The $m = 0$ term in the series corresponds to elastic scattering, while the $m = 1$ term can be examined within the harmonic approximation of the lattice dynamics; the instantaneous displacement can be written as:

$$u_j(t) = \frac{1}{\sqrt{Nm_j}}\sum_{k,\nu}\mathrm{e}_j(\mathbf{k}, \nu)\mathrm{e}^{i(\mathbf{k}\cdot\mathbf{r}_j)Q(\mathbf{k},\nu)} \tag{18}$$

where the term $\mathbf{Q}(\mathbf{k}, \nu)$ is the normal mode coordinate for a phonon of wave vector $\mathbf{k}$ and branch n, and $\mathbf{e}_j(\mathbf{k}, \nu)$ is the normalized vector that gives the relative displacements of each atom. Treating the normal mode coordinate as a quantum operator, it can be shown that the $m = 1$ term contributes the following term to the dynamical scattering factor:

$$\begin{aligned}S_1(\mathbf{Q}, \omega) &= \frac{1}{N}\sum_{j,k}\overline{b}_j\overline{b}_k \mathrm{e}^{i(\mathbf{Q}\cdot[\mathbf{R}_j-\mathbf{R}_k])}\mathrm{e}^{-(W_j-W_k)} \\ &\quad\times\int\langle[\mathbf{Q}\cdot u_j(t)][\mathbf{Q}\cdot u_k(0)]\rangle \mathrm{e}^{-i\omega t}\,\mathrm{d}t \\ &= \frac{1}{N}\sum_{\nu}\frac{\hbar}{2\,\omega(\mathbf{k}, \nu)}|F_\nu(\mathbf{Q})|^2 \\ &\quad\times([1 + n(\omega)]\delta\,(\omega + \omega(\mathbf{k}, \nu) + n(\omega)\delta(\omega - \omega(\mathbf{k}, \nu))))\end{aligned} \tag{19}$$

where the phonon structure factor component is given as:

$$F_\nu(\mathbf{Q}) = \sum_j \frac{\overline{b}_j}{m_j}\mathrm{e}^{-W_j}\mathrm{e}^{i\mathbf{Q}\cdot R_j}Q\cdot \mathrm{e}(\mathbf{k}, \nu) \tag{20}$$

This expression for the single-phonon dynamical scattering factor has to be examined in a little more detail. Because we consider only the creation or annihilation of a single phonon, the δ functions identify that scattering from a phonon of angular frequency $\omega(\mathbf{k}, n)$ takes place such that changes in the energy of the neutron beam take place only at $\pm\omega(\mathbf{k}, n)$. The likelihood that phonon scattering occurs is determined by the thermal distribution of phonons, which were described using Bose–Einstein statistics such that distribution $n(\omega) = 1/(\mathrm{e}^{\hbar\omega/k_BT} - 1)$ where $n(\omega)$ is the number of phonons of frequency ω for a given temperature, T. In the case where there has been a loss of neutron energy, the situation corresponds to a scattering event that has taken place following the creation of a phonon, and this process occurs with probability $[1 + n(\omega)]$. If the scattering event takes place such that there is a gain in energy of the scattered neutron beam, this corresponds to situation where the neutron absorbs a phonon; here the probability of this process is given by the number of phonons $n(\omega)$. At sufficiently high temperatures, the intensity from a single phonon is proportional to:

$$S_1(\mathbf{Q}, \omega) \propto \frac{k_BT}{\omega^2}\delta(\omega \pm \omega(\mathbf{k}, \nu)) \tag{21}$$

In both cases, the intensity of scattering is determined by the phonon structure factor that takes into account the relative positions of atoms, the relative orientation of the scattering vector $\mathbf{Q}$, and the displacement of the atoms. These factors determine the so-called selection rules for the one phonon neutron scattering process. It should be noted that the restrictions associated with the one phonon scattering event described here are certainly not as restrictive as the selection rules associated with the optical equivalent analogs of Raman or infrared spectroscopy (*see* ***Vibrational Spectroscopy***). This property of the nuclear scattering can be useful in separating measurements for which there are a large number of phonons for any wave vector $\mathbf{k}$. The terms in the expansion for $m > 1$

involve *multiphonon* processes. However, these processes prove to be much less informative because these processes do not yield enough structure in measured spectra to be useful, and understanding the behavior of these processes is mostly motivated by the need to subtract them from absolute measurements of intensities in both inelastic and total scattering measurements.

The single-phonon coherent inelastic processes described above are often used for measurements of phonon dispersion curves with single crystal samples[11,12] (Figure 6). These studies are not trivial, and as a result, it is often the case that measurements will only focus on a small subset of all phonon modes (particularly the lower energy modes). Examples of measurements of relatively complete sets of dispersion curves of minerals include calcite,[13] sapphire,[14] and quartz.[15] It should be appreciated that the measurements of the high frequency modes are particularly difficult. It can be seen from equation (21) that the one phonon intensity scales as ω^{-2}. Because other spectroscopic probes can access these phonon modes more readily, and their variation across a range of wave vectors is often slight, it is often not worth attempting to measure complete sets of dispersion curves. Moreover, the experimental difficulties increase with more complex minerals. Examples of partial sets of dispersion curves include the olivines—forsterite[16] and fayalite,[17] pyrope,[18] andalusite,[19] and zircon.[20]

Inelastic coherent scattering measurements using single crystals may focus on selected modes. For triple-axis spectroscopy, the work of Shirane *et al*. sets the standard by which most other studies can be gauged (Figures 7 and 8). For additional examples, see the monograph by Shirane, Shapiro and Transquada.[21] Measured phonon densities of

states have been reported for complex minerals such as almandine,[22] pyrope,[23] sillimanite, kyanite,[24] orthoenstatite,[25] and fayalite.[26] With spectrometers such as the MARI instrument at ISIS, it is now possible to perform inelastic scattering measurements from powdered samples as functions of **Q**. The value of these types of measurements is that they enable comparisons to be made between the excitation spectra of different phases. It has been shown by these measurements using INS that spectra of silica glass are closely related to the spectra of the two phases of cristobalite.[27]

There has been a considerable effort in the physics and chemistry communities to use INS methods to study magnetic dynamics, which can often be described as *spin waves*. Measurements of spin wave dispersion curves can provide information about the interactions between atomic magnetic moments, the so-called *exchange interactions*. There have been comparatively few INS measurements on magnetic minerals. INS methods have been used to produce spin wave dispersion curves for hematite.[30] Crystal field magnetic transitions in cobalt bearing cordierite, and spinel phases have also been studied by INS.[31]

2.3.2 Formalism for Incoherent Scattering

General Considerations. Hydrogen is the ideal atom for investigating the incoherent scattering of neutrons, since the cross section for incoherent scattering is large relative to its own coherent scattering cross section and the cross sections of most atoms likely to be encountered in natural materials. This is true when hydrogen is a constituent part of a molecule, such as water or methane. Hence, consider a single hydrogen atom in a molecule, its position at time t being given by $\mathbf{r}(t)$, where $\mathbf{r}(t) = \mathbf{R}(t) + \mathbf{d}(t) + \mathbf{u}(t)$, and $\mathbf{R}(t)$ is the position of the center of mass of the molecule and $\mathbf{d}(t)$ is the position of the hydrogen atom relative to the molecular center of mass, assumed to have constant magnitude but variable direction, and $\mathbf{u}(t)$ is the vibrational motion of the atom about its ''average'' position (where $|d| \gg |u|$). The vibrational motions associated with $\mathbf{u}(t)$ are much faster than the rotational motion of the molecule, which is why we can

treat the behavior of the bond vector $\mathbf{d}(t)$ separately from the vibrational displacement $\mathbf{u}(t)$. We are interested in evaluating the quantity $\langle e^{iQ^o-[\mathbf{r}(t)-\mathbf{r}(0)]}\rangle$. This can be written as

$$\langle e^{iQ^o-[\mathbf{r}(t)-\mathbf{r}(0)]}\rangle = \langle e^{iQ^o-[\mathbf{R}(t)-\mathbf{R}(0)]}e^{iQ^o-[\mathbf{d}(t)-\mathbf{d}(0)]}e^{iQ^o-[\mathbf{u}(t)-\mathbf{u}(0)]}\rangle \quad (22)$$

If the translational, rotational, and vibrational motions are not coupled, we can perform the averages on the three exponential terms separately, obtaining the total function (with self-explanatory notation), $F_{\text{inc}}^{\text{tot}}(\mathbf{Q},t) = F_{\text{inc}}^{\text{trans}}(\mathbf{Q},t) \times F_{\text{inc}}^{\text{rot}}(\mathbf{Q},t) \times F_{\text{inc}}^{\text{vib}}(\mathbf{Q},t)$. When we take the Fourier transforms, we have the convolution of the incoherent inelastic scattering functions for the three types of motion:

$$S_{\text{inc}}^{\text{tot}}(\mathbf{Q},\omega) = S_{\text{inc}}^{\text{trans}}(\mathbf{Q},\omega) \otimes S_{\text{inc}}^{\text{rot}}(\mathbf{Q},\omega) \otimes S_{\text{inc}}^{\text{vib}}(\mathbf{Q},\omega)$$

In practice the various types of motion within materials occur on sufficiently different time scales and so the effects of the convolution do not cause any major problems in the analysis of incoherent neutron scattering data; these problems mostly occur in the study of molecular fluids.

Incoherent neutron scattering is an excellent tool for characterizing the motion of individual molecules on the atomic level as they diffuse through a crystalline or liquid medium, or at the interface of a bulk solid, or within a porous media. This can be followed by examining the time dependence of $\mathbf{R}$. One example that has been exhaustively studied is the diffusion of hydrogen atoms in metals such as palladium. In these systems, atomic hydrogen enters the metal via interstitial sites, and then ''hops'' from site to site rapidly. Diffusion within molecular fluids or within surface-adsorbed molecular films on the surface of graphite or MgO are other examples. In these studies, incoherent neutron scattering provides direct information about the time constants for the diffusion, the temperature dependence, and some information of the diffusion mechanism. *Isotropic diffusion* might occur, for example, in a simple liquid. In this situation it can be assumed that there is no potential to be concerned with, hence we can use a standard rate equation for molecular diffusion (i.e. Fick's second law):

$$\frac{\partial G}{\partial t} = D\nabla^2 G \quad (23)$$

Where G is the probability distribution function $G(\mathbf{r}(t), \mathbf{r}(0))$ first introduced in equation (13), which we rewrite as $G(\mathbf{r}, t), \mathbf{r} = \mathbf{r}(t) - \mathbf{r}(0)$, and D is the diffusion constant consistent with the *Fickian* diffusion.

This standard expression for the diffusion with boundary conditions, $G(\mathbf{r}, 0) = d(\mathbf{r})$ and $\int G(\mathbf{r}, t)d\mathbf{r} = 1$ for all t has the solution:

$$G(\mathbf{r}, t) = (4\pi Dt)^{-3/2}e^{-r^2/4Dt} \quad (24)$$

where r is the modulus of $\mathbf{r}$. Inserting this solution into the equation for the intermediate scattering function (noting that for the present case the probability $p(\mathbf{r})$ is constant for all values of $\mathbf{r}$), leads to the result $F_{\text{inc}}(\mathbf{Q}, t) = \exp(-DQ^2t)$, where Q is the modulus of $\mathbf{Q}$, and N is the number of atoms. Fourier transformation of this expression gives the final incoherent scattering function for the Fickian diffusion:

$$S_{\text{inc}}(\mathbf{Q},\omega) = \frac{1}{\pi}\frac{DQ^2}{(DQ^2)^2 + \omega^2} \quad (25)$$

Notice that the final scattering function for the case of isotropic diffusion is just a Lorentzian function centered at $\omega = 0$ with a frequency width that varies with Q^2 and an amplitude that varies as Q^{-2}. Further inspection of this expression shows us that the width varies directly with the diffusion constant D, and thus the time constant associated with the diffusion. Normally, the energy width associated with the diffusion is significantly narrower than the phonon frequencies, usually by several orders of magnitude when compared to phonon frequencies, and hence this scattering is often referred to as *quasi-elastic scattering*. In fact, the motion and time scales associated with diffusion are so slow that special instruments have been designed and built for *incoherent* quasi-elastic neutron scattering (QENS) studies. The typical resolution of a QENS instrument will range from 10^8 to 10^{10} Hz, which is much finer than the typical value of 10^{11} Hz for a triple-axis spectrometer.

What has just been outlined is a simple introduction to diffusion in fluids and model studies; however, when considering crystalline materials, this very elementary model needs to be modified in order to address a position-dependent potential. The diffusion constant is generally a tensor rather than a scalar quantity, a reflection of the fact that the motion will be easier in some directions than in others. While the more realistic case is obviously more difficult to analyze, the general form of the Q^2-dependent Lorentzian term is usually retained, even if the solution involves the superposition of several Lorentzian functions. However, significant insight and progress can be made in these more realistic and complicated situations. Restricting our attention to large length scales, or small $\mathbf{Q}$, allows for the individual components of the motion (particularly the lowest order component) to be extracted. Working with powders, and therefore imposing an average over all orientations of the crystalline lattice, reduces the difficulties associated with the tensor nature of the diffusion (i.e., that it is anisotropic) and may not be a significant limitation on accuracy if the diffusion is only significant along one direction in the crystal. If diffusion is limited to primarily lattice sites such that the motion is one of ''hopping'' from lattice site to lattice site due to the periodic potential of the crystal, then there will be an *elastic incoherent scattering signal* when $\mathbf{Q}$ is equal to a reciprocal lattice vector. This elastic scattering contains information about the strength of the periodic potential. In the limit where the jump is instantaneous, that is, much less than the average time that an atom dwells at the lattice site, then standard jump diffusion

models can be used in the interpretation of the quasi-elastic scattering. The monographs by Bee[32] and Hempelmann[33] are two excellent resources in that they discuss many experimental and theoretical examples, including the development of the mathematical formalism.

Neutron Characterization of Vibrational Motions. As noted above, the time scales for phonon motion get significantly longer for translational diffusion, but within the formalism described, both the positional terms **R** and **u** contain a time dependence. An accurate, but somewhat simplified view of the temporal behavior would allow us to assign the low frequency lattice vibrations (phonons) where the molecules move as rigid bodies to the **R** term, while **u** could be assigned to the internal vibrational motions of the molecules (i.e., high frequency). This decoupled view is generally a reasonable assumption and can be characterized if the incoherent response is measured over the proper range. The so-called phonon density of states is the form of $S_{\text{inc}}(\omega)$ if the result is averaged over all **Q** and weighted by the appropriate incoherent neutron cross sections. If hydrogen is present in the sample, the motions of the hydrogen atoms will dominate the recorded spectrum because hydrogen has a large incoherent scattering cross section, making it ideally suited to perform vibrational spectroscopy on such systems. Coupled with the fact that the high frequency modes have only a weak dependence of wave vector density of state, measurements typically exhibit sharp phonon peaks. Furthermore, incoherent neutron scattering can be used as an effective tool for vibrational spectroscopy because there are no symmetry related selection rules (as there are in optical scattering techniques like IR and Raman) which make certain transitions unobservable. Despite the phonon spectrum being at a much higher frequency than the translational and rotational motions, the QENS is convoluted with the vibrational spectrum. This convolution gives rise to a Debye–Waller prefactor to the proper QENS intensity in the same way as in the case of coherent neutron scattering. There are numerous examples of using neutrons to characterize the vibrational spectrum of a sample, but one of the more effective illustrations of this for inorganic systems involves hydrated crystalline systems like the zeolites, or minerals like gypsum, or metal oxides containing tetrahedrons of aluminum (AlO_4) or silicon (SiO_4), like analcime or leutice. An excellent recent monograph that addresses the use of neutrons in vibrational spectroscopy has recently been published by Mitchell, Parker, Ramirez–Cuesta, and Tomkinson.[34] An example of the vibrational spectrum of a C_{60} fullerene is shown in Figure 9.

Rotational Motions. In addition to molecular vibrational motions, one can use neutrons to characterize the rotation of a molecule about its center of mass. If the position of the hydrogen atoms in a molecule rotates as a function of time in such a way that the relative positions of the atoms move with a *constant radius* **d**, but the motion is such that the terminus of the vector **d** moves randomly or ergotically on the surface of the sphere; this motion is referred to as *rotational diffusion*. This motion can also provide insight into the nuclear density. An example of this is shown in Figure 10.

It is instructive to first consider isotropic rotational diffusion of an atom, which is a simple but somewhat accurate description of a molecular liquid like liquid methane just below T_{melting}, a situation wherein the centers of mass of the molecules remain stationary, but the molecules rotate freely about their centers of mass. If we use the polar angle $\boldsymbol{\Omega} = (\theta, \phi)$ to define the orientation of the vector **d**, the probability distribution function, **G** (see equation 12), which

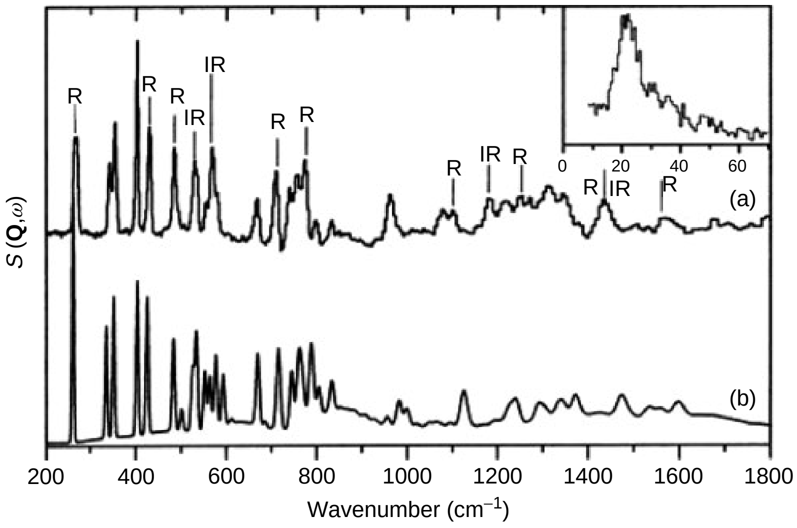

Figure 9 (a) Inelastic neutron scattering spectrum of C_{60}, buckyballs recorded at 20 K and (b) calculated spectrum using Density Functional Theory (DFT) methods from Parker and co-workers (Mitchell *et al.*[34] © World Scientific Publishing Company). R and IR indicate Raman and IR active modes, respectively; all other modes are optically forbidden. The lattice (phonon) modes are shown in the inset

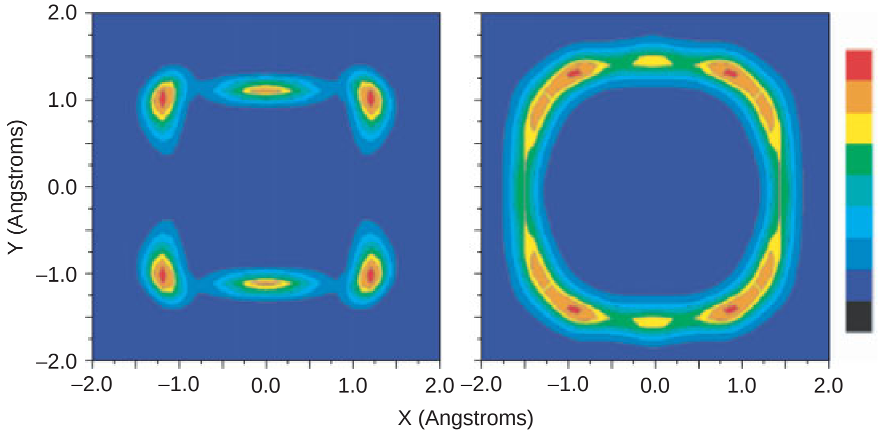

Figure 10 Contour plots of calculated (a) and measured (b) nuclear density for the methyl group in lithium acetate dihydrate. In both cases, four peaks of strong intensity are found at the corners of the square, and weaker peaks are observed at the middle of the upper and lower sides

is a function of $\mathbf{\Omega}(t)$ and $\mathbf{\Omega}(0)$, $\mathbf{G}(\mathbf{\Omega}(t), B(0))$ becomes the probability of finding the vector **d** at the orientation $\mathbf{\Omega}(t)$ when the orientation at $t = 0$ was $\mathbf{\Omega}(0)$. The similarity to the translational diffusion case can be made apparent by considering that the rotational rate law is expressed as: $\partial\mathbf{G}/\partial t = D_R\nabla^2_\Omega G$, where D_R is the *rotational diffusion constant.* The time constant for the rotational motion is found by taking the inverse of D_R; as with most problems involving spherical motion some simplification of this expression can be realized by using spherical coordinates for the operator, ∇^2_Ω. However, this is where the simplicity ends. A full treatment of the solution can be found in many places; the monograph by Bee[32] is still the best exposition of the mathematics involving rotational diffusion. The solution is given by

$$G(\mathbf{\Omega}(t), \mathbf{\Omega}(0)) = 4\pi \sum_{l=0}^{\infty} \mathrm{e}^{(-D_R l(l+1)t)} \sum_{m=-l}^{+l} Y_m^l(\mathbf{\Omega}(t)) Y_m^{l*}(\mathbf{\Omega}(0)) \quad (26)$$

As usual, there are the spherical harmonics or the complex conjugates (identified by the *). This expression can be inserted into the intermediate scattering function where one gets the following expression containing the regular Bessel functions j_l:

$$F_{\mathrm{inc}}(\mathbf{Q}, t) \propto j_0^2(Qd) + \frac{1}{\pi}\sum_{l=1}^{\infty}(2l+1)j_l^2(Qd)\mathrm{e}^{(-D_R l(l+1))t} \quad (27)$$

The more useful form of this expression is found by considering the incoherent scattering function obtained by taking the Fourier transform to get

$$S_{\mathrm{inc}}(\mathbf{Q}, \omega) \propto j_0^2(Qd)\delta(\omega) + \frac{1}{\pi}\sum_{l=1}^{\infty}(2l+1)j_l^2(Qd)\frac{D_R l(l+1)}{(D_R l(l+1))^2 + \omega^2} \quad (28)$$

where $\delta(\omega)$ is the Dirac delta function. The two terms in the above expression warrant some discussion. The first term is the elastic peak centered at $\omega = 0$ and is dependent on $\boldsymbol{Q}$, while the second term (often referred to as a *quasi-elastic* component) is a summation of Lorenztian peaks. The Lorenzian *linewidths* depend on D_R and increase with l, but are independent of $\boldsymbol{Q}$. For example, the $l = 1$ term has a linewidth equal to $2D_R$. It is noted that the *quasi-elastic* component *amplitude* depends on $\boldsymbol{Q}$ because it appears in the argument of the Bessel functions. This is an elementary description of the rotational behavior without considering the contribution due to the so-called crystal field effects that result in a much more complicated expression for the incoherent scattering function (see Ref. 32 for more details). Nonetheless, the essential features have been included, namely, an elastic and quai-elastic component of the behavior here. The barrier to rotational motion can be quantified using the temperature dependence of the quasi-elastic linewidth. It is often found that the rotational reorientation rate follows an Arrhenius behavior given by $(1/\tau) = D = D_0\mathrm{e}^{-(E_R/RT)}$, where E_R is the activation energy associated with the rotational motion.

2.3.3 *Bragg Diffraction and Coherent Elastic Scattering*

There have been some excellent encyclopedic contributions in the past by Cheetham[35] and Vogt[36] on crystallography and structure determinations using neutrons so, the formalism of the topic will be briefly touched on, for completeness (*see* ***Neutron Diffraction***). Equation (19) above can be written for $m = 0$ term as:

$$F_0(\mathbf{Q}, t) = \frac{1}{N}\sum_{j,k}\overline{b}_j\overline{b}_k\mathrm{e}^{i\mathbf{Q}\cdot[\mathbf{R}_j-\mathbf{R}_k]}\mathrm{e}^{-(W_j-W_k)} = \frac{1}{N}\left|\sum_j\overline{b}_j\mathrm{e}^{i\mathbf{Q}\cdot\mathbf{R}_j}\mathrm{e}^{-W_j}\right|^2 \quad (29)$$

which is time independent. The Fourier transform of this term introduces a delta function into the scattering function which takes the form: $S_0(\mathbf{Q}, \omega) = (1/N)|\sum_j \overline{b}_j\mathrm{e}^{i\mathbf{Q}\cdot\mathbf{R}_j}\mathrm{e}^{-W_j}|^2\delta(\omega)$, which is equivalent to the elastic form ($\omega \rightarrow 0$ limit

of $S(\mathbf{Q},\omega)$) of the scattering function discussed earlier. The usual form of the structure factor for Bragg diffraction can be arrived at by starting with the intermediate scattering function for coherent scattering and noting that $\sum_j \overline{b_j}\langle e^{i(\mathbf{Q}\cdot\mathbf{R}_j)}\rangle = \sum_j \overline{b_j} e^{i(\mathbf{Q}\cdot\mathbf{R}_j)}\langle e^{i(\mathbf{Q}\cdot\mathbf{u}_j)}\rangle = \sum_j \overline{b_j} e^{i(\mathbf{Q}\cdot\mathbf{R}_j)} e^{-\langle[\mathbf{Q}\cdot\mathbf{u}_j]^2\rangle}$. Bragg diffraction is naturally used to determine the structures of crystalline solids, but the expression can be used for systems like glasses as long as there is no diffusion and the atoms vibrate about their equilibrium positions. This expression would not be useful for a liquid since, by their very nature, the atoms diffuse in a liquid. Bragg diffraction studies can be performed on powders, where Rietveld refinements are the method of choice for data analysis. The advent of high intensity TOF powder diffractometers like General Materials Diffractometer (GEM) at ISIS have enabled structural refinements with exquisite accuracy for a wide range of materials. Figure 11 is one of numerous examples of the high quality of the diffraction pattern and an illustration of the attendant crystal structure. There are numerous monographs dedicated to the Rietveld method for extraction of detailed crystal structural information. The one by Young[37] is especially comprehensive. Bragg diffraction using neutrons can also be performed using single crystals; the review by Artioli in 2002[38] is a nice presentation. While diffraction using single crystals yields structural information with higher precision than powder diffraction, one pays the price of the increased time necessary for a single measurement which sometimes limits the studies to a few temperatures or pressures. A new generation single crystal TOF diffractometer is being constructed at the SNS where the emphasis will be on investigating a new generation of novel materials with unique properties, biomimetics, magnetic structures, soft matter, nanomaterials, thermoelectrics, and so on.

Neutron Diffraction from Layered and Two-Dimensional Systems. While single crystal surfaces and interfaces are readily studied using X-ray and electron diffraction techniques, neutrons can only be applied to such interfacial studies if high surface to volume materials can be used, or where large beam footprints are employed such as in reflectometry studies. As noted above, these studies typically involve materials like clays, mica, graphite, and silica. One of the earliest studies relevant to the discussion here is that of Warren[40] who explained how the diffraction from crystalline powders of random layer materials (like graphite and carbon blacks) exhibit diffraction patterns with characteristic lineshapes that are shaped like a sawtooth. Warren considered a model system composed of a random layer lattice structure arranged parallel and equidistant from one another, but a random translation parallel to a layer and rotation about the normal. Warren explained his results by noting that the calculated lineshape was a direct result of the powder averaging of a perfect two-dimensional (2D) reciprocal lattice of rods that correspond to the real space ''sheets'' of carbon that form the basal plane of graphite. Figure 12 shows schematically how the asymmetric sawtooth line shape arises, while Figure 13 is a plot of the diffraction pattern from a randomly oriented material that is a collection of 2D planes. This diffraction profile is often referred to as the ''Warren'' lineshape. His argument holds true for other lamellar materials as well, so it is relevant to our discussion here.

Since we are considering a 2D system, we note that this is a monomolecular system and all of the centers of mass of the molecules are in the same plane (even if individual nuclei in the molecule are not). $S(\mathbf{Q})$, introduced earlier in this chapter, therefore only depends on the component of $\mathbf{Q}$ projected onto the scattering plane, $\mathbf{Q}_{\text{parallel}}$. Just as Warren did, the case of lamellar systems like graphite and mica can now be considered, assuming that the scattering system has random orientations of the crystallites about an axis normal to the basal (or 2D) plane. Because the magnitude of the parallel component of the structure factor $S(\mathbf{Q})$ is the relevant quantity

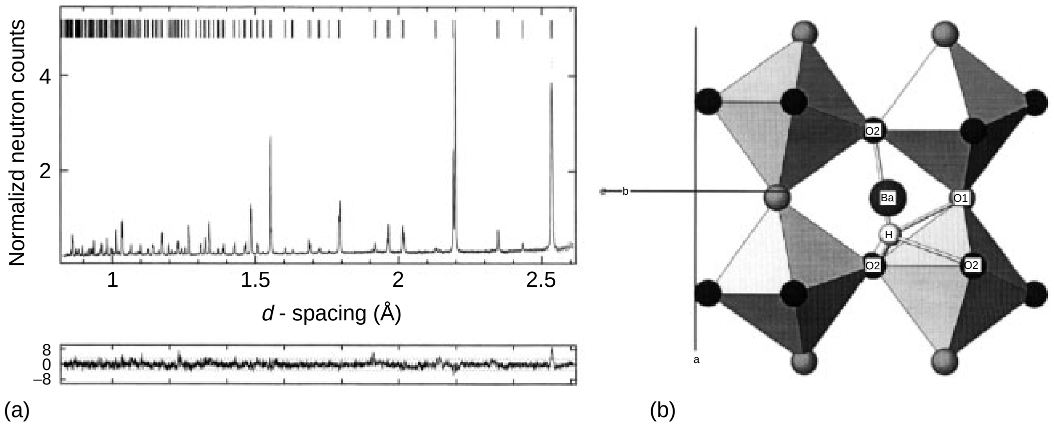

Figure 11 (a) Rietveld refinement of $BaCe_{0.9}Y_{0.1}O_{2.95}$ at 4.2 K. Observed data: dots; calculated profile: full line and difference/Estimated Standard Deviation (ESD) plot. (b) The refined structural site for the proton in $BaCe_{0.9}Y_{0.1}O_{2.95}$ at 4.2 K. (Reproduced with permission Knight[39] © 2000, Elsevier)

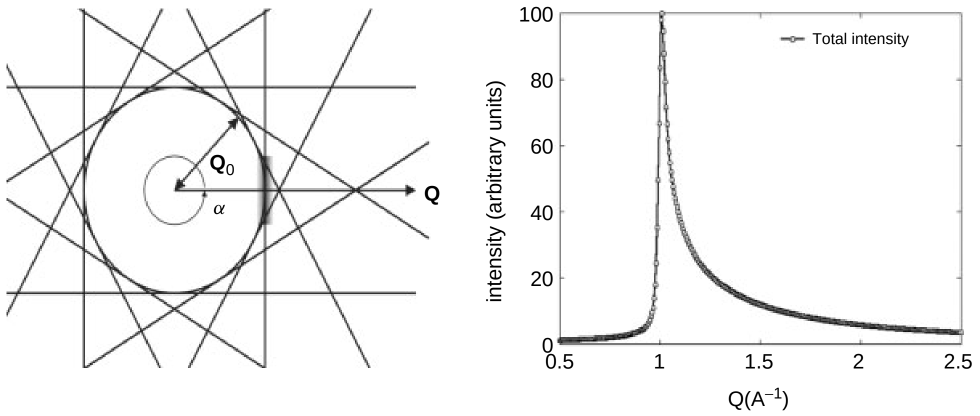

Figure 12 (a) Schematic representation of how the projection of Bragg rods leads to the asymmetric shape shown in the Warren lineshape figure illustrated in panel (b). The origin of this asymmetry is discussed in the text. This diffraction pattern uses a Lorentzian profile for the structure factor of the Bragg rod. (Reprinted with permission Arnold, Chanaa, Clarke, Cook and Larese[41] © 2006, American Physical Society)

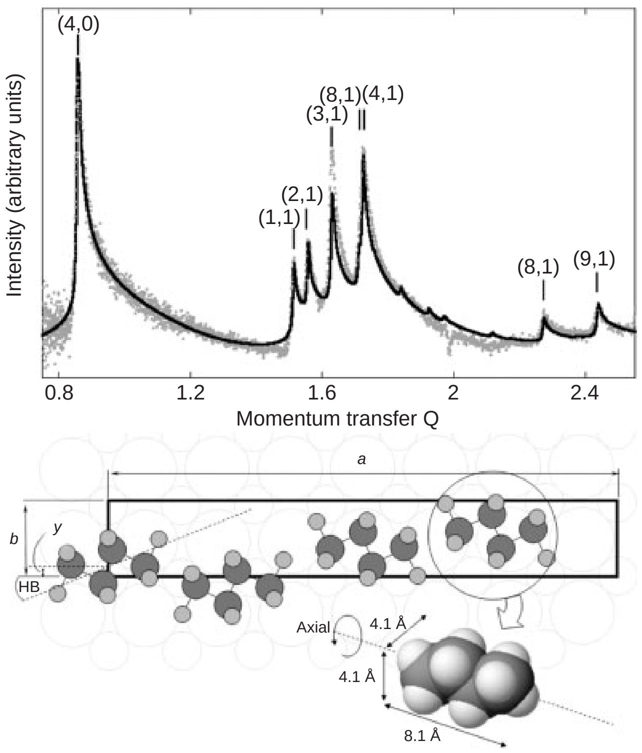

Figure 13 (a) Neutron diffraction study of the structure of a single layer of butane adsorbed to a MgO(100) surface. The sawtooth shaped peaks in the diffraction pattern indicate that the molecular film is two-dimensional. Panel (b) illustrates how the four molecules in the unit cell ($a = 29.5$ Å; $b = 4.21$ Å) are arranged. The molecules are found to ''register'' with the MgO lattice with cell a $2\sqrt{2} \times 7\sqrt{2}$ configuration[41]

we note that:

$$S(Q_{parallel}) = \frac{1}{2\pi}\int_0^{2\pi} S(Q_{parallel}, \xi)\, d\xi \qquad (30)$$

where ξ is the angle made by $\mathbf{Q}_{parallel}$ with respect to an arbitrary reference direction in the scattering plane. Finally, an average must be made over the distribution of the surface normal to the individual crystallites that make up the powdered sample. Figure 14 illustrates the geometry for a single crystallite. This figure shows a crystallite (labeled as the primed coordinate system), where the surface normal (z' axis) is oriented at an angle θ with respect to the unprimed laboratory frame. The primed frame is chosen so that both the primed and unprimed y axes lie in the same plane and the z' axis lies in the yz plane of the lab frame. For this illustration let us chose the $\boldsymbol{Q}$ vector to be along the y axis. Hence $\mathbf{Q}_{parallel}$ can be given by:

$$Q_{parallel} = |Q\hat{y} - (Q\bullet\hat{z}')\hat{z}| = Q(1 - \sin^2\theta\sin^2\phi)^{1/2} \qquad (31)$$

where $\mathbf{y}$, $\hat{z}$ and $\hat{z}'$ are unit vectors pointing along the respective primed and unprimed axes, some straightforward vector

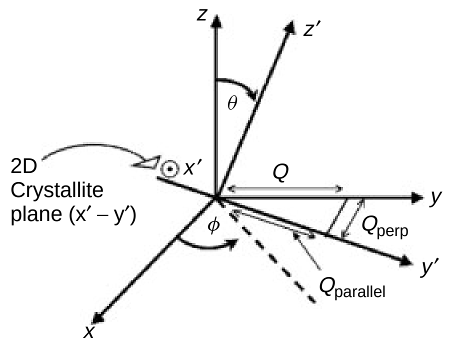

Figure 14 Scattering geometry for a 2D crystallite with the surface normal (z') tilted with respect to the fixed laboratory z axis. Note that the x' axis comes out of the plane of the paper. (Reprinted with permission Larese, Harada, Passell, Krim and Satija[45] © 1988, American Physical Society)

geometry can be used to express the unit vector $\hat{z}'$ in terms of the laboratory (unprimed) frame. If the probability distribution of the crystallite plane normals per unit solid angle is $P(\theta)$, then the fraction of plane normals within the solid angle $\sin\theta \, d\theta \, d\phi$ is given by their product $(P(\theta)\sin\theta \, d\theta \, d\phi)$ by combining our results from above and assuming that $F(\mathbf{Q})$ only depends on the magnitude of $\mathbf{Q}$, we find that the cross section can be written as:

$$\frac{d\sigma}{d\Omega} = B^2|F(Q)|^2 \int_0^{2\pi} d\phi \int_0^{\pi} d\theta \sin\theta P(\theta) S[Q(1 - \sin^2\theta \sin^2\phi)^{1/2}] \tag{32}$$

While this is the essence of what is required to calculate the cross section, it is noteworthy to indicate that Warren deduced that in the neighborhood of the two-dimensional reciprocal lattice vector τ_{hk} for a finite-sized 2D crystallite of coherence length, L, the structure factor can be approximated by:

$$S(\mathbf{Q}) = \rho_0(L/a)^2 e^{-[|\mathbf{Q}_{\text{parallel}} - \tau_{hk}|^2 L^2/4\pi]} \tag{33}$$

Numerous authors have more recently expanded the expression for the cross section given by equation (32) in various ways. Most of this work is for determining the structure of adsorbed films on solid substrates in particular graphite. The details of these expansions can be found in Stephens *et al.*,[42] Dutta *et al.*[43] and Dimon *et al.*[44] The work of Dimon *et al.*[44] is particularly noteworthy in that it finds that a Lorentzian distribution gives a more satisfactory fit to the lineshape. Our recent experimental evidence suggests that the Lorentzian lineshape can be successfully used to describe the scattering profile of adsorbed molecular films on substrates like graphite foam and MgO where a truly random distribution of the crystallites seems to be realized. Figure 13 illustrates the overall quality of the Lorenztian lineshape description for a monolayer butane film adsorbed on MgO(100) surfaces. So far, the focus has been on describing the lineshape for 2D solid systems; however, in cases where the range of spatial correlations is restricted to near neighbor and next near neighbor coordination rings, and where translational mobility also is present (i.e., 2D liquid/fluids), these lineshapes would broaden in response to the decay of the spatial correlations. This discussion, will later indicate how inelastic and quasi-elastic scattering can be used in conjunction with diffraction to gain further microscopic information about the details of the dynamics in interfacial solids and fluids.

It is of some interest to consider the situation where one of the idealized 2D systems that have been addressed can be followed in a layer-by-layer growth mode from a strictly 2D plane to one that is more 3D like. Such is the situation in the formation of multilayer molecular films adsorbed to uniform substrates or where epitaxial metal or soft matter growth is realized in chemical vapor deposition, molecular beam epitaxy or polymeric deposition systems. The ‘‘lineshape’’ discussion above has to be modified to account for the development of the third dimension of order in the system. Conceptually this is rather straightforward. Instead of considering, as Warren[40] did, an ideal 2D reciprocal lattice composed of an ordered array of uniform rods, the reciprocal lattice for an idealized multilayer (e.g., two to five individual layers) system is characterized by

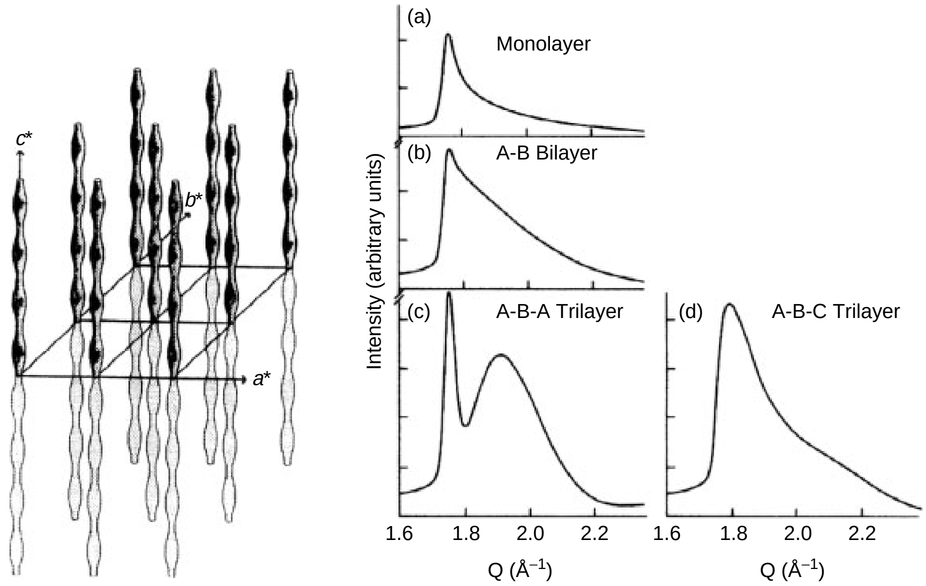

Figure 15 (left) Schematic view of a modulated lattice of rods characteristic of a spatially finite bilayer structure. (right) Model lineshape calculations for a powder-averaged diffraction profile resulting from an A-B stacking sequence for (a) monolayer, (b) bilayer, (c) trilayer thick film, (d) illustrates the diffraction profile for an A-B-C trilayer. A triangular, commensurate, close-packed structure was used in each case. The in-plane lattice spacing was the same in all cases. The interplane distance was held fixed between all layers[45]

an array of modulated rods, where the functional form of the modulation of those rods represents the details of the spatial distribution of the scatters in the direction perpendicular to the original 2D plane. Stephens *et al.*[42] considered the multilayer diffraction situation in X-ray scattering studies, while Larese and his collaborators considered how neutron scattering could be used to follow the growth and melting of atomic and molecular systems on graphite. Figure 15 illustrates how neutron diffraction (ND) patterns evolve with film thickness for the growth of ideal two- and three-layer close-packed films on the graphite basal plane.

2.3.4 Magnetic Scattering with Neutrons

The treatment presented here could be extended to address magnetic materials as well. For the sake of completeness and as an illustration, the magnetic scattering of a neutron beam (unpolarized) can be written equivalently to equation 4 presented earlier as:

$$F_{\text{magnetic}}(\mathbf{Q},\infty)=\frac{1}{N}\left|\sum_{j}\mathbf{q}_j p_j\langle e^{i\mathbf{Q}\cdot r_j}\rangle\right|^2 \qquad (34)$$

The vector $\mathbf{q}$ is the magnetic interaction vector given by $\mathbf{q}=\mathbf{m}/m-\mathbf{Q}(\mathbf{Q}\cdot\mathbf{m})/Q^2\text{m}$, where $\mathbf{m}$ is the magnetic moment of an atom or ion. If we express the angle between the magnetic moment and the magnetic vector as α then we can write $q=|\mathbf{q}|=sin\alpha$. The magnetic scattering amplitude p is given by:

$$p=\frac{e^2\gamma}{2mc^2}gJf \qquad (35)$$

where γ is the magnetic moment of the neutron, e is the electronic charge, m is the neutron mass, c is the speed of light, g is the *Landé factor*, J is the total orbital angular momentum and f is the form factor (which depends on Q and has similar behavior to the X-ray atomic form factor). The product gJ is the magnetic moment of the atom. p has numerical values that are very similar to the neutron nuclear scattering length, b. While this is an extremely important field in neutron scattering, a complete discussion would be the topic for an entire article in this compendium. The formalism for magnetic scattering can be developed in a manner that parallels what has been presented here for the elastic and inelastic scattering, so that a characterization of the structure and dynamics of magnetic material could be described. Furthermore, all of the standard monographs listed at the beginning of this article provide excellent descriptions of magnetic scattering.

3 APPLICATIONS

Neutron scattering has been vital in a multitude of applications, especially as more and more scientists discover its usefulness. Traditionally, neutrons have been primarily used in inorganic chemistry as a probe for magnetic properties. Neutron sources and instrumentation continue to improve, and the impact on neutron scattering continues to broaden. As already mentioned in the text, neutron scattering has been utilized for inorganic studies in geology, magnetic ordering, hydrate and hydride compounds, and confined systems. The following briefly overviews a cross section of interesting applications of neutron scattering related to inorganic chemistry. Due to the large number of techniques and instruments that are employed around the world under the label ‘‘neutron scattering’’, this set of examples is in no way an exhaustive list, but it is intended to be a very small sample for illustrative purposes. It is therefore broken into several categories: bioinorganic, anthropological, electrochemical, engineering (stress and strain), geological, magnetic, catalysis, and rotational motion.

3.1 Bioinorganic Applications

To study complex bioinorganic systems, researchers must use a large number of complementary techniques. Neutron scattering, particularly diffraction, has been used because of the neutron’s unique sensitivity to the hydrogen/deuterium element. Neutrons provide information, not only about the bioinorganic molecule, but also information about the solvation shell (water around the bioinorganic molecule). Since biological samples can be difficult to prepare, the nondestructive nature of neutron scattering has a particular appeal.

In particular, Sukumar *et al.*[46] used the Protein Crystallography Station (PCS) at LANSCE to investigate the structure of amicyanin, a Type I blue copper protein. The study was used to identify the positions of key hydrogens within the protein, something that even high resolution and high intensity studies using X rays cannot properly determine.

3.2 Anthropological Applications

An interesting application of neutron scattering techniques is the use of neutrons to determine the validity of artifacts. Because neutron scattering (specifically using thermal to cold neutrons) is a nondestructive technique, it can be utilized to probe sensitive, priceless artifacts. Leever *et al.*[47] used the GEM neutron diffractometer at ISIS to do a comparative, structural analysis of two harquebusier breastplates. In the study, it was determined that the structural makeup of the two breastplates was different; hence one was verified to date around 1600–1650 A.D., while the other was a replica from the late 19th century.

3.3 Applications Involving Electrochemical Processes

Neutron scattering experiments allow a large degree of freedom in the sample environment, since materials such as Al and V are used as windows and sample cans. This

allows neutrons to be used as a probe *in situ* during chemical processes. Vivet *et al.*[48] have used ND to study the hydrogen cycle within AB_{5+x}Ni–MH negative electrode materials. The hydrogen cycle is vital to the long-term performance of the electrode, hence the life of the electrochemical cell. The study shows that Fe- and Mn-substituted electrodes exhibit a three-phase process and cycle life comparable to commercial electrodes that use the more costly Co as the substitute.

3.4 Applications Involving Stress Determination in Materials

Neutrons provide a unique, nondestructive probe for determining residual stress in materials. Traditionally, laboratory-based X-ray generators were used, but because of the generally small penetration depth, only limited information is available nondestructively. Bruno *et al.*[49] have used the D1A two-axis diffractometer at the ILL to analyze the interface residual stress in Mo-coated steel gear wheels. This work was used to develop a new experimental method for similar studies.

3.5 Geological Applications

The geosciences have recently started to take advantage of neutron spectroscopy. This technique can be used to study the structure and dynamics of various complex minerals that have subtle phase transitions. Neutrons are particularly useful in studying the diffusion of hydrogen in minerals, especially the motion/dynamics of water molecules in small cavities found in various zeolites. Cole *et al.*[50] cite an example of using vibrational incoherent neutron spectroscopy. These authors display spectra of analcime in various states of hydration with a comparison to the similarly structured leuctite. These spectra show the coupling of the water molecules to the vibrations of the network of silica and alumina tetrahedra. They also show an example of a quasi-elastic spectrum that can be obtained from the rotations of water molecules in analcime. This is an example of the high resolution needed in QENS experiments.

3.6 Applications Involving Magnetic Materials

Neutron scattering is a powerful method for studying the spin structure and spin excitations of magnetic materials. Mirbeau *et al.*[51] utilized the TOF spectrometer, IN5, at the ILL to study the energy sublevels, spin structure, and spin excitations of Mn_{12}-acetate magnetic nanoclusters. Determination of energy level spacing allowed for the identification of higher order terms in the spin Hamiltonian. The relative intensity of low energy peaks can be used to determine the zero field coefficient of the Hamiltonian.

Polarized neutrons may be utilized to measure magnetic ordering. Mook *et al.*[52] investigated magnetic ordering of $YBa_2Cu_3O_{6.45}$ using the SPINS spectrometer at NCNR (NIST Center for Neutron Research), the IN20 spectrometer at ILL, and Oak Ridge National Laboratory's HB-1 spectrometer. Researchers obtained results which indicate that a small magnetic moment is present, primarily in the c-axis direction, at a temperature less than 200 K.

3.7 Applications Involving Catalysis

Various types of neutron scattering can be utilized to extract data on structure and dynamics for novel catalytic materials. By selectively deuterating an SSZ-13 zeolite, Cheetham and others[41] used ND performed on the Dual Beam Neutron Spectrometer (DUALSPEC) diffractometer at the Chalk River Laboratories and found that two acid sites are present in the unit cell of the zeolite. INS can be used to probe the mechanism of the catalytic reaction by looking at the change in the vibrational modes of the adsorbed molecules on the surface. Lennon *et al.*[53] found that the interaction of HCl with a η-alumina catalyst results in the dissociative adsorption of HCl, in which the hydroxyl groups terminally bound to Al are replaced by chlorine. INS spectra reveal an in-plane deformation mode, δ (OH), that can be resolved into two bands located at 990 and 1050 cm^{-1}.

3.8 Applications Involving Rotational Tunneling

Quantum rotational tunneling can be observed in thin adsorbed films using INS. Larese *et al.*[45,54] have used INS to probe the free rotor line of methane for an adsorbed methane film on MgO(100) nanocubes. At monolayer coverage of methane, the MgO substrate restricts the free rotation of the molecules; hence there are no free rotation signals. Formation of a second layer causes the first layer of molecules to move slightly further away from the surface, effectively lowering the overall interaction of the first layer molecules with the surface. This reduces the overall attractive hold the substrate has on the near-surface molecules. Molecules in the second layer are further from the surface, and thereby naturally experience a lower attraction to the surface and a lower barrier to rotation. The origin of the two signals in the neutron spectrum are likely due to hindered rotations of molecules in the near-surface layer (peak near 0.9 meV) and the molecules in the second layer (peak near 1 meV). Methane molecules in the first layer, not covered by molecules in the second layer, still experience a large barrier to rotation. Finally, the bulklike neutron signals near 1.1 meV, that appear with the addition of third layer of molecules, can be traced to the basic building block of the face centered cubic (fcc) solid (i.e., the three-layer A-B-C stacking arrangement). It is not surprising that this is the thinnest film where an interaction potential for a *fcc* solid could be realized. These results represent the first direct evidence of how combined adsorption studies and neutron measurements of the rotational dynamics can be used to examine the thickness dependence of the intermolecular and the molecule–substrate interaction potentials.

4 ABBREVIATIONS AND ACRONYMS

DFT = density functional theory; DUALSPEC = dual beam neutron spectrometer; ESD = estimated standard deviation; fcc = face centered cubic; GEM = general materials diffractometer; HFBR = high flux beam reactor; HFR = high flux reactor; ILL = institute laue langevin; *INS = inelastic neutron scattering*; KENS = KEK neutron source; LANSCE = los alamos neutron science center; NIST = National institute of standards and technology; RF = radiofrequency; QENS = quasi-elastic neutron scattering; SNS = spallation neutron source; TOF = time-of-flight; $N(E)$ = spectral distribution; E = energy; N = number; k = Boltzmann's constant; T = temperature; $\boldsymbol{k}$ = wave vector; $\boldsymbol{Q}$ = scattering vector; $\boldsymbol{k}_i$, $\boldsymbol{k}_f$ = incident, final wave vector; ω = angular frequency; $S(\boldsymbol{Q}, \omega)$ = dynamical structure scattering factor; $\mathbf{r}_j$ = jth particle positon; t = time; $\rho_j(\mathbf{Q}, t)$ = Fourier transform of the spatial component of the number density; δ = Dirac delta function; $f_{jk}(Q, t)$ = cross-correlation function; b_j = scattering length of nucleus j; $F(\mathbf{Q}, t)$ = intermediate scattering function or structure factor; $F_{\text{coh}}(\mathbf{Q}, t)$ = coherent term of intermediate scattering function; $F_{\text{inc}}(\mathbf{Q}, t)$ = incoherent term of intermediate scattering function; σ_j^{inc} = incoherent scattering cross section of jth nucleus; σ_j^{coh} = coherent scattering cross section of jth nucleus; $G(\mathbf{r}(t), \mathbf{r}(0))$ or G = probability distribution function; $\mathbf{r}(t)$ = position at time t; $\mathbf{r}(0)$ = position at time 0; $p(\mathbf{r})$ = probability of finding the atom at position, $\mathbf{r}$, at time, $t = 0$; $\mathbf{R}_j$ = average position of atom j; $\mathbf{u}_j(t)$ = instantaneous displacement of atom j from its average position; $\mathbf{e}^{-\mathrm{Wj}}$ = normal thermal factor; $Q(\boldsymbol{k}, \nu)$ = normal mode coordinate for a phonon of wave vector $\boldsymbol{k}$ and branch n; $\mathbf{e}_j(\boldsymbol{k}, \nu)$ = normalized vector representing relative displacements of each atom; $\mathrm{F}_\nu(\mathbf{Q})$ = phonon structure factor component; $\omega(\boldsymbol{k}, n)$ = angular frequency as a function of wave vector; $\mathrm{n}(\omega)$ = number of phonons of frequency ω; $\mathbf{R}(t)$ = position of the center of mass of H_2; $\mathbf{d}(t)$ = position of the hydrogen atom relative to the molecular center of mass; $\mathbf{u}(t)$ = vibrational motion of the atom about its ''average'' position; D = diffusion constant consistent with the *Fickian* diffusion; r = modulus of $\mathbf{r}$; d = constant radius; $\boldsymbol{\Omega} = (\theta, \phi)$ = polar angle; $\mathbf{G}(\Omega(t), B(0))$ = probability of finding the vector $\mathbf{d}$ at the orientation $\Omega(t)$ when the orientation at $t = 0$ was $\Omega(0)$; $\partial\mathbf{G}/\partial t$ = rotational rate law; D_R = rotational diffusion constant; τ = time constant; $\mathrm{E_R}$ = activation energy associated with rotational motion; μ = magnetic moment; $\mathrm{m_n}$ = mass of a neutron; MeV = megaelectron volt.

METHOD SUMMARY

Acronyms, Synonyms

- PMR (Proton Magnetic Resonance)—obsolete.

Measured physical quantities

- Transitions between nuclear spin energy levels are modulated by:
  - chemical shift and chemical shift anisotropy
  - scalar and quadrupolar coupling between spins
  - exchange between spins
  - relaxation times (T_1, T_2, $T_{1\rho}$).

Information available

- number of *types* and number of *each type* of NMR active nuclide present
- relative *disposition* of NMR active groups
- *exchange rates* and *pathways* between sites
- *distance* between NMR active nuclei
- *reaction pathways*
- *ion pairing* and *ion contacts*
- spectra can be *quantitative*
- mobility and molecular dynamics both in solution and in solids
- long and short range order in crystalline, amorphous, multiphase and micro-heterogeneous materials
- imaging of flow and diffusion in catalytic pellets and reactors
- diffusion coefficients, dispersion and flow hydrodynamics.

Information not available, limitations

- useful NMR active nuclei not available for all important transition metals and ligand donors
- relatively low sensitivity
- relatively long NMR timescale, ca 10^{-7} s, limiting routine detection to long-lived species and slow-exchange rates

- quadrupolar nuclei giving broad lines and paramagnetism causing extreme line broadening
- very broad ^{1}H lines in solid-state NMR due to very strong (ca. 100 kHz) homonuclear dipolar interactions
- very long T_1 relaxation times for rare (^{13}C, ^{29}Si) and ''large'' (^{207}Pb, ^{112}Cd, etc.) spin-1/2 nuclei in solid-state NMR
- only first-order quadrupolar interactions for $I = (2n + 1)/2$ quadrupolar nuclei (i.e., ^{27}Al, ^{23}Na, ^{51}V, ^{11}B) efficiently eliminated by MAS.

Examples of questions that can be answered

- What is the chemical environment of the nuclide (via the chemical shift)?
- What neighbours does the nuclide have (via the scalar coupling)?
- What is the topology of the molecule (via scalar couplings and correlation spectroscopy)?
- Is chemical exchange or ligand dynamics occurring (via variable temperature or saturation transfer measurements)?
- Are these groups proximal in space (via Overhauser spectroscopy)?
- Is a reaction occurring (via e.g., in situ methods, isotopic labelling, *para*-hydrogen)?
- How many crystallographically nonequivalent sites (with similar chemical environment) are present in the structure?
- What is the content of the amorphous phase in the material?
- What is the distance between different nuclei in a solid (via measurements of heteronuclear dipolar coupling constants)?
- Are any domains present in a solid and what are their sizes?
- What are the transport properties of a porous catalyst and its structure?

Major advantages

- NMR can obtain direct structural information on solution, semiliquid, gel, crystalline and amorphous samples.
- The technique is multinuclear and nuclide-selective; no resonances from other nuclides appear in the spectra.
- Topology of the NMR active parts of the molecule can be obtained directly from the spectra.
- Structure of (the NMR active parts of) molecules can be deduced with confidence.
- Topology of the exchange and reaction pathways of the NMR active parts of the molecule can be obtained directly from the spectra.
- The through-space interactions can be probed via Overhauser spectroscopy.
- Instantaneous excitation of spins is possible, allowing complex systems to be simplified using two-dimensional techniques.
- Presence of protons in solid materials can be useful for the enhancement of the signal of rare spins via cross-polarisation.

Major disadvantages

- The low sensitivity requires (relatively) high concentration samples and (relatively) long acquisition times for most *inorganic* samples.
- The spectra of paramagnetic samples are not easily obtainable.
- Little or no direct information about NMR inactive sites, for example, (effectively) all halides except ^{19}F, is available.
- A *unique* determination of metal environment may depend on inductive effects and experience.
- High-resolution spectra, in which all sites are resolved, are only obtained
  - in solution or in the gas phase,
  - for spin 1/2 nuclides,
  - in the slow-exchange limit.

Sample/Instrument constraints

- Depending on spectrometer field and the nuclide under study, sample concentrations, in solution, of 0.1 $\sim$ 400 mM are typically required to give spectra of good quality in reasonable (2 $\sim$ 300 min) time; two-dimensional spectra do not require higher sample concentrations.
- For solid-state NMR measurements at least ca. 80 mg (4 mm rotor) or ca 25 mg (2.5 mm rotor) of sample is needed.
- Signal-to-noise improves linearly with sample strength and as the square of number of transients recorded.
- Degassed samples are usually preferred for experiments studying relaxation phenomena.
- Degassed samples may require inconveniently long recovery delays in two-dimensional experiments.
- Most inorganic samples can be successfully studied at moderate strengths of magnetic field (9.4 T; ^{1}H = 400 MHz). Higher field spectrometers may cause chemical shift anisotropy broadening with some nuclei (e.g., ^{31}P).
- Field gradient techniques are not always preferred for 2D spectra of inorganic samples (e.g., HMQC).
- Good shimming is essential.

- Vibration may destroy the desired signal in 2D experiments.
- Magic-angle spinning is essential for practically all solid-state NMR experiments implying:
  - very fast spinning rates are needed to significantly improve ^1H resolution,
  - static NMR is very useful for spin-1 quadrupolar nuclei.
- High-power *rf* fields (ca. 100 kHz) are essential both for the observing and decoupling channels.

1 INTRODUCTION

NMR spectroscopy is today perhaps the most widely used spectroscopic tool in inorganic chemistry for the characterization of inorganic compounds. The power of NMR spectroscopy in the characterization of unknown compounds follows from the sensitivity of the chemical shift to the chemical environment and the presence of scalar couplings between spins that allow the topology of the spin system to be mapped. Recently solid-state NMR has grown into an indispensable method for the determination of the structure and dynamics of organic solids, inorganic materials, and composites. In addition to information on the molecular structure (similar to the high-resolution NMR), solid-state NMR can probe the organization of a material in the solid state without any need for its dissolution. The initial solid-state NMR methodology[1,2] aspired to acquire spectra with resolution, comparable to that in the solution high-resolution NMR spectra, by the elimination of a significant line broadening due to the presence of anisotropic magnetic interactions (using magic-angle spinning (MAS), high-power heteronuclear decoupling etc.). These interactions (i.e., dipolar couplings, chemical shift anisotropy (CSA), quadrupolar coupling) are averaged out in liquids due to the rapid molecular tumbling.[3,4] Modern solid-state NMR methods employ these interactions to derive structural information about a solid under study, often not available from other characterization techniques. Applications of solid-state NMR in catalysis range from the determination of the structure of heterogeneous catalysts,[5] understanding of the interactions between the surface of the pores and guests,[6] and also monitoring catalytic transformations in situ.[7,8]

A description of the theoretical basis of solid-state NMR spectroscopy is beyond the scope of this article. Nevertheless, such knowledge is essential for the understanding the main concepts of solid-state NMR and is extensively covered by recent reviews and books.[4,9,10] The anisotropic magnetic interactions, responsible for the significant broadening of the lines, can be described by the respective Hamiltonians. Generally, both the geometric and spin parts in these Hamiltonians can be used to eliminate their effects on the overall appearance of the spectra or reintroduce specific interactions via the manipulation of a pulse program. For instance, in the heteronuclear dipolar coupling Hamiltonian for the $I-S$ spin pair (equation 1, Figure 1):

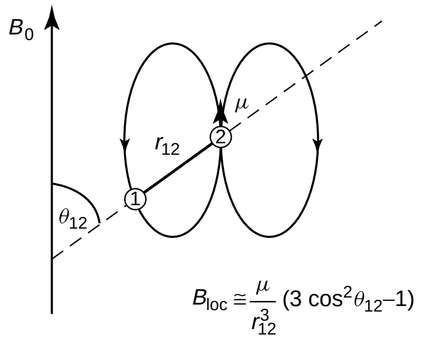

Figure 1 Heteronuclear dipolar interactions

$$\hat{H}_D^{hetero} = -\mathrm{d}_{IS}(3\cos^2\theta - 1)\hat{I}_Z\hat{S}_Z,\ \mathrm{d}_{IS} = \frac{\mu_0}{4\pi}\frac{\hbar^2\gamma_I\gamma_S}{r_{IS}^3} \quad (1)$$

d_{IS} is the dipolar coupling constant depending on the $I-S$ distance r_{IS} and gyromagnetic ratios (γ); $\hat{I}_z$ and $\hat{S}_z$ are the projections of spin operators for I and S spins on the z-axis.

The geometric part of the heteronuclear dipolar coupling Hamiltonian is as follows:

$$H_{D(geom)}^{hetero} = -\mathrm{d}_{IS}(3\cos^2\theta - 1) \quad (2)$$

and includes both the $I-S$ intermolecular distance and the part depending on the orientation of the intermolecular vector with respect to the external magnetic field B_0. The term $(3\cos^2\theta - 1)$ is also present in the Hamiltonians describing chemical shift anisotropy, homonuclear dipolar interactions and first-order quadrupolar interactions.

The aim of this applications article is not to review the spectroscopic information in the literature—such a task is clearly beyond the scope of any review—but rather to guide the reader through the application of multipulse and two-dimensional techniques both in solution and the solid state that the author have found particularly useful in studying inorganic systems. The goal is to provide enough background to allow the reader to determine the applicability of NMR to new inorganic research problems and enough technical advice to get started on the right experimental path. Readers interested in application of NMR to biological inorganic chemical problems should *see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Metallobiomolecules***.

2 TECHNICAL BACKGROUND

2.1 Acquisition of the NMR Spectrum of an ''Inorganic'' Nuclide

Setting up an NMR spectrometer to observe an ''inorganic'' nuclide, X, is little different from setting up for observation of carbon-13; a known sample, giving a ''strong'' signal should be selected and a trial spectrum recorded. The 90° transmitter and decoupler pulses are then measured. There are, however, a few wrinkles. Although IUPAC have issued recommended reference *frequencies* for all nuclei, these are not in universal use, so the chemical shift given in the literature for the selected test compound may be on a ''different'' ppm scale and hence not appear at the ''expected'' position (or, indeed, at all) in the spectrum. Furthermore, the receptivity of the desired nucleus may be so low that a suitable test sample for direct observation and measurement of the 90° pulse simply does not exist. This section seeks to offer guidance on what to do in these situations.

2.1.1 The Spectrometer

- Is the spectrometer capable of measuring nuclide X, or is it ^{1}H and ^{13}C only? Ask *and* check the hardware yourself.
- Has anyone measured nuclide X on this spectrometer before? It might seem obvious, but ask!
- Can the probe be tuned to the nuclide of interest?
- Is the probe direct, or inverse? The former is good for direct observation with or without INEPT enhancement. The latter will give poor signal-to-noise in direct experiments since the sample does not fill the coil space, but is much preferred for indirect detection via, for example, a heteronuclear multiple quantum coherence (HMQC) or heteronuclear single quantum coherence (HSQC) experiment.
- Is the spectrometer/probe capable of variable temperature operation? Dynamic samples need to be measured at low temperatures to freeze out the dynamic processes. Quadrupolar nuclei are often best observed at high temperatures; the increased molecular tumbling rates help to average out the quadrupolar line-broadening interaction.
- Finally, what is the ^{1}H frequency? In common parlance spectrometers are referred to as a ''400'', or ''360'', or ''500''. However, this does not usually correspond to the actual spectrometer ^{1}H frequency. For example, the default frequency of a Bruker spectrometer is 0.13 MHz above this, that is, 400.13 MHz, etc. Furthermore, the frequency may have been shifted ±0.07 MHz from the default value during installation to prevent interference with another, nearby spectrometer of the same nominal ^{1}H frequency.
    - It is very unlikely that the protons of tetramethylsilane (TMS) will resonate at exactly the notional spectrometer frequency. *Measure* a proton spectrum of a standard sample containing TMS and note the absolute TMS frequency. Compare this with the spectrometer's base ^{1}H frequency.
    - Use the *measured value* (in the appropriate lock solvent) in calculating the observation frequency for other nuclides on the IUPAC scale. Best of all, add TMS to the sample of interest (if it's compatible) and record a ^{1}H NMR spectrum as well.

2.1.2 The Test Sample

- Always use a test sample of known chemical shift. It is usually unwise to attempt the first observation on the ''real'' sample of interest. If no suitable test sample exists because of low sensitivity, see the section on determining pulse lengths in adverse situations in the subsequent text.
- Was the chemical shift in the literature measured on the IUPAC scale or some other scale?
- Calculate the expected absolute frequency on the IUPAC scale for the test sample *versus* the *measured* absolute frequency of TMS on your spectrometer.
- Use a short pulse length and moderate power hard pulse—check what has been used before for nuclides of similar γ. Once you have found the signal of interest, measure the 90° transmitter pulse. Measure several pulses of different length; you should observe a sinusoidal variation in the intensity of the NMR resonance (Figure 2).
    - If the intensity reaches a plateau as the pulse length increases, or varies randomly, then the probe is ''breaking down''. Reduce the pulse power and try again.
    - If the intensity initially varies sinusoidally but then the sinusoidal envelope ''stretches'' as the pulse length

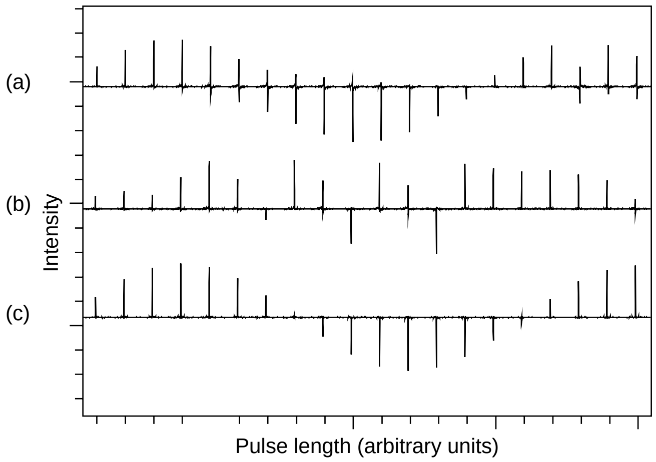

Figure 2 ^{119}Sn 90° transmitter pulse measurement. $SnMe_4$ in $CDCl_3$. (a) Signal 100 ppm off-resonance gives phase distortion, which can be severe, as pulse length varies. (b) Probe breakdown gives random intensity variations. (c) Correct

increases, you are not allowing a sufficient recovery delay between measurements. Increase the recovery delay or add a relaxation agent such as Cr(acac)$_3$.

2.1.3 The 90° Decoupler Pulse

Two situations now confront the inorganic chemist—interest in ^{1}H{X} direct and ^{1}H,X indirect spectroscopy; in these cases the X decoupler pulses will be on the first decoupler channel; or interest in samples where neither nuclide is proton? In this case, the X decoupler pulses will be on the second decoupler channel, variously denoted, ''second decoupler channel'', ''Y channel'', ''f3'', etc. *Consult* the manufacturer's applications department for advice if you are not sure.

^{1}H{X} Direct and ^{1}H, X Indirect Spectroscopy. This is no different from setting up the decoupler pulses for ^{1}H{^{13}C}—you will need a sample in which ^{1}H couples to X.

- Use the appropriate pulse sequence provided by the manufacturer (DECP90 on Bruker machines).
- Tune the probe to the correct frequencies. For low γ nuclei, or nuclei with very large chemical shift ranges, make sure the probe is tuned for the resonance frequency of the sample you are using, for example, the chemical shift range of ^{103}Rh can exceed the width of the probe resonance.
- Position the relevant resonances of ^{1}H in the center of the spectrum (to avoid phase shifts as the pulse length increases) and set the decoupler frequency so that X is on-resonance. Make sure you are using a ^{1}H 90° pulse and that the mixing delay is set to $1/2J_{HX}$. Start with the X pulse power determined above and a *shorter* X pulse length. Increase the X pulse length and look for the *zero* crossing. This corresponds to the decoupler 90° *pulse*, NB *not* the 180° pulse.
- Check the probe is not mismatching on the X channel.
- Make sure that the phase of the lines of the multiplet inverts as you go through the zero crossing point (Figure 3). If the phase does not invert, then you are probably far off-resonance for nucleus X. Double check the X channel is on-resonance—is your test sample's chemical shift on the IUPAC scale or some other? Is the manufacturer's default X frequency on the IUPAC scale or some other? Has someone changed the default X frequency on your spectrometer? Start again.

X, Y Indirect Spectroscopy. The easiest way to measure the 90° pulse on the second decoupler channel is to use the same sample as above, but switch the X nucleus from the first to the second decoupler channel. Load the appropriate, manufacturer supplied pulse program; on Bruker machines this is DECP90F3. Proceed as above.

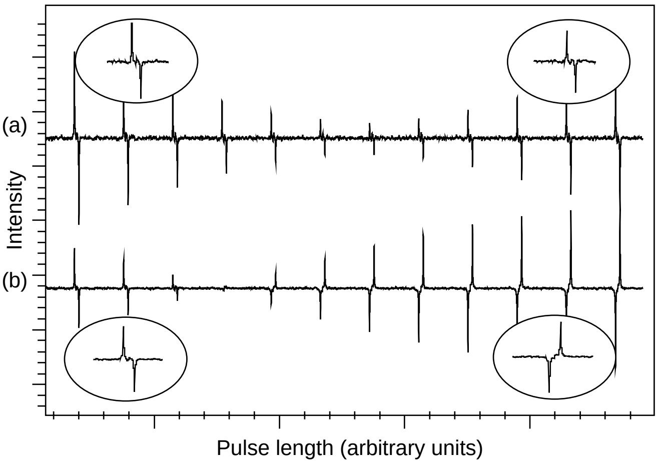

Figure 3 ^{15}N 90° decoupler pulse measurement via ^{31}P, using Bruker pulse program DECP90F3, sample [Pt(C$_5$H$_5$^{15}N)(PPh$_3$)Cl$_2$] in d$_8$-THF. (a) decoupler off-resonance—antiphase doublet does not invert, gives a false result. (b) decoupler on-resonance, correct

If no suitable sample is available to measure the decoupler pulse via ^{1}H, then use a sample containing an XY spin pair, where X gives a strong signal showing coupling to Y. Observe X and decouple Y. Centre the resonances of X in the observation window. Use an X 90° transmitter pulse and set the mixing delay to $1/2J_{XY}$. Use DECP90F3 or the equivalent, manufacturer supplied pulse program. Proceed as above.

2.1.4 Determining Pulse Lengths in Adverse Situations

If the nuclide is of very low receptivity and/or low natural abundance, is there a nuclide of approximately the same γ and of reasonable receptivity that will allow pulse lengths that are ''good enough'' to be measured? For example, GeMe$_4$ is a good substitute to measure the 90° transmitter pulse for nuclides with resonance frequencies in the range ^{57}Fe to ^{187}Os, which includes ^{103}Rh.

Are you ever going to measure X directly? If not, then you only need the decoupler 90° pulse length; proceed as above.

2.1.5 Pulse Sequence

A brief outline of the pulse program for each experiment is given in the following sections. Where phase cycling is necessary, this is noted in the accompanying text. This is intended to help the reader follow what is going on at each stage of the experiment; it is not intended as an explanation of the workings of the pulse program, references are given for the interested reader.

2.2 Acquisition of the NMR Spectrum of a Solid or Semi-Solid Sample

2.2.1 *Magic-Angle Spinning*

MAS is routinely used in solid-state NMR spectroscopy for eliminating the effects of chemical shift anisotropy, heteronuclear dipolar interactions and first-order quadrupolar interactions. In this method the sample is rotated about the axis inclined at 54.74° with respect to the external magnetic field B_0, so that the average of the geometric term in nuclear spin interactions $(3\cos^2\theta - 1) = 0$.[11,12] Except for some specific applications of static wide-line solid-state NMR spectroscopy (i.e., for ^{2}H or for the determination of CSA patterns), the MAS is an essential feature of solid-state NMR spectroscopy and can also be used in variable temperature mode. The MAS methodology can also be used for high-resolution studies of viscous liquids and soft solids.[13,14]

The rate of MAS needed for the elimination/reduction of the effect of anisotropic magnetic interactions depends on the nuclei under observation and the strength of the interactions present. If the rate of rotation is comparable to the strength of an anisotropy, then in addition to the main isotropic chemical shifts the spectrum will contain a set of spinning sidebands separated from the main peak by $n\omega_r$ (ω_r is the MAS rate) (Figure 4). The sidebands can be used for the estimation of the size of CSA (Herzfeld–Berger method[15]). However, in the case of a complex spectrum these lines can obscure main resonances. Therefore the MAS rate should be carefully optimized. One can also apply sideband elimination methods described in the subsequent text (total supression of spinning side bands (TOSS) pulse sequence[16]).

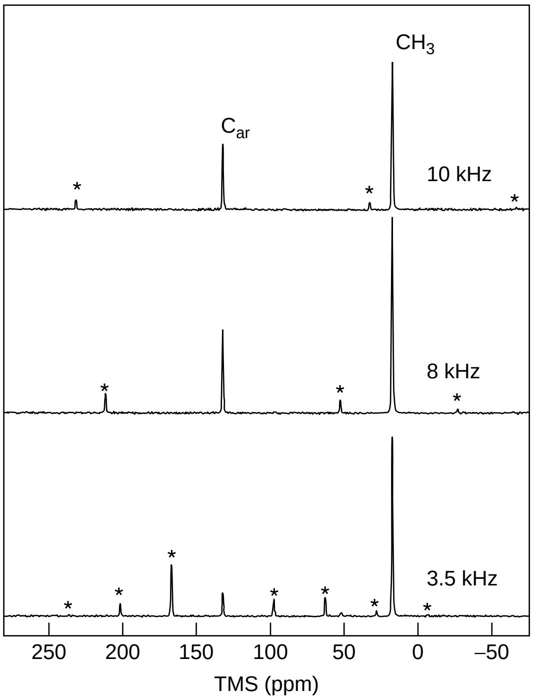

Figure 4 ^{1}H–^{13}C CP/MAS NMR spectra of hexamethylbenzene recorded at different MAS rates (* spinning sidebands corresponding to the aromatic peak at 132.2 ppm)

The probe heads supplied with modern solid-state NMR spectrometers vary in the diameters of the coils and, therefore, in the maximum MAS rate achievable. Recent developments in MAS technology led to the first commercial ultrafast MAS probe heads with MAS rate up to 65 kHz employing rotors with 1.2 mm diameter.[17] When selecting an appropriate probe head, one should take into account the sensitivity of a nucleus under study. The faster the MAS rate, the smaller the amount of the sample required. Typically, one employs MAS rates of 4–15 kHz. The lower end of these rates is covered by the probe heads with large MAS rotors (ca. 7 mm in diameter) suitable for nuclei with very low natural abundance and long relaxation times (^{29}Si, ^{15}N etc.). The fast and ultrafast MAS probe heads are particularly suitable for ^{1}H and ^{19}F nuclei.

MAS is ensured by the supply of compressed gases and can be performed at different temperatures. Spinning in boil-off N_2 is preferable to dried air. Spinning in nitrogen enables a wide temperature range of solid-state NMR experiments (from 173 to 423 K using an ordinary MAS probe head). The temperature range of experiments in dried air is significantly narrower due to both possible oxidation of the probe components at high temperatures and the presence of traces of water even at moderately low temperatures (253–283 K). The MAS results in increased temperature of the rotor due to friction, even in compressed gases. This effect is particularly noticeable at fast MAS rates and low temperatures when the temperature of a spinning gas measured at the entrance point to the probe head can be significantly different from the real temperature of the sample. The correct temperature of the MAS experiments should be derived from the calibration of a probe head using the temperature dependence of chemical shifts. $Pb(NO_3)_2$ is the most widely used standard for such calibrations,[18] although other standards (^{13}C NMR in d-camphor or pivalic acid,[19] ^{7}Li NMR of $Li_{0.24}La_{0.54}TiO_3$ for very high temperature MAS,[20] ^{119}Sn NMR of $Sm_2Sn_2O_7$ for fast MAS[21]) have been proposed.

2.2.2 *Setting up MAS*

Correct setting of the magic angle is essential in solid-state NMR spectroscopy. The most commonly used method relies on the ^{79}Br resonance in solid KBr. ^{79}Br is a quadrupolar nucleus (spin 3/2) ensuring a short relaxation time. The ^{79}Br first-order quadrupole coupling on the satellite transition ($\pm 3/2 \leftrightarrow \pm 1/2$) produces a set of distinct spinning sidebands. When the magic angle is set correctly, one should be able to identify at least 10 pairs of spinning sidebands. The setting of the magic angle can be performed using the ^{79}Br free-induction decay (FID) via the observation of rotational echoes. The correct MAS corresponds to the FID with the largest number of rotational echoes.

Some solid-state NMR experiments require significantly more accurate setting of the magic angle (satellite transition magic-angle spinning (STMAS)[22]). The setting of the magic angle can be checked conveniently using the secondary standard for ^{13}C spectra hexamethylbenzene (HMB). The position of the methyl resonance can be used for setting the ^{13}C chemical shift, while the aromatic peak should be observed at (132.2 ± 0.2) ppm provided that the magic angle is set correctly. The HMB is a convenient standard for setting the conditions for ^{1}H–^{13}C cross-polarization (CP) experiment (see below).

2.2.3 *High-Resolution Magic-Angle Spinning method (HR-MAS)*

High-resolution magic-angle spinning (HR-MAS) NMR spectroscopy is a new method aimed at bridging the gap between the high resolution and solid-state NMR methodologies. This method relies on the MAS of ''semi''-liquids/solids so that the anisotropic magnetic interactions resulting in a significant broadening of spectral lines can be removed and typical high-resolution NMR experiments (described earlier) can be applied.[13] The HR-MAS NMR has been applied successfully for a variety of biomedical systems including drug-delivery materials, cells, and biological tissues.[13,23,24] The HR-MAS NMR probe heads can be used with conventional high-resolution spectrometers supplied with the MAS units.

2.2.4 *Heteronuclear Decoupling*

The broadening due to heteronuclear dipolar coupling is a serious problem for the observation of a spectrum even when MAS is applied. The effect of heteronuclear dipolar coupling can be removed by *rf* irradiation of the ^{1}H channel.

Heteronuclear decoupling can be achieved using different methods. The easiest pulse sequence involves *high-power irradiation of the ^{1}H channel* during the acquisition of ^{13}C. Although this pulse sequence is very straightforward to setup, the power level on the ^{1}H channel is often very high as it should be set at least three times as high as the strongest heteronuclear dipolar coupling in the system (since the directly bonded ^{1}H–^{13}C dipolar coupling is about 22 kHz, the ^{1}H power should be set to ca. 70 kHz). This is easily achievable using medium or fast MAS rate probe heads, but can be problematic for larger sample volumes (ca. 7 mm rotor diameters). The high-power decoupling should be applied for the whole length of the FID which can cause further complications due to arcing and overheating of the sample which might be detrimental for sensitive biological samples. Typically, the ^{1}H pulse is set on-resonance. The presence of the efficient ^{1}H–^{1}H dipolar coupling network ensures the efficient transmission of the ^{1}H pulse between different protons. These disadvantages of high-power decoupling can be eliminated using multiple-pulse decoupling sequences which can also be applied with fast MAS. The Two Pulse Phase Modulated (TPPM) decoupling[25] uses continuous irradiation with two pulses of flip angle θ_p and phases that differ by $\Delta\phi$. Both θ_p and $\Delta\phi$ depend on the spinning rate and the sample and need to be optimized. Since the optimization on the sample is not always feasible, the best standard for the optimization is glycine (methylene resonance). Usually the TPPM sequence achieves better decoupling than high-power decoupling at the same *rf* power. Other methods which found numerous applications in other pulse sequences include small phase incremental alteration decoupling (SPINAL),[26] amplitude-modulated TPPM and XiX.[27]

2.3 Referencing

Referencing of heteronuclear NMR spectra can be a source of confusion. In an effort to establish universal NMR standards, and hence chemical shift scales, IUPAC have recently adopted a procedure in which *all* NMR spectra are, effectively, referenced to the ^{1}H signal of TMS.[28]

The procedure can be summarized thus:

1. Record a ^{1}H NMR spectrum of TMS in the same solvent as that used for the real sample. If TMS is compatible with the sample under study, then simply add TMS to the sample and record the ^{1}H NMR spectrum.
2. Note the *absolute* frequency of TMS $= \Theta_{TMS}$.
3. Look up the reference frequency, Ξ_X, (against TMS = 100 MHz exactly) for the nuclide of interest (X) in Table 1 or 2.
4. The zero of the ppm scale for the nuclide X is then $\Xi_{X^*}\Theta_{TMS}/100$ MHz, exactly.
5. Enter this value into the appropriate parameter on the spectrometer, for example, SF1 on a Bruker Avance spectrometer.
6. Record the NMR spectrum of the sample of interest.

Tables 1 and 2 also give the reference compound on which each chemical shift is based. It should be noted that:

1. Under the IUPAC scheme, these compounds act as *secondary* references.
2. Some of the reference compounds chosen by IUPAC differ from common practice, for example, many (most) workers reference ^{103}Rh to $\Theta_{Rh} = 3.16$ MHz when $\Theta_{TMS} = 100$ MHz.
3. Some reference compounds are extremely hazardous, for example, $Fe(CO)_5$, $HgMe_2$, OsO_4, $PbMe_4$. In these cases the IUPAC scheme should be followed.
4. For ^{15}N, the chemists' preferred reference, $MeNO_2$, differs from that chosen by structural biologists, NH_3. Some manufacturers (e.g. Bruker) use the structural biologists reference as the default. Shifts on the IUPAC scale are approximately 380.5 ppm less positive than on the NH_3 scale, for example, on the IUPAC scale, $\delta(^{15}NH_3) = -380.4$ ppm. The exact correction required depends on the resonance frequency of the sample.

Table 1 The spin properties of selected spin-1/2 nuclei. (Adapted from R. Harris *et al.*[28] © IUPAC)

(a) Ratio, expressed as a percentage, of the resonance frequency of the reference to that of the protons of TMS at infinite dilution (in practice at $\varphi = 1\%$) in $CDCl_3$.
(b) M, molarity in mol dm^3 (solution); m, molality in mol kg^{-1} (solvent). See Ref. 28 for further details.
(c) D^C is the receptivity relative to that of ^{13}C, see *NMR and the Periodic Table*, R. K. Harris and B. E. Mann (Eds.), Academic Press (1978).
(d) By defnition.
(e) The precise values 3.160 000 MHz and 21.400 000 have also been suggested as the references for ^{103}Rh and ^{195}Pt, respectively.[29,30]
(f) Subject to considerable variation with temperature.
(g) Long-lived radioactive isotope.
(h) The high toxicity of this compound means its use should be discouraged.

5. The chemical shifts of many nuclides of interest to the inorganic chemist, for example, ^{31}P, ^{103}Rh, and ^{195}Pt, show large temperature, concentration and/or solvent shifts; referencing to an absolute frequency, rather than a compound makes good sense.
6. Given the above, the temperature, and concentration, as well the solvent, need to be given in reporting data.

3 APPLICATIONS

3.1 INEPT Sensitivity Enhancement

The guidance given in the previous section should allow the acquisition of a simple 1D NMR spectrum from appropriate inorganic NMR samples. However, the signal-to-noise ratio may be very low, either because of low natural abundance, or low inherent sensitivity. If the nucleus of interest (S, the *indirectly detected* spin), couples to a higher γ nucleus (I, the *detector* spin), sensitivity enhancement should be considered. The best 1D method for inorganic samples is INEPT since the sensitivity enhancement is greater than that of DEPT (distortionless enhancement by polarization transfer) and the spectral editing features of DEPT are not usually required.[31] In the authors' experience, refocussed INEPT, with or without decoupling, is the best choice, since this yields spectra similar in appearance to normal 1D spectra, although there is some slight loss of signal intensity due to the longer pulse sequence (Figure 5).[32,33] Note that integrals in polarization transfer experiments are dependent on factors such as the efficiency of polarization transfer and the number of I spins to which the insensitive nuclide S couples. Thus, integrals are *not* a good measure of the number of nuclei present.

3.1.1 *Pulse Sequence*

Figure 6 illustrates the pulse sequence for INEPTRD. p1 excites the I spin magnetization, d2, p2, d2, and p5 create

(a) Ratio of the resonance frequency of the reference to that of the protons of TMS at infinite dilution (in practice at $\varphi = 1\%$) in $CDCl_3$.
(b) M, molarity in mol dm^3 (solution); m, molality in mol kg^{-1} (solvent). See Ref. 28 for further details.
(c) $l = (2I + 3)Q^2/I^2(2I - 1)$. The values are quoted, arbitrarily, to 2 significant figures.
(d) D^C is the receptivity relative to that of ^{13}C.
(e) Radioactive, with a long half-life.
(f) saturated.

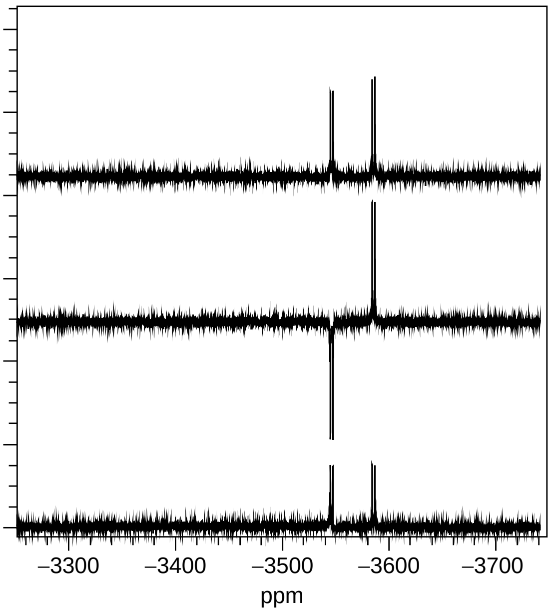

Figure 5 $^{195}Pt\{^1H\}$ NMR spectra of $[Pt(C_5H_5{}^{15}N)(PPh_3)Cl_2]$ recorded in THF: (bottom) normal spectrum; (middle) with INEPT enhancement from ^{31}P, $\gamma_I/\gamma_S = 40.48/21.50 \sim 2$, note the antiphase multiplet; (top) with refocused INEPT enhancement from ^{31}P, note slight loss of intensity due to signal dephasing during the longer pulse sequence

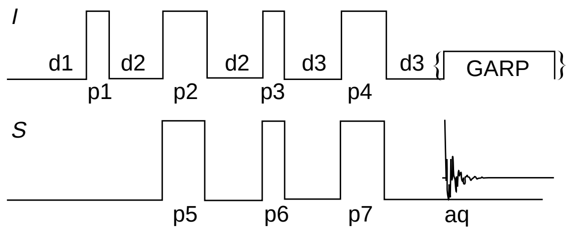

Figure 6 INEPTRD pulse sequence

a spin echo after the second d2. p3 and p6 transfer this I spin magnetization to S. If $d2 = 1/4J$ then antiphase S spin magnetization results and is enhanced by the ratio γ_I/γ_S. In addition, the ''normal'' S spin magnetization contributes a ''normal'' spectrum to the signal, hence the intensities *within* the multiplets are distorted. d3, p4, and p7 remove this distortion and correct the phase within the multiplets giving a spectrum that looks ''normal'' but is enhanced by γ_I/γ_S. $d3 = 1/(\pi J.\surd\ \arcsin(n))$, where n is the number of coupled I spins. GARP (globally optimized alternating-phase rectangular pulses), rather than WALTZ, decoupling is normally used to decouple heteronuclei and is optional.

Advantages

- It is simple to implement, little can go wrong provided pulses and delays are set accurately.
- It gives the strongest signal.
- The enhancement is greatest if $\gamma_I \gg \gamma_S$ and is independent of the sign of γ.
- The number of coupled I nuclei can be determined directly from the multiplicity if decoupling is *not* used; cf indirect methods where this information is not routinely available.
- The pulse sequence repetition rate is determined by relaxation of the I spins which is often faster than that of the S spins.

Disadvantages

- The enhancement is sensitive to accurate setting of the coupling constant $J(IS)$.
- The enhancement is sensitive to the value chosen for d3. Incorrect setting of d3 can severely degrade the spectrum.
- Greater enhancement, giving a spectrum in less time, might be available by an indirect method such as HMQC.
- If I is not ^1H, then a three-channel machine, and triple resonance probe are required.

Acquisition tips

- Use the pulse program, and phase cycling sequences supplied with your instrument. Make sure all necessary experimental parameters are set as described by the manufacturer. The manufacturer should provide sequences with and without I decoupling.
- The *minimum* number of scans is defined by the phase cycle. The total number of scans must be an integral multiple of this.
- Inspect your spectrum after a few scans have been recorded to see all is well.
- Make sure that d3 is set correctly.

Processing tips

- Process normally.

3.2 Selective Observation of *S* Spin Satellites

It is frequently necessary to detect the signals arising from only those spins of nuclide 1 (I) that are coupled to nuclide 2 (S). For example, it may be necessary for chemical reasons to record the ^1H NMR spectrum of a metal–hydride in protio-, rather than deutero-solvent (Figure 7), or it may be that the exact value of the coupling $J(IS)$ is required for a polarization transfer experiment, but cannot be measured directly from the spectrum of I due, for example, to a low natural abundance of S (Figure 8). There are many ways that this can be achieved, the most popular of which is the 1D

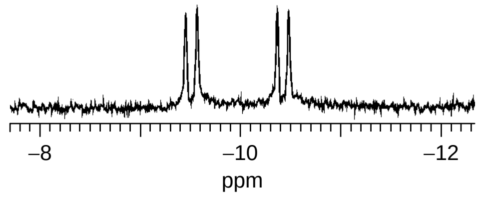

Figure 7 $^{1}H,^{31}P$ 1D HMQC phase cycle selected NMR spectrum of $[PdH(LL)(solv)]^+$, (LL = 1, 2-bis((di-tert-butylphosphino)methyl) benzene) recorded in MeOH at 295 K. Note: resonances not coupled to ^{31}P are suppressed, allowing the metal–hydride resonance to be seen clearly in protio solvent

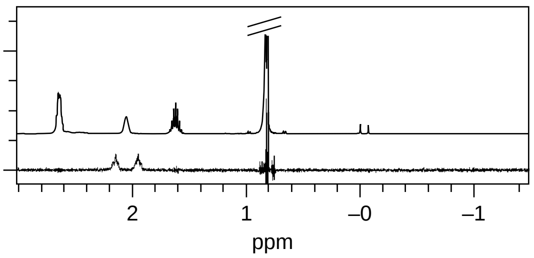

Figure 8 ^{1}H NMR spectrum of $[(N_3(P(Bu^i)_2)_3]$ in $CDCl_3$ at 295 K: (top) normal 1D spectrum; (bottom) $^{1}H,^{15}N$ 1D HMQC gradient-selected spectrum. Note ^{15}N satellites are readily observed at natural abundance

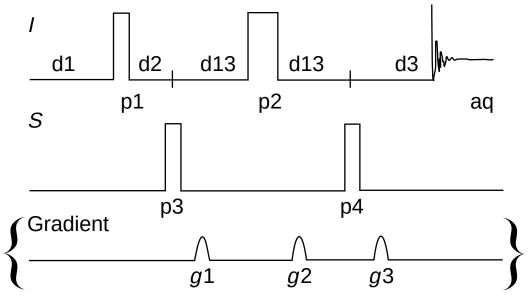

Figure 9 Gradient-accelerated 1D HMQC pulse sequence

HMQC experiment which can be run either as a gradient or nongradient experiment (Figure 9).[34]

3.2.1 Pulse Sequence

The I spins are first excited by p1 = 90° (Figure 9) and IS coupling allowed to develop during d2. p3 creates multiple quantum coherence. d13–p2–d13 allows a short delay for evolution and refocuses the I chemical shifts. The magnetization is converted back into observable magnetization by p4. Either phase cycling, or gradient selection can be used to cancel signals arising from molecules containing NMR silent ''S'' nuclei. d2 is set to select the desired IS spin coherences, normally d2 = $1/2J$, however, in systems in which I couples to more than one S spin this will result in distortions due to multiple S spin flips. The spin system should first be simulated to determine the optimum value of d2.[35] d3 is omitted in the nongradient version, and should be calculated by the pulse program in the gradient version. The recycle delay d1, is a compromise between relaxation of the I spin and experimental time.

Advantages

- It is straightforward to setup.
- Gradient selection or phase cycling removes signals from isolated I spins allowing the satellites resulting from coupling to S to be clearly seen in the spectrum of I.
- Multiplets are correctly phased.
- In principle only one scan is required although more scans may be necessary for weak samples.

Disadvantages

- The effect depends on $J(IS)$; it cannot preserve magnetization from all IS spin pairs if $J(IS)$ varies widely.
- The success of the experiment depends on reasonably accurate setting of d2, that is, $J(IS)$ must be known with reasonable accuracy.
- The signal intensity is modulated with offset, so in an extreme case, if more than one S spin is present, an unfortunate choice of offset may give zero intensity. This problem can be minimized by including a 180° S pulse to refocus S spin chemical shifts.[36]

Acquisition tips

- Use the pulse program, and phase cycling sequences supplied with your instrument. Make sure all necessary experimental parameters are set as described by the manufacturer.
- d2 = $1/2J(IS)$, if the I spin couples more or less equivalently to more than one S spin, try d2 = $1/4J(IS)$.
- Centre the resonances of interest in both spectral windows.
- Set the gradient ratios to obey.

$$g1(\gamma_I + \gamma_S) + g2(-\gamma_I + \gamma_S) + g3(-\gamma_I) = 0$$

Processing tips

- Process normally.

3.3 Selective Observation of Selected Spectral Regions

An alternative solution to the problem of selectively observing, for example, the ^{1}H NMR spectrum of a metal–hydride in protio-, rather than deutero-solvent is to excite just that region of the NMR spectrum that contains signals of interest. This can be done using a shaped soft pulse, using a DANTE (delays alternating with nutation for tailored excitation) type sequence or, on a modern

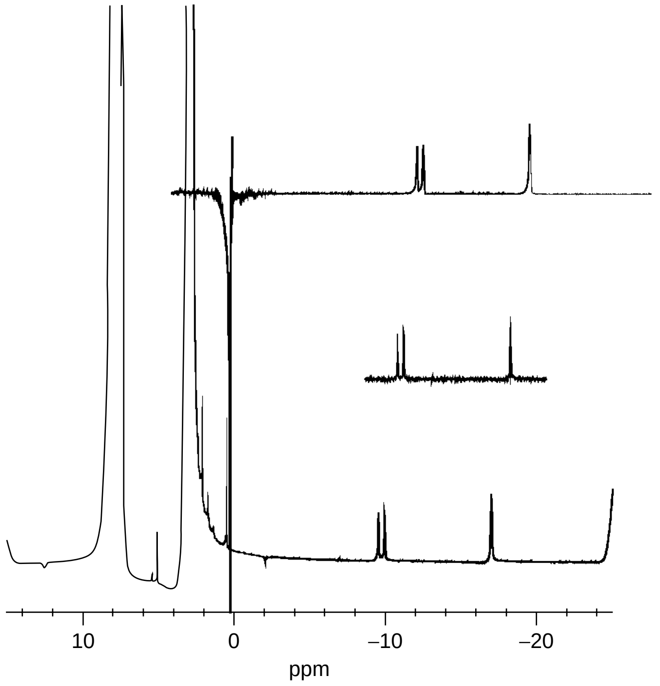

Figure 10 ^{1}H NMR spectrum of Wilkinson's hydride, $[Rh(H)_2(PPh_3)_3Cl]$, recorded in C_7H_8:CD_2Cl_2 (1:1) with: (bottom) no filtering, (middle) digital filtering, and (top) using a DANTE-Z pulse. Note the suppression of the solvent resonances. The distortions at the edges of the bottom spectrum are artefacts from digital filtration

spectrometer equipped with a digital filter, simply by selecting the region of interest. None of these methods use spin–spin coupling to edit the spectrum; this has the advantage that these methods can be applied to any resonance; the disadvantage is that they are not applicable to the selective observation of spin satellites. Figure 10 compares the ^{1}H NMR spectra of Wilkinson's hydride, $[Rh(H)_2(PPh_3)_3Cl]$, recorded with no filtering, with digital filtering and using a DANTE-Z pulse to excite selectively the hydride region of the spectrum.[37]

3.3.1 Pulse Sequence

The DANTE-Z excitation sequence $(\theta_{\phi 1} - \tau - \theta_{\phi 2} - \tau)_n$ uses a train of hard pulses and phase cycling to align the excited magnetisation along z, cf DANTE which aligns the magnetization at the selected tip angle (Figure 11). DANTE-Z, therefore, requires an additional read pulse. Do not use DANTE-Z in a saturation transfer experiment, Section 3.5.1, use the simple DANTE sequence.

Advantages

- It is straightforward to setup.
- The DANTE-Z sequence effectively suppresses the sinc oscillations that occur using the simple DANTE sequence or Gaussian pulses.

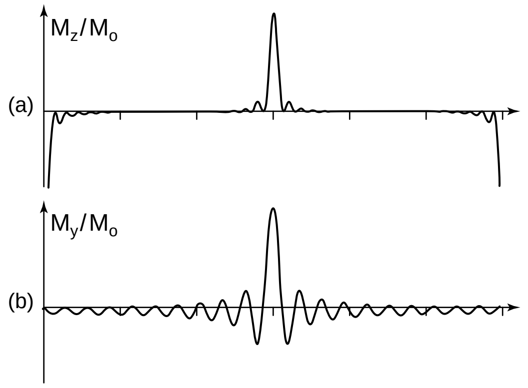

Figure 11 Excitation profiles for the DANTE-Z (top) and DANTE (bottom) pulse sequences. Note the almost complete suppression of the sinc oscillation using DANTE-Z excitation. (Reprinted from *J. Magn. Reson.*, **83**, Boudot, D.; Canet, D.; Brondeau, J.; Boubel, J. C., 'DANTE-Z—A New Approach for Accurate Frequency-Selectivity using Hard Pulses', 428–439. © 1989, with permission from Elsevier)

- DANTE pulse sequences do not require spectrometers equipped with shaped pulses.
- DANTE pulse sequences do not require spectrometers equipped with digital filtering.
- Spin–spin couplings are not used/required to select resonances.

Disadvantages

- It cannot be used to observe spin satellites selectively.

Acquisition tips

- Use the pulse program, and phase cycling sequences supplied with your instrument. Make sure all necessary experimental parameters are set as described by the manufacturer.
- Centre the resonances of interest in the spectral window.

Processing tips

- Process normally.

3.4 Indirect Detection of Insensitive Nuclei and Heteronuclear Correlation Spectroscopies in Solution

In many cases the inorganic chemist will be interested in the NMR spectrum of a nuclide of low sensitivity (denoted *S* or *indirectly detected* spin) in a compound containing a high-sensitivity nucleus (denoted *I* or *detector* spin). If scalar coupling exists between the two nuclides, then the 2D HMQC and HSQC techniques offer an alternative to direct observation.[34,38,39] The distinction between HMQC and HSQC is that *IS*-magnetization is stored as either multiple

(HMQC) or single (HSQC) quantum coherence during the t_1 evolution period. The sensitivity of any NMR experiment is proportional to the gyromagnetic ratios of the starting and the detected spins as $\gamma_{\text{start}}\gamma_{\text{detect}}^{3/2}$. For HMQC and HSQC-type experiments, $\gamma_{\text{start}} = \gamma_I$, $\gamma_{\text{detect}} = \gamma_I$, hence the sensitivity $\sim \gamma_I^{5/2}$ (*cf* a direct, polarization transfer experiment such as INEPT, $\gamma_{\text{start}} = \gamma_I$, $\gamma_{\text{detect}} = \gamma_S$, sensitivity $\sim \gamma_I\gamma_S^{3/2}$). Additionally, HSQC and HMQC provide a correlation map linking coupled sensitive and insensitive spins. However, the number of coupled sensitive spins is not directly available from the multiplicity patterns in the HSQC and HMQC spectra.

Notes:

1. The normal convention places the I spin on the x-axis and the indirectly detected S nucleus on the y-axis. The I dimension is referred to as $F2$, the S dimension as $F1$. This does not correspond to the channel labelling on Bruker spectrometers, f1 (observe channel), f2 (1st decoupler), f3 (2nd decoupler), etc.
2. Use of HMQC and HSQC for sensitivity enhancement is most appropriate where the detector has a high γ *relative to* the insensitive nuclide. HMQC/HSQC cannot compensate for low natural abundance of the insensitive spin since only the satellites from coupling to S are detected.
3. Isotopic enrichment can be used where a suitable detector has low natural abundance but is readily available in enriched form, for example, ^{13}CO in metal carbonyl clusters, or to boost the number of insensitivie spins, for example, ^{15}N.
4. The HSQC pulse sequence is longer than that of HMQC, thus is more affected by pulse errors and relaxation during the pulse sequence; HMQC is thus inherently more sensitive. However, passive coupling between detector spins is not present in F1 in HSQC spectra but is in HMQC. Therefore, if *II* coupling is present (e.g., coupling between protons, or ^{13}C, or ^{31}P being used as detector spins), the collapse of these multiplets into a singlet will compensate for the intrinsically lower sensitivity of the HSQC sequence.
5. The relaxation time of the I spins affects the signal intensity as $[1 - \exp(-D1/T_{1I}.)]$, where $D1$ is the recycle time. If the I spin has a very long T_1, for example, ^{13}C in a degassed sample, it has been suggested that addition of a relaxation agent may be beneficial. However, the presence of the relaxation agent will also increase dephasing of the desired multiple-quantum coherence during the pulse sequence. Care should therefore be taken when employing a relaxation agent.
6. Particular problems are encountered where the detector I couples to more than one S spin since the assembly of S spins can act as a unit. The result is false coherences relating the I spin to the sums or differences of the frequencies of the S spins and intensity distortions. In the worst case this can result in an HMQC spectrum in which only coherences resulting from ''multiple S spin transitions'' are seen. *None* of these transitions occur at the chemical shift of the S spin (Figure 12).[35]

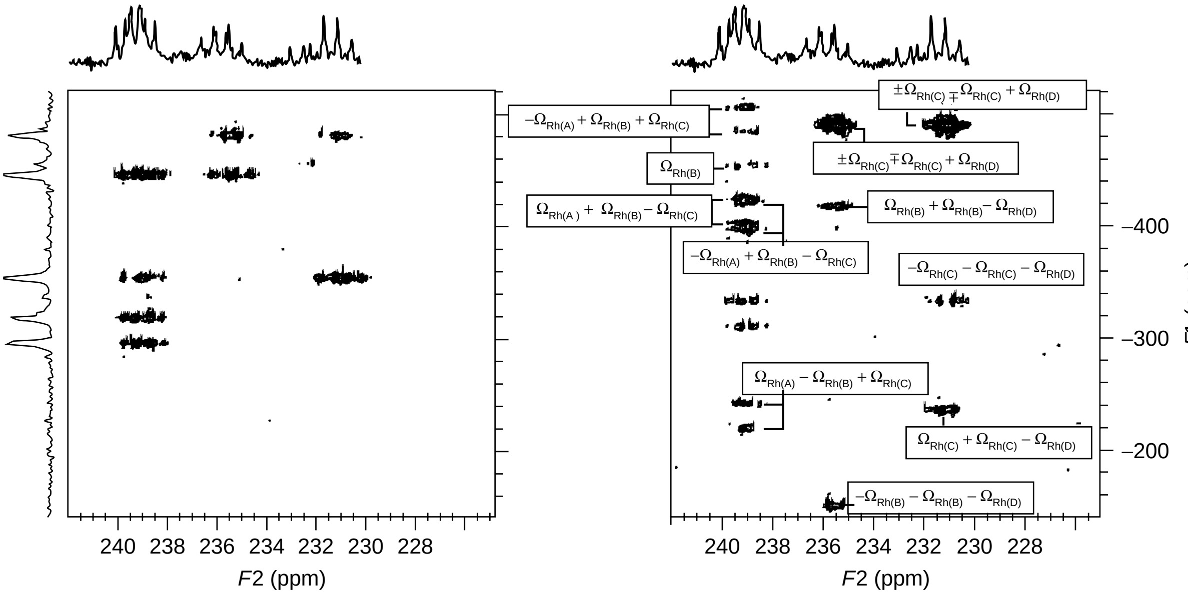

Figure 12 Using the conventional delay $d2 = 1/2J$ results in false coherences relating the I spin to the sums or differences of the frequencies of the S spins, and intensity distortions. In the worst case this can result in an HMQC spectrum in which only coherences resulting from ''multiple S spin transitions'' are seen. Inverse detected HMQC $^{13}C\{^{103}Rh\}$ NMR spectrum of $[Rh_6(CO)_{15}\{P(C_6H_4F)_3\}]$; left ''unconventional'' mixing time $= 1/(5J)$ gives ''single spin'' Rh transitions only, correlations appear at the correct δ_{Rh}; right, ''conventional'' mixing time $= 1/(2J)$, gives ''multiple Rh spin transitions''. Only ONE of these transitions occurs at a Rh chemical shift

Gradient Acceleration

It is debatable whether gradient acceleration offers any advantage in HMQC/HSQC spectroscopy.[40] The situation will be different for different *S* spins depending on the natural abundance. The decision to use gradient acceleration depends on sample concentration and may even be influenced by environmental factors. The final decision will depend on the following considerations:

1. In gradient-accelerated HMQC only one coherence pathway is selected, that is, *half* the signal intensity is *discarded*.
2. However, suppression of T_1 noise is much better in gradient spectroscopy.
3. Where the *S* nuclide is less than 100% abundant, breakthrough of signals from molecules containing NMR silent ''*S*'' nuclei is better suppressed by gradient selection.
4. Sensitivity improved gradient experiments are available, however, the increased length of the pulse sequences allows for dephasing of the desired magnetization. Therefore, the theoretical sensitivity enhancement is not always obtained. Furthermore, the sensitivity improvement is often restricted to a particular spin system (usually one *I* spin and one *S*).
5. T_1 noise problems are exacerbated by environmental factors such as sample vibration, sample spinning, building vibrations and temperature variations. Gradient selection seems better able to cope in such adverse situations—although the real solution is better control of the environmental disturbance.

Thus overall S/N may be better in the gradient-accelerated experiment, even though the signal is weaker. Paradoxically, therefore, it may be useful to use gradient acceleration to suppress the noise in the spectra if the indirectly observed spin has low natural abundance. Gradient acceleration also offers the possibility of acquiring HXQC spectra using a single scan per $F1$ increment on strong samples. Thus, for example, in favourable cases, ^{1}H-detected ^{15}N HMQC spectra, at natural abundance, can be recorded in ca. 15 min. In unfavourable cases, ^{31}P-detected, ^{195}Pt HMQC spectra can be markedly inferior to the nongradient spectrum.

The case for using phase cycle, rather than gradient, selection is:

1. In phase cycle selection both coherence pathways are selected, that is the signal intensity is *doubled.*
2. Many *S* nuclides have high natural abundance (^{89}Yb, ^{103}Rh, ^{109}Ag, etc.); suppression of signals from molecules containing NMR silent ''*S*'' nuclei is not an issue.
3. If the *intensity* of the desired signal is the limiting factor, then phase cycle selection is preferred. A phase cycle selection version of HMQC that uses a spin-lock to purge signals from molecules containing NMR silent ''*S*'' nuclei has been developed—poor man's gradient-heteronuclear multiple quantum coherence (PMG-HMQC). This allows acquisition of an HMQC spectrum of a strong sample using 1 or 2 scans per increment, that is, the same time saving as gradient selection.

Instrumental Considerations

HMQC spectra using ^{1}H as the detector (I) spin can be recorded on a conventional two-channel NMR spectrometer with a ''normal'' broad band, or selective dual, probe head. However, better signal-to-noise will be achieved using an inverse probe head due to the better filling factor.

For HMQC spectroscopy in which both the detector *I* and indirect *S* nuclei are ''heteronuclei'', a third spectrometer channel is required. An inverse broadband, triple resonance probe head in which the inner coil is tuned to ^{1}H, *I* and ^{2}D lock, and the outer coil is broadbanded is then the best option, particularly where a single *I* nuclide or ^{1}H will be used for detection. Such probe heads are ''stock items'' for some manufacturers (Bruker). Although it may be possible to build probe heads in which two channels are broadbanded, the lead time on such a probe head is likely to be long, and the performance markedly inferior due to the technical difficulties involved.

If gradient acceleration is to be used, a gradient unit in the spectrometer and gradient coils in the probe head are also necessary.

Phase Sensitive Detection

Phase-sensitive versions of the experiments below are available and afford Lorentzian lineshapes from which coupling constants can be determined reliably after phase correction.

Suggested HMQC Experiments

1. The Basic HMQC Experiment
   This is recommended for the inexperienced user—all that is needed if the insensitive nucleus has high abundance.
2. PMG-HMQC
   This is highly recommended by Berger and Braun for nongradient HMQC and is useful when large (kHz) coupling constants result in ''negative'' gradient delays.
3. Gradient-selected HMQC/HSQC with GARP decoupling, see discussion earlier.

3.4.1 *The Basic HMQC Experiment*

The basic HMQC pulse sequence (Figure 13) is the shortest, simplest HMQC experiment and gives the best sensitivity. It is used both to determine the chemical shifts of an insensitive nuclide (spin *S*) coupled to a nuclide of higher sensitivity (spin *I*) and to correlate the coupled pairs of *I* and *S* spins. The experiment is not phase sensitive hence lineshapes are not Lorentzian and coupling constants cannot

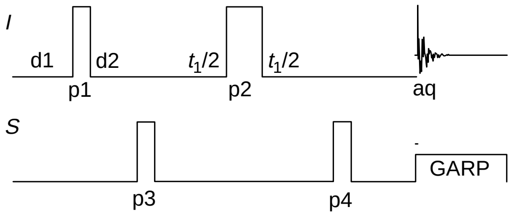

Figure 13 Basic HMQC pulse sequence

be measured accurately. Use this for samples in which the insensitive nuclide *S* has *high* natural abundance.

Pulse Sequence. The *I* spins are first excited by $p1 = 90°$ (Figure 13) and *IS* coupling allowed to develop during d2. The magnetization is then converted to multiple-quantum coherences by p3 and stored while the $t_1/2$ incrementing delays create the second dimension. The magnetization is converted back into observable magnetization by p4; p2 refocuses the *I* chemical shifts removing them from the second dimension. Phase cycling is used to cancel signals arising from molecules containing NMR silent ''*S*'' nuclei. d2 is set to select the desired *IS* spin coherences, normally $d2 = 1/2J$. However, in systems in which *I* couples to more than one *S* spin, this will result in distortions due to multiple *S* spin flips. The spin system should first be simulated to determine the optimum value of d2.[35] The recycle delay d1, is a compromise between relaxation of the *I* spins and experimental time.

Advantages

- The sequence is simple to implement, little can go wrong.
- The short pulse sequence minimizes relaxation during the active part of the sequence.
- The sequence gives the strongest signal.
- Couplings to third nuclei appear in both dimensions and couplings between *I* and *S* spins occur only in $F2$.
- The correlations of interest flank the T_1 noise and breakthrough signals.

Disadvantages

- T_1 noise and breakthrough of signals from molecules containing NMR silent ''*S*'' nuclei can be problematic.

Acquisition tips

- Use the pulse program, and phase cycling sequences supplied with your instrument. Make sure all necessary experimental parameters, for example, number of transients per increment, number of variable delays in the pulse sequence, are set as described by the manufacturer.
- Measure J(IS) via the 1D HMQC experiment in Section 3.4.1 given earlier.
- The *minimum* number of transients per increment is defined by the phase cycle. The total number of transients per scan must be an integral multiple of this.
- You can inspect your spectrum at any time after two increments have been recorded; there is no need to acquire all increments before transforming the data. Thus a quick check to see all is well is recommended. Note, however, that resolution and S/N improve dramatically as more increments are completed.
- Run a quick series of experiments to locate the resonances of interest, then reduce the sweep width in $F1$. It may be quicker to record several spectra, with narrow sweep width, than attempt to include several resonances with widely varying chemical shifts in a single experiment.
- It is always better to record more data points in $F2$ than to zero-fill this dimension afterwards during processing.
- For samples containing more than one *S* spin, first simulate the spectrum to determine if multiple *S* spin transitions need to be eliminated (Figure 14).[35]
- If decoupling of *S* is needed in $F2$ then add a delay d2 after p4 and use GARP decoupling. A filter to block the $F1$ decoupling irradiation is essential in the lock channel.
- If *I* is not ^{1}H, then ^{1}H decoupling can be applied either throughout the pulse sequence or just during acquisition.
- A BIRD filter (bilinear rotation decoupling) can be used to suppress signals from molecules containing NMR silent ''*S*'' nuclei when the insensitive nuclide *S* has *low* natural abundance.

The BIRD Filter.

Pulse Sequence

The BIRD filter[41] is a selective T_1 filter, removing signals from molecules containing NMR silent ''*S*'' nuclei (Figure 15). *I* spin magnetization from molecules containing *I* coupled to *S* evolves under scalar coupling and experiences both 180° pulses p2 and p6. p2 refocuses the chemical shifts and p6 interchanges the *S* spin labels in the *I* multiplets. Thus, when $d2 = 1/2J$, magnetisation from *IS* coupled spins is refocused along $-y$. p3 rotates this magnetization to $+z$. *I* spin magnetization from molecules containing NMR *silent* ''*S*'' nuclei does not evolve under *IS* coupling and does not experience p6. As a result, it is refocused along $+y$ by the 180° pulse p2. p3 rotates this magnetization to the $-z$ axis. During d3, T_1 relaxation of the $-z$ magnetization occurs, d3 is set so that this magnetization is at the zero crossing point before proceeding to the HMQC sequence. p7 removes artefacts.

The HMQC Sequence

This is as in the previous experiment, but an additional delay d2 is included after the last *S* spin pulse (p9) to refocus *IS* spin coupling and allow GARP decoupling.[42]

Advantages

- BIRD filter helps to remove signals from molecules containing NMR silent ''*S*'' nuclei, essential if decoupling

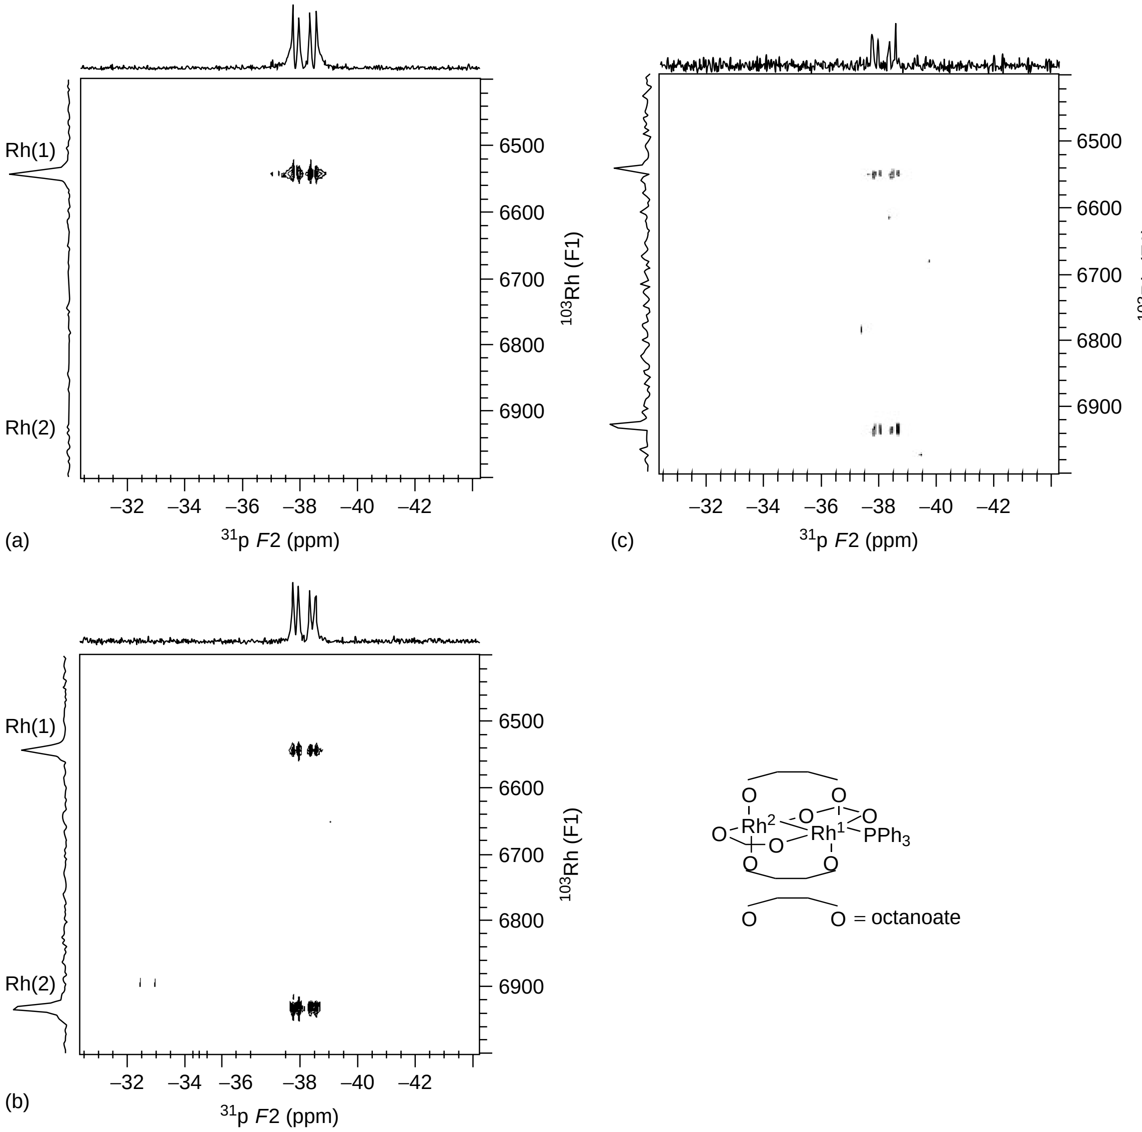

Figure 14 ^{31}P,^{103}Rh HMQC spectrum of [Rh_2(μ-octanoate)$_4$(PPh_3)] in $CDCl_3$ at 295 K recorded with (a) d2 = 1/(2.^2J(RhP) = 5.2 ms, note the *absence* of a correlation between P and Rh(2) and the *presence* of a correlation between P and Rh(1); (b) d2 = 7.7 msec a delay calculated to optimize the experiment to observe correlations to *both* Rh(1) and Rh(2); (c) d2 = 1/2.^2J(RhP) = 14.7 ms, the conventional delay to optimize correlations to Rh(2). Contours in each spectrum drawn at the same levels

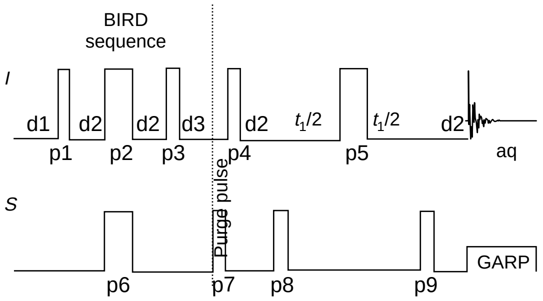

Figure 15 HMQC pulse sequence incorporating a BIRD filter to suppress magnetization from molecules containing NMR *silent* ''*S*'' nuclei

is to be applied in $F2$ since the desired signals would otherwise be overlaid by breakthrough signals.

Disadvantages

- Setup is more complex.
- Longer pulse sequence results in increased relaxation during the active part of the sequence.
- T_1 noise is not suppressed and suppression of breakthrough signals is not 100% effective.
- Very long relaxation delays can be required to achieve good results with inorganic samples having long T_1s—in which case consider the poor man's gradient (PMG) experiment in Section 3.4.2, instead.

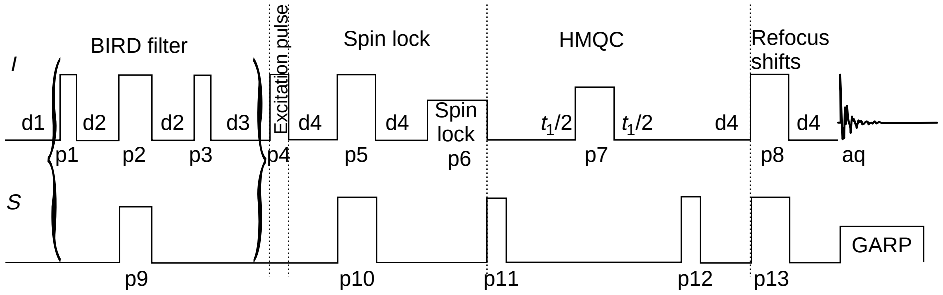

Figure 16 ''Poor Man's Gradient'' version of the HMQC sequence

Acquisition and processing tips

- d3 is most easily set using a simple 1D inversion recovery experiment. Usually the sample will be strong enough to observe a spectrum with a single scan. Inspect the spectrum and vary d3 until the intensity is *minimized*.

Processing tips

- Zero-fill in $F1$, truncate in $F2$.
- Exponentially multiply in $F2$, use a shifted sine bell in $F1$.
- Forward linear prediction can be applied in $F1$ but may give artefacts and degrades the signal-to-noise.
- Spectra are not phase sensitive, transform in magnitude mode, do not phase correct.
- Passive, I spin homonuclear couplings appear in $F1$.
- The behaviour of foldback in $F1$ is not easily predicted.

3.4.2 Phase-Sensitive PMG-HMQC

This variant uses a spin-locking pulse to suppress signals from molecules containing NMR silent ''S'' nuclei. A BIRD filter can be added to achieve excellent suppression of these unwanted signals. GARP decoupling of S and WALTZ decoupling of ^{1}H (if $I \neq {}^1$H) can be added to improve signal-to-noise by removing *IS* and $I-{}^1$H couplings.[43,44] This type of spin-lock sequence has been dubbed the PMG since it gives almost as good suppression, from almost as few scans, as gradient selection but without the need for a gradient equipped spectrometer. However, the full benefit is rarely obtained since the pulse sequence is longer, so more dephasing of the desired magnetization during the pulse sequence occurs (Figure 16). HMQC sequences with the BIRD filter but without the spin lock are available, see Experiment 3.4.1. Phase-sensitive acquisition gives Lorentzian lineshapes allowing coupling constants to be measured accurately. Use this for samples in which the insensitive nuclide S has *low* natural abundance, or for very strong samples when 2 transients per increment will give a good spectrum. Do not use if relaxation times are short.

Pulse Sequence. Figure 16 illustrates the pulse sequence for PMG-HMQC.

The BIRD Filter. The BIRD filter is optional (see Experiment 3.4.1). If used, d3 is set so that the undesired magnetization from molecules containing NMR silent ''S'' is at the zero crossing point before proceeding to the spin-lock sequence. d2 $= 1/2J(IS)$ (Figure 16).

The Spin Lock. p4 excites the I spin magnetization that survives the BIRD filter. I spin magnetization from molecules containing NMR *silent* ''S'' nuclei does *not* evolve under *IS* coupling and does *not* experience p10, so is refocused along $+y$ by the 180° pulse p5. I spin magnetization from molecules containing I coupled to S *does* evolve under scalar coupling and so experiences both 180° pulses p5 and p10. p5 refocuses the chemical shifts and p10 interchanges the S spin labels in the I multiplets. Thus, when d4 $= 1/4J$, magnetization from *IS* coupled spins is aligned along $+/-x$. A spin-lock pulse (with phase x) preserves this magnetization while that of isolated I spins is dephased. Two types of spin-locking pulse have been advocated in the literature, a soft long pulse, p3 around 10 ms at 20 dB attenuation or a hard pulse, p3 $=$ 2 ms, at 3 dB attenuation. p4, d4 p5, d4 p6 and p10 replace p1, d2 in Experiment 3.4.1, thus, d4 $=$ d2$/2 = 1/4J$, but see comment on multiple S spin systems above.

The HMQC sequence is as in the previous experiments but is extended with 180° pulses and delays to refocus the chemical shifts.

Advantages

- The spin lock removes signals from isolated I spins. Suppression of unwanted signals can approach that of gradient selection.
- GARP decoupling can be used to improve the signal-to-noise ratio by collapsing $J(IS)$ in $F2$.
- Only two scans per transient are required (Figure 17).

Disadvantages

- This is a more complex setup.
- Much longer pulse sequence results in increased relaxation during the active part of the sequence.

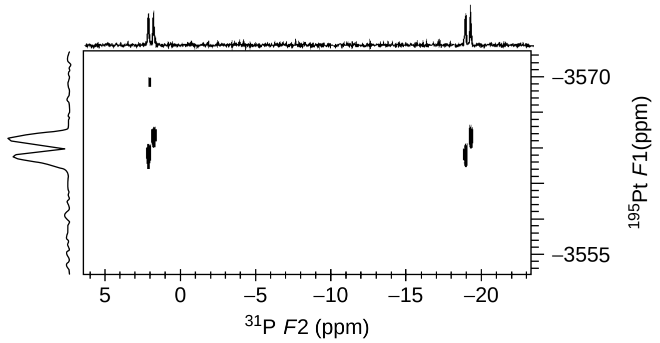

Figure 17 Phase sensitive ^{31}P,$^{195}Pt\{^1H\}$ PMG-HMQC spectrum of [Pt($C_5H_5{}^{15}N$)(PPh_3) Cl_2] in THF at 295 K. A standard gradient experiment could not be used due to the large ^1J(P–Pt). NS = 2, spin-lock pulse duration 5900 µs, 14 dB attenuation, total acquisition time 15 min. Further reductions in experiment time, or improved resolution in $F1$ could be achieved by using a smaller spectral width in the ^{195}Pt dimension. SW = 125 ppm, with 128 increments was used here. Compare the signal-to-noise achieved in the ^{195}Pt spectrum with that in Section 3.1

Acquisition tips

- See Basic HMQC sequence (Experiment in Section 3.4.1).
- A filter to block the $F1$ decoupling irradiation is essential in the lock channel.
- d3 is most easily set using a simple 1D inversion recovery experiment (Experiment in Section 3.4.1).
- Use the pulse program, and phase cycling sequences supplied with your instrument. Make sure all necessary experimental parameters are set as described by the manufacturer.
- Make sure the correct phase sensitive type is selected as indicated in the manufacturers documentation (time proportional phase increment (TPPI)).
- The spin-locking pulse is traditionally set at 10 ms with typically 20 dB attenuation; more recently 2 ms at 3 dB attenuation has been used. The best values will be spectrometer, probe, and nucleus dependent and must be found by experiment. Be careful not to use so much power that the probe breaks down.

Processing tips

- See Basic HMQC sequence (Experiment in Section 3.4.1).
- The spectra are phase sensitive; use the transformation protocol recommended by the instrument manufacturer. Do not use magnitude calculation.
- Spectra must be phase corrected in both dimensions—all peaks positive.
- Passive, I spin homonuclear couplings appear in $F1$.

3.4.3 Gradient-Accelerated HMQC and HSQC

Gradient acceleration of HMQC and HSQC sequences reduces the sensitivity but can be advantageous if strong samples are used.

Pulse Sequences. The HMQC sequence is the same as the basic experiment but includes an additional delay (d3) after the last S spin pulse (p4) for refocusing of IS spin coupling to allow GARP decoupling (Figure 18). Gradients, not phase cycling, are used to select the desired coherences so a single transient per increment can be used.

The HSQC sequence (Figure 18) is built around two INEPT transfers (Experiment in Section. 2.1). The first generates a single-quantum coherence $-2I_{Iz}I_{Sy}$. During t_1, which creates the second time dimension, the S chemical shifts evolve. The second INEPT sequence transfers the magnetization back to I. During d2, observable proton magnetization modulated by the S chemical shifts develops. The 180° I pulse p4 eliminates $I-S$ couplings in $F1$.

Choice of Pulse Sequence. Many variants of these basic pulse sequences exist. HMQC sequences are often preferred in studies of low-γ metal nuclei, while HSQC sequences are preferred by authors interested in ^{15}N. The present authors' experience is in line with these ''prejudices''. We have found versions incorporating adiabatic decoupling of third nuclei (e.g., ^1H,^{15}N HSQC with adiabatic decoupling of ^{31}P) particularly useful (Figure 19).

Advantages

- Gradient selection removes signals from isolated I spins and $T1$ noise from the spectra.

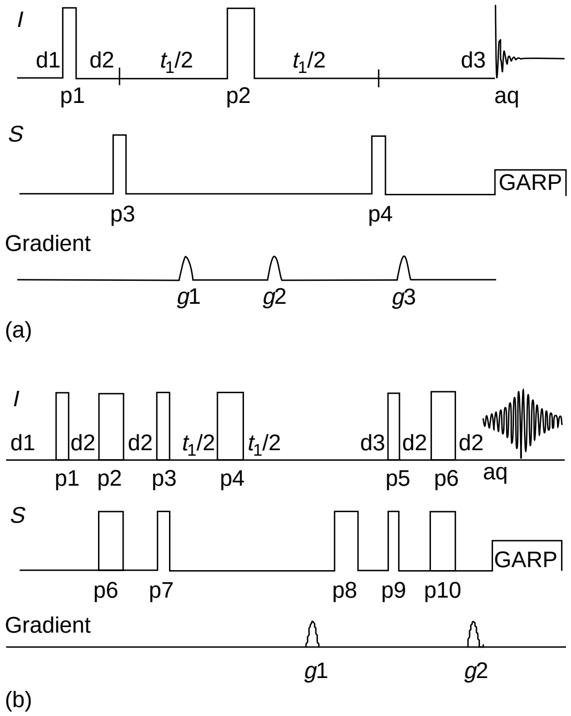

Figure 18 Gradient-accelerated HMQC (a) and HSQC (b) pulse sequences

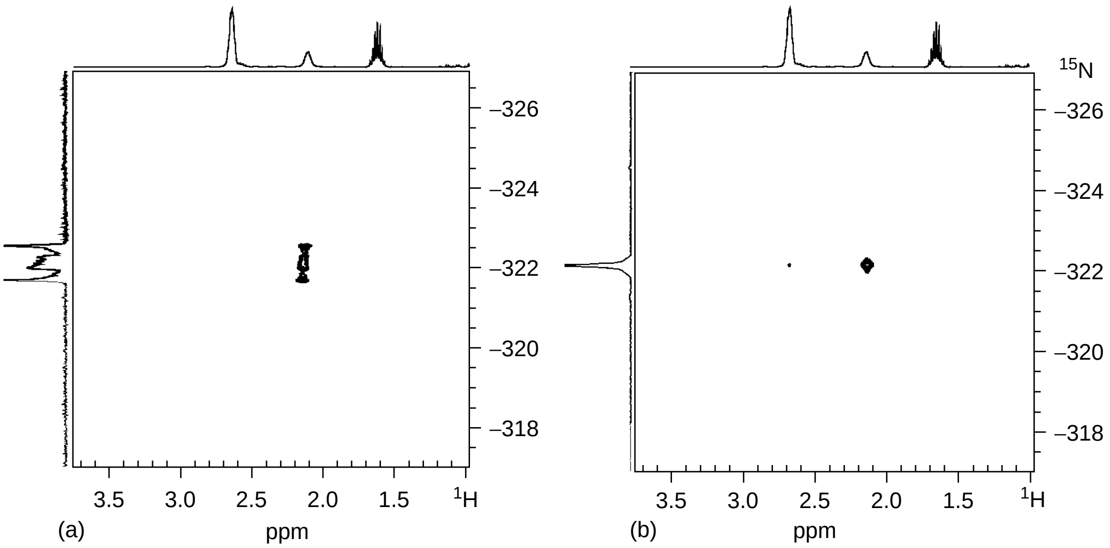

Figure 19 ^{1}H,^{15}N{^{15}N} HSQC spectra of $[(N_3(P(Bu^i)_2)_3]$ in $CDCl_3$ at 295 K recorded without (a) and with (b) CHIRP60 adiabatic ^{31}P decoupling pulse. Bruker pulse program hsqcetf3gpsi2

- GARP decoupling improves the signal-to-noise ratio.
- Only two scans per transient are required for phase-sensitive spectra, one for magnitude data.
- Passive couplings are not present in HSQC.

Disadvantages

- Only one coherence pathway is selected resulting in a 50% loss of signal intensity. Sensitivity improved versions restore some of this loss at the expense of a longer pulse sequence.

Acquisition tips

- Use HSQC if passive coupling between I spins is present.
- Use the pulse program, and phase cycling sequences supplied with your instrument. Make sure all necessary experimental parameters are set as described by the manufacturer.
- Modern spectrometers should have routines for calculating the gradient ratios correctly.

  For HMQC set $g1$, $g2$, and $g3$ to satisfy

$$g1(\gamma_I + \gamma_S) + g2(-\gamma_I + \gamma_S) + g3(-\gamma_I) = 0$$

  For HSQC set $g1$ and $g2$ to satisfy

$$g1(\gamma_S) - g2(\gamma_I) = 0$$

- For HMQC the number of scans per increment must be a multiple of 2.
- For HSQC use at least 16 dummy scans, some authors additionally recommend DS = 2* NS.
- For HMQC, d2 $= 1/(2J)$, for HSQC, d2 $= 1/(4J)$. d3 positions the pulses following the gradient pulse correctly and is normally calculated by the pulse program.

Processing tips

- See Basic HMQC sequence (Experiment in Section 3.4.1).
- If phase-sensitive acquisition is used, phase all peaks positive.

3.5 Dynamic NMR Spectroscopy

The use of variable temperature to study dynamic systems is well documented, however, a few comments on the accuracy, or not, of temperature calibration, and some guidance on simulation of variable temperature (VT) spectra might be helpful.

Calibration of the VT unit

1. If the probe thermocouple is intended to be user removable, first check that it reports the correct temperature by removing the thermocouple from the probe and recording the temperatures reported for liquid nitrogen, melting ice, and boiling water.
2. Next check the temperature reported for a sample in the probe; two strategies are possible:
   (a) Prepare a dummy sample containing some suitable solvent. Push a *calibrated*, nonmagnetic thermocouple through the NMR tube cap. Place the sample/thermocouple assembly into the magnet and record the sample temperature reported by the spectrometer VT unit and the calibration thermocouple.

Plot a temperature correction graph. Your spectrometer may have routines to make this correction in the spectrometer's software.

(b) The temperature dependence of the chemical shift difference $\Delta\delta$ between the CH_3 and OH protons of anhydrous methanol is known. Thus, by recording the ^{1}H NMR spectrum of anhydrous methanol at several temperatures a calibration curve can be plotted. Berger and Braun (see Section 5) give the following relations:

$$T[\mathrm{K}] = -114.83\Delta\delta + 471.85 \quad 1.4965 < \Delta\delta < 1.75999$$

$$T[\mathrm{K}] = -125\Delta\delta + 490 \quad 1.76 < \Delta\delta < 2.07999$$

$$T[\mathrm{K}] = -140\Delta\delta + 521.33 \quad 2.08 < \Delta\delta < 2.43$$

The recorded and actual temperatures of the sample should be within 1–2 K. This systematic error should be borne in mind when reporting, for example, reactions rates, and thermodynamic parameters.

For high temperature calibrations, Berger and Braun recommend 1,2-ethanediol.

Simulation of spectra

Band-shape analysis can be a powerful mechanistic tool, affording exchange rates, from which activation parameters can be derived via Arrhenius and/or Eyring plots. Thus, possible exchange/reaction mechanisms can be distinguished. Care, however, is needed since:

- Near the slow- and fast-exchange limits, other factors will contribute significantly to the line width; rate constants determined near these limits will be inaccurate.
- Chemical shifts can be temperature dependent. Although it is possible to fit both the chemical shifts and the rate constants simultaneously, the two will be correlated.
- Coupling constants are less temperature dependent and should be fixed at the values measured from the slow-exchange limiting spectrum.
- Small amounts of impurities may have a large effect on reaction rates and may provide additional exchange pathways.
- Minor species which cannot be directly observed due to their low concentration may affect the behaviour of the major species, resulting in spectra that are difficult to interpret.
- Band-shape analysis gives ''pseudo-first-order rate constants''; a good kinetic model for the proposed dynamic processes is also required to relate these ''pseudo-first-order rate constants'' to what is happening chemically.
- The presence of more than one dynamic process can only be proved by a difference in computed rate constants. However, the errors in the rate constants are always large. NB: It is important to realize that a difference in coalescence temperatures does not imply a difference in rate constants.

Several packages are available in addition to the instrument manufacturer offerings, for example, gNMR, http://home.cc.umanitoba.ca/~budzelaa/gNMR/gNMR.html. Follow the instructions and remember that sample concentration is important. Once the rate constants have been extracted, the thermodynamic parameters of activation can be obtained via an Eyring plot.

3.5.1 *Saturation Transfer Exchange Spectroscopy*

If the dynamic process is too slow to allow study by conventional variable temperature methods, then saturation transfer can be used to study the exchange.[45] Two selective, 1D strategies are useful:

Selective Inversion Using a DANTE Pulse.

Pulse sequences

The DANTE pulse sequence is shown in Figure 20b. A peak that is exactly on-resonance or an integral multiple of 1/d2 Hz off-resonance, experiences the cumulative effect of the n p1 pulses. Other resonances see a random excitation that effectively sums to zero. In exchange experiments, a variable delay (vd) is inserted between the end of the DANTE pulse train and the read pulse, p2. During vd, magnetization is transferred between exchanging sites.

Acquisition tips

- Use the DANTE sequence provided by your instrument manufacturer.
- Choose d2 such that sideband excitation (which occurs at integral multiples of 1/d2), does not interfere with other resonances in the spectrum. When the variable delay is very short, the inverted resonance appears in emission and all other signals should be in absorption.
- Choose n and p1 such that $n^*\mathrm{p1} = 90°$ pulse. The selectivity is approximately $1/(n^*\mathrm{d2})$.
- p1 is typically 1 μs, attenuate the pulse power if necessary.
- Set the peak to be inverted exactly on-resonance.

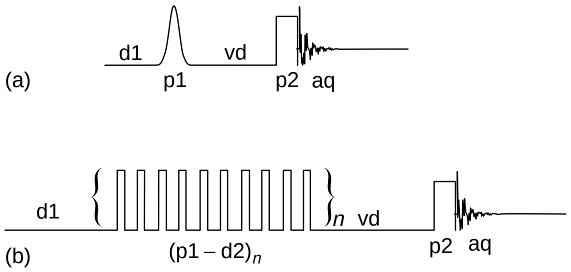

Figure 20 Saturation transfer experiment using: (a) Selective inversion by a shaped pulse; or (b) a DANTE pulse sequence. Do not use the DANTE-Z sequence, Section 3.3, in saturation transfer experiments

- d1, the recovery delay, must be ca. 5–10 T_1. An inadequate relaxation delay will give spurious results.
- p2 is a 90° read pulse.
- vd is a variable delay during which exchange can occur. By acquiring spectra with different values of vd, the exchange rate can be obtained.

Advantages

- DANTE is highly selective; it can be used in crowded regions of the spectrum.
- Appropriate for instruments that do not have shaped pulses.

Disadvantages

- Care must be taken in setup—watch out for excitation side bands.
- Quantitative treatment requires knowledge of the T_1 relaxation times.

Selective Inversion Using a Shaped Pulse. Gaussian shaped pulses[46] are designed to excite only a narrow frequency range. Various shaped pulses intended for refocusing, inversion or 90° excitation are now available as routine experiments on modern spectrometers. The width of the excited region is set by the pulse length and the pulse power adjusted to achieve the desired flip angle.

Pulse sequence and acquisition tips

- p1 (Figure 20a) is typically a 50 ms, Gaussian inversion pulse. It is usually sufficient to use the routines supplied with the spectrometer to calculate the required attenuation. (Choose the pulse length to achieve the desired selectivity, for Gaussian pulses *longer* pulses are *more* selective, and adjust the pulse power to suit.)
- d1 must be ca. 5–10 T_1. An inadequate relaxation delay will give spurious results.
- p2 is the read pulse.
- vd is a variable delay during which exchange can occur. By acquiring spectra with different values of vd, the exchange rate can be obtained.

Advantages and disadvantages

- Not as selective inversion as using DANTE.
- Appropriate for instruments that have shaped pulses.

Processing tips

- Use ca. 2 Hz exponential multiplication.
- For accurate integrations, zero-fill the FIDs, baseline correct the spectra, and correct the slope and bias of the integrals individually.
- When the vd is very short, the inverted resonance appears in emission and all other signals in absorption (Figure 21). As the vd increases, chemical exchange leads to the inverted magnetisation being partially transferred to other sites. At the same time spin-lattice relaxation is taking place. Therefore, a biexponential recovery is observed; for the inverted resonance the two exponentials have the same sign, while the exponentials have opposite signs for resonances involved in exchange with the inverted site. For simple two-site exchanges, a quasi spin-lattice relaxation time, T_1, is obtained by plotting $\ln(\Sigma(I_o) - \Sigma(I_{vd}))$ *versus* vd, the vd time, where $\Sigma(I_o)$ is the summed equilibrium intensity of the irradiated resonance and its exchange partner and $\Sigma(I_{vd})$ the summed intensity at time vd. T_1 is the inverse of the slope of the line. The rate constant for exchange is then obtained by plotting $\ln(I_{Ir} - I_{Ex})$ *versus* vd, where I_{Ir} is the intensity of the irradiated resonance and I_{Ex} that of the resonance of the exchanging site at time vd. The slope of the line is $(2k + 1/T_1)$. The procedure assumes that the spin-lattice relaxation time is identical at the two sites. See Akitt and Mann for more details.[47]

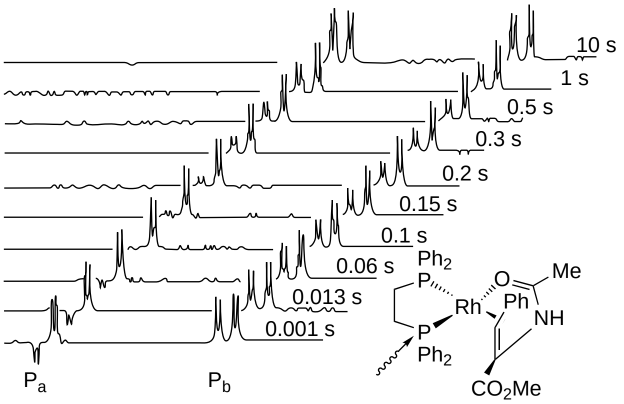

Figure 21 Saturation transfer experiment; the downfield branch of the P_a doublet of 1 was inverted using a DANTE selective excitation pulse. The exchange of the magnetization was followed as a function of mixing time. T_1 was found to be 1.26 s and $k_{exchange} = 2.85\,s^{-1}$ at 300 K. (From J. M. Brown, and P. A. Chaloner and G. A. Morris (1987) *J. Chem. Soc. Perkin Trans. 2*, 1583. Reproduced by permission of The Royal Society of Chemistry)

3.5.2 *EXSY Spectroscopy*

Exchange spectroscopy (EXSY) is a two-dimensional method that can detect chemical exchange and fluxional processes *before* line broadening occurs (Figure 22).[49,50]

Pulse Sequence. The pulse sequence (Figure 23) is identical to that for phase sensitive, nuclear overhauser effect spectroscopy NOESY). The first pulse tips the magentization into the *xy* plane. This is coded with the chemical shift information during the incrementing delay t_1. The second pulse tips the coded magnetization into the $-z$ direction. Exchange occurs during the delay d2. p3 is a read pulse. Phase cycling is used to suppress unwanted COSY signals and the axial peaks.

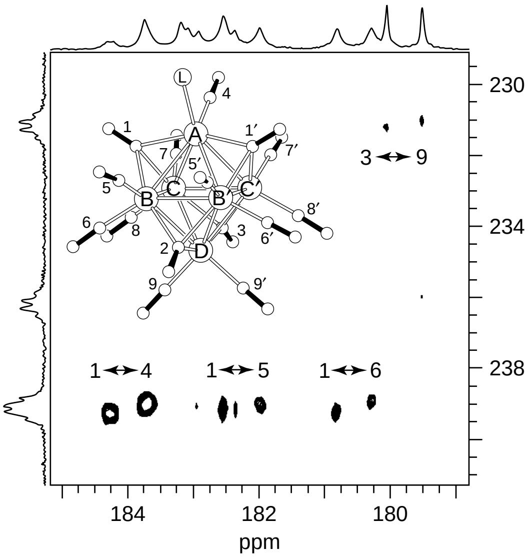

Figure 22 ^{13}C EXSY spectrum showing stereospecific exchange correlations between bridging and terminal carbonyls in $[Rh_6(CO)_{15}\{P(4\text{-}(MeO)C_6H_4)_3\}]$, in $CDCl_3$ at 274 K; $\tau_{mix} = 0.02$ s

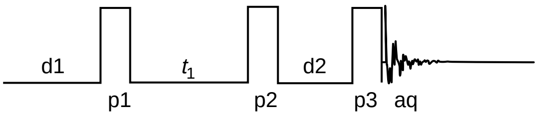

Figure 23 EXSY pulse sequence

Advantages

- Complex exchange networks, for example, CO fluxionality in a metal carbonyl cluster, can be readily mapped.
- EXSY peaks are very strong, and are unlikely to be confused with NOESY peaks.
- A gradient version is available. EXSY and diagonal peaks are positive, NOESY peaks negative—use the gradient-accelerated NOESY sequence supplied with your instrument.

Disadvantages

- Rates are not readily extracted from the spectra.[51]
- A zero result may reflect the experimental conditions chosen, rather than no exchange.
- The nongradient version is relatively time consuming due to the need for phase cycling.

Acquisition tips

- Use the pulse program, and phase cycling sequences supplied with your instrument. Make sure all necessary experimental parameters are set as described by the manufacturer.
- Record the spectrum in phase sensitive mode using TPPI.
- d2 is mixing time, ideally.

$$d2 = \frac{1}{(T_1^{-1} + k_{AB} + k_{BA})}$$

However, since the rates are usually not known, d2 must be set by trial and error; try 0.5–1 s.

- If several exchange processes, with different rates, are occurring, several values of d2 will be needed.

Processing tips

- Zero-fill in $F1$, truncate in $F2$ to obtain a (roughly) square matrix.
- Exponentially multiply in $F2$, use a shifted sine bell in $F1$.
- The spectra are phase sensitive, so apply real Fourier Transformation with TPPI.

3.5.3 Gradient Accelerated HOESY Spectroscopy

Heteronuclear overhauser effect spectroscopy (HOESY) is the heteronuclear equivalent of NOESY. It is useful when scalar coupling information is unhelpful or not available.[52] It is also useful in determining the relative dispositions of the cation and anion in solutions of organometallic salts, where the anion is fluorinated. Several excellent reviews have appeared recently.[53–56] HOESY can provide valuable information about cation–anion interactions, especially in systems for which both the anion and cation contain NMR-active nuclei of high receptivity (e.g., ^{1}H or ^{19}F), and several magnetically distinct nuclei are present in each ion, so that different anion–cation orientations can be distinguished (Figure 24). Overhauser enhancements decrease rapidly with increasing separation of the nuclei, however, this is not usually a limitation since, most often, we are interested in studying systems in which ion pairing affects the reactivity. For this to be the case, a proportion of intimate ion pairs, albeit transient in nature, must be present. Quantitative analysis requires a reference distance. Inevitably, this will be an *intra*molecula*r* distance in the anion or cation, however, the contacts we want to measure will be *inter*ionic distances, between sites on the cation and anion. The reference nuclei should have the same correlation time as the pair of nuclei of interest, thus, if accurate interionic distances are to be obtained, the correlation times must also be checked. The anion–cation distances obtained will be average values reflecting the transient nature of an ion pair, rotation of, or within, the ion pair, and internal motions. In practice, the distances obtained are usually accurate to about 10%.[57] Both gradient and nongradient versions are useful. Here the gradient-accelerated version is described (Figure 25).

Pulse Sequence. The S spins are excited by p3 and evolve under the chemical shift during t_1. p1 refocuses IS coupling and creates $-I_z$ magnetization. p4 flips the

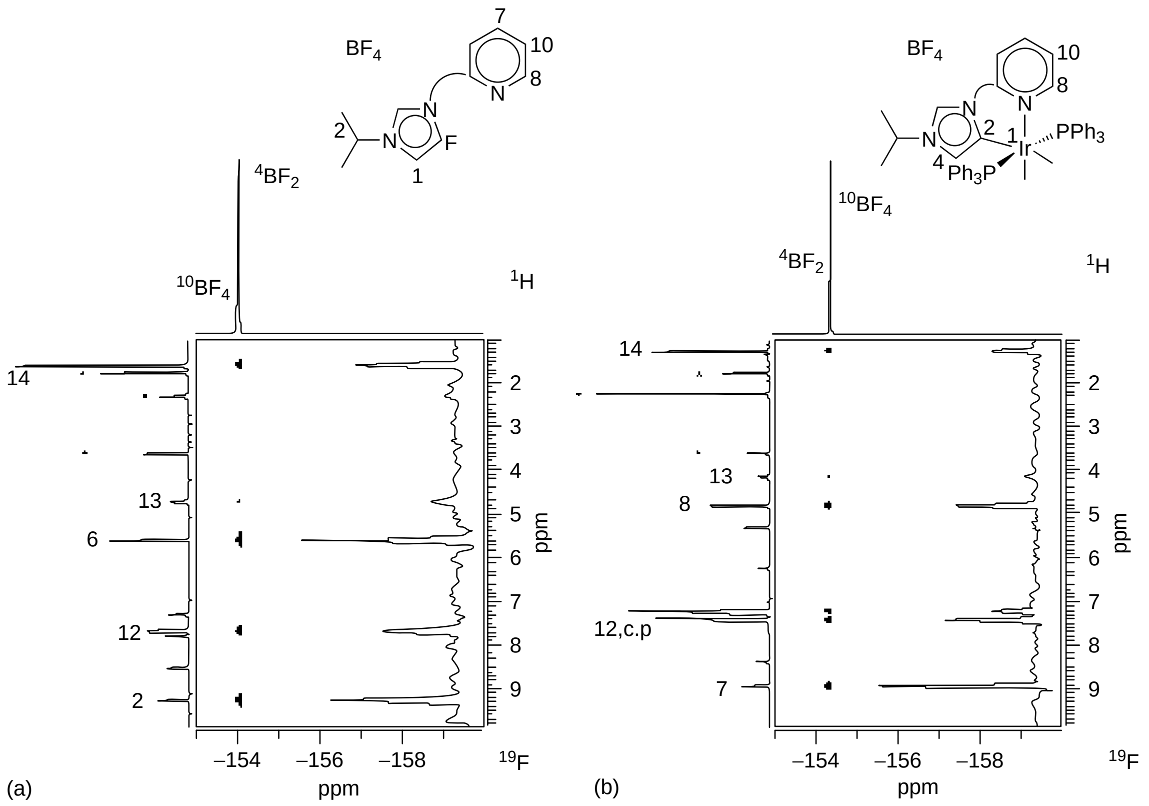

Figure 24 ^{19}F,^{1}H-HOESY NMR spectra (376.65 MHz, 323 K, THF-d_8) of (a) and (b) showing the selective interactions of the anion with the indicated protons. ''*'' THF and water resonances. (Reprinted with permission from L. N. Appelhans, *et al.* (2005) *J. Amer. Chem. Soc.* **127**: 16299–16311. © 2005 American Chemical Society)

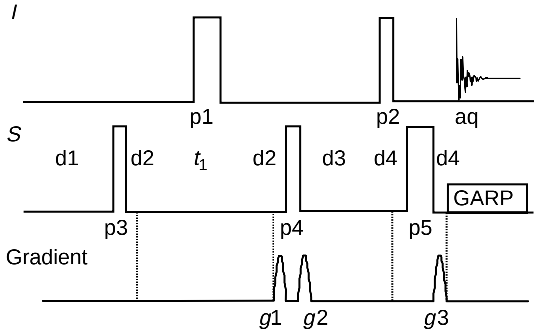

Figure 25 Pulse sequence for gradient-accelerated version HOESY

S magnetization, which now contains its chemical shift information, to $-z$ as well. Cross relaxation occurs during d3 + d4 giving a heteronuclear nOe. Gradient $g1$ causes dephasing during t_1, with the factor $g1\gamma_S$. p2 generates $-I_y$ magnetization which is refocused by $g3$ when $g1\gamma_S = g3\gamma_I$. $g2$ dephases any ''left-over'' transfer magnetization.

Advantages

- Considerable time savings result from inverse detection and gradient selection.
- Only one scan per transient is required.

Disadvantages

- Problems have been reported if the indirectly detected *S* nucleus has a long relaxation time.
- Like NOESY, HOESY is a dynamic, not equilibrium, measurement. A zero result may reflect the experimental conditions chosen, rather than no nOe.

Acquisition tips

- Use the pulse program, and phase cycling sequences supplied with your instrument. Make sure all necessary experimental parameters are set as described by the manufacturer.
- Set $g1$ and $g3$ to satisfy

$$g1\gamma_S = g3\gamma_I$$

  $g2$ is a homospoil gradient pulse, its duration is not critical.
- d2 and d4 equal $g1$ and $g3$ gradient durations, typically 1 ms.
- d3 is the mixing time.

Processing tips

- Zero-fill once in $F1$, apply exponential multiplication in $F2$ and a shifted sine bell squared in $F1$.
- The spectra are not phase sensitive, use magnitude calculation.

3.5.4 *Pulsed Field Gradient—Spin Echo (PGSE) Diffusion Spectroscopy*

Pulsed gradient spin-echo (PGSE) NMR diffusion methods were first introduced ca. 40 years ago by Stejskal and Tanner, and are now enjoying renewed interest from inorganic NMR spectroscopists since they provide a reliable method of studying phenomena such as the relative volume of a compound, hydrogen bonding, host/guest encapsulation, and ion pairing. The technique can be used either in 1D, or as a 2D experiment with chemical shift in one dimension and the diffusion coefficient in the other—diffusion ordered spectroscopy (DOSY) (Figure 26). DOSY can also be used to aid the resolution and assignment of complex mixtures especially where the molecules are relatively large and thus give complicated NMR spectra. Although potentially quantitative, integrating DOSY cross peaks is not straightforward. On the other hand PGSE routinely gives diffusion constants that are accurate to ~2%.[52,53]

Pulse Sequence. The stimulated echo experiment (Figure 27) with p1 = p2 = p3 = 90°, is recommended by Pregosin since, in this version, T_1, rather than T_2, is the effective relaxation path during time Δ. Since T_2 must be shorter than T_1, a better signal-to-noise ratio is obtained. The effect of the two gradient pulses is to defocus, and then refocus, the magnetization. If, during the time Δ, the molecules diffuse from their positions after the first gradient pulse, the effective magnetic field experienced by the spins of those molecules will be different during both gradient pulses. This results in incomplete refocusing of the spins and a consequent decrease in the intensity of the corresponding NMR signal. By recording a series of spectra, varying one of the following; gradient strength G, length δ, or the delay Δ, the diffusion coefficient, D (often called a ‘‘*self-diffusion constant*’’), can be obtained (equation 3).

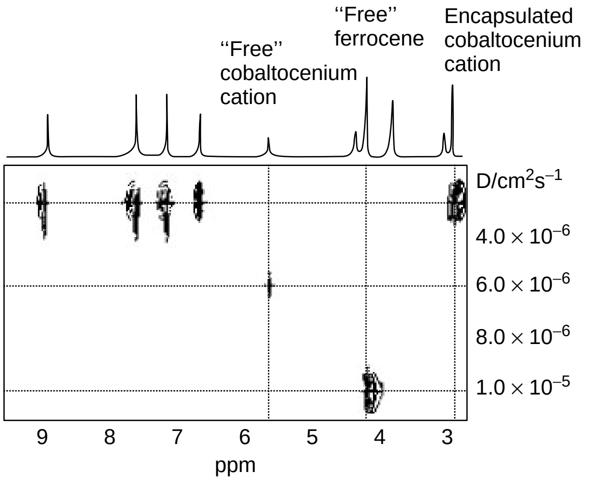

Figure 26 The DOSY spectrum of a solution containing a tetraureacalix[4]arene host, ferrocene, and cobaltocenium cation in $C_2D_4Cl_2$, recorded at 400 MHz, 298 K. The signal at $\delta = 2.72$ ppm has the same D as all the signals of the calixarene indicating encapsulation. The signals of the free ferrocene and cobaltocenium cation at $\delta = 4.06$ and 5.61 ppm, respectively, have much higher diffusion coefficients. (Adapted with permission from Cohen, Y.; Avram, L.; Frish, L. (2005) *Angew. Chem., Int. Ed.*, **44**:520. © 2005 Wiley-VCH)

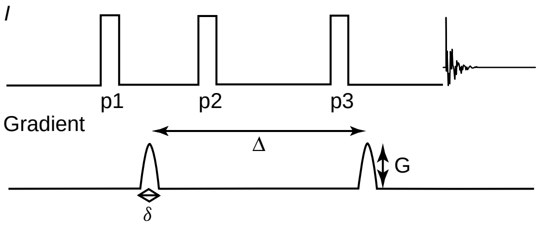

Figure 27 Pulse sequence for stimulated echo PGSE diffusion spectroscopy

$$\ln\left(\frac{I}{I_0}\right) = -(\gamma_X\delta)^2 G^2 \left(\Delta - \frac{\delta}{3}\right) D \quad (3)$$

Advantages

- The results can be accurate to ±2%.
- The diffusion constants for each chemical shift can be determined simultaneously (for a given nuclide).
- For ^{1}H and ^{19}F, PGSE measurements can be recorded in 1 ~ 2 h.
- Only small quantities of material (usually 1–2 mM solutions) are required.
- The components of a mixture can be measured simultaneously (as long as they give resolvable NMR resonances).
- The complexes do not need to be isolable; thus measurements can be made on several species in equilibrium.

Disadvantages

- Great care in setting up the experiment is required if reliable results are to be obtained.
- The gradient strength (G) must be known accurately.
- Temperature control of the sample must be precise; the experiment is sensitive to thermal convection currents within the sample.
- If ion pairing is being studied, both anion and cation must have a suitable NMR label.

Acquisition tips

- Use the pulse program, and phase cycling sequences supplied with your instrument. Make sure all necessary experimental parameters are set as described by the manufacturer.
- Normally the gradient strength is varied.
- Use rectangular gradient pulses, ca. 0–8 ms duration, strength 0–0.2 Tm^{-1}, 0–0.02 s. The exact values will be sample dependent and depend on which parameter is chosen to be varied.
- Do not spin the sample.

Processing tips

- Process all spectra identically.
- For accurate integrations zero fill the FIDs, baseline-correct the spectra, and correct the slope and bias of the integrals individually.
- Use a solvent resonance to normalize the integrals.
- Plot $\ln(I_g/I_0)$ against Δ, $\delta^2(\Delta - \delta/3)$, or G^2, depending on which parameter was varied. *D* is obtained from the gradient of the line (Figure 28).
- The hydrodynamic radius can be obtained from *D* by substitution in the Stoke–Einstein equation (4)

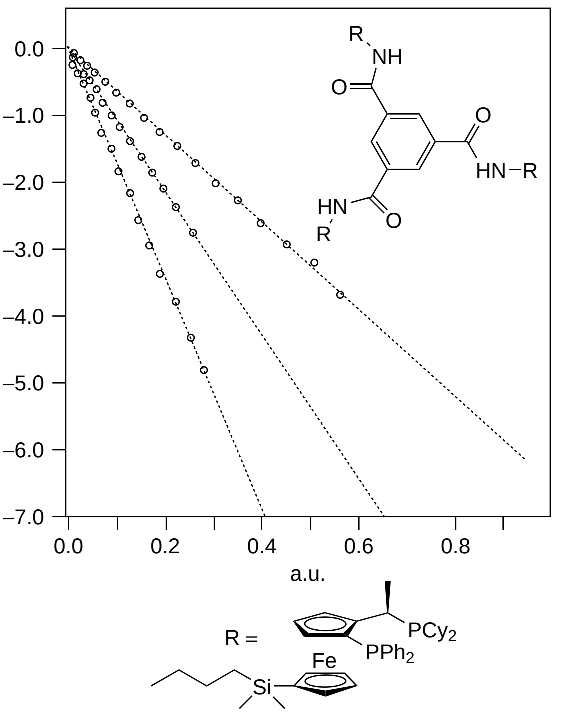

Figure 28 Plot of $\ln(I/I0)$ *versus* G^2 (in arbitrary units) for the first, second, and third generation ferrocene dendrimers based on **A**. The largest compound shows the smallest slope $\propto D$. (Reprinted with permission from D. Valentini, M.; Pregosin, P. S.; Ruegger, H (2000) *Organometallics* **19**: 2551. © 2000 American Chemical Society)

$$D = k_B T / n.\pi \eta . r \tag{4}$$

where η is the viscosity and r the hydrodynamic radius n is usually taken to be 6; however, a value of 4 has also been used when solute and solvent have similar molecular size.

3.6 High Pressure NMR Spectroscopy

High pressure NMR techniques find application in inorganic chemistry in studies of reaction mechanisms in coordination chemistry, where they are used to determine, for example, volumes of activation,[61,62] and in in situ studies of homogeneous catalysis.[63–72] High pressure NMR cells for imaging studies have also been described.[73,74] The equipment required is often highly specialized, pressures in the kilobar range being required for studies of volumes of activation. In studies of reacting homogeneous catalysts, where it is self-evident that it is the concentration of dissolved gas, rather than simply the gas overpressure that is of critical importance (Figure 29),[71,75] some method of gas–liquid mixing that breaks the gas–liquid interface is essential.[76–78] Some workers have suggested that, with care, and suitable protection, and at low pressure, this can be achieved simply by shaking the Roe sapphire tube.[66] This is not to be recommended and is expressly forbidden in some laboratories. The simplest alternative is a dip tube that bubbles gas through the solution,[79] however, such a system still requires ca. 3 min to achieve

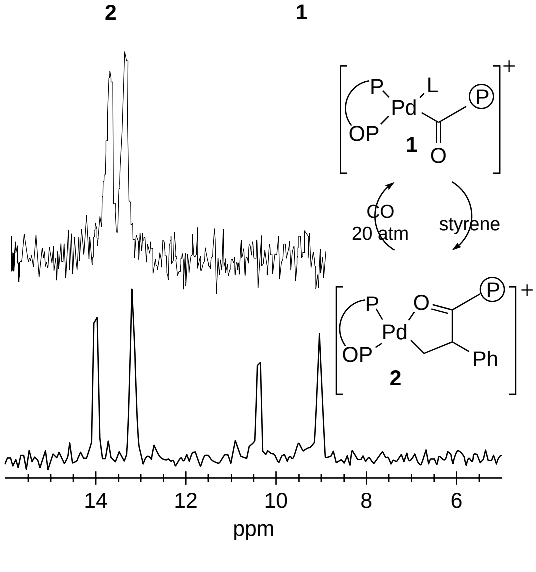

Figure 29 In situ $^{31}P\{^1H\}$ HPNMR spectra (phosphine region) of the co-polymerisation of CO with styrene catalysed by Rh-BINAPHOS: (a) in a zirconia NMR tube, recorded at 202.5 MHz; (b) in a bubble column reactor, recorded at 81.0 MHz. Note only the alkyl intermediate **2** is observed in the unmixed HPNMR tube due to inefficient mass transfer of CO into solution. In the bubble column, delivery of CO to the catalyst is efficient, and so the acyl intermediate **1** is also observed[71]

saturation of the liquid with gas.[80] More complex designs include those of Merbach[81] and Jonas[82] which use mechanical stirrers, that of Bargon and Woelk,[63] which sparges gas through the solution, and the author's bubble column reactor.[78] Yet another alternative is to recirculate the reaction solution between a conventional stirred reactor and the spectroscopic cell;[65] however, care must be taken to ensure gas depletion does not occur while the reaction solution is in the transfer lines/spectroscopic cell. These designs can all achieve efficient mixing of gas with liquid but are more complex to operate.

The Sapphire HPNMR Tube. First introduced by Roe in the 1980s, these have become popular and are in widespread use. More recently, a variant using PEEK tubes has appeared.[83]

Advantages

- The tube can be used in the pressure range 1 to >200 bar.
- It can be used in conventional NMR systems.
- Tubes can be purchased from commercial suppliers.

Disadvantages

- Sapphire tubes are susceptible to unpredictable, catastrophic failure.
- Sapphire tubes require protection from chips and scratches.
- Dissolved gas is rapidly depleted from *reacting* systems.
- Batch operation; experiments requiring changes in gas composition must be performed as a series of separate experiments.

Acquisition tips

- Take great care handling the tubes, make sure the surfaces of the tube are not chipped or scratched.
- Always use a blast shield around pressurized tubes to protect the operator (also applies to PEEK tubes).
- Use a fishing line and (nonmagnetic) hook to insert the sample into the magnet.
- Do not use the lift gas to insert the tube into the magnet; chipping of the base of the tube will almost certainly result. The face of the air bearing may also be damaged by the tube.
- Do not quench tubes, thermal or pressure shock will stress the sapphire and may lead to catastrophic failure.

Autoclave Cells. The NMR probe is constructed inside a high pressure autoclave.[61,62,84] Autoclave cells are principally used for volume of activation studies.[61,62] Toroid cells have been used for studies of organometallic reactions.[64]

Advantages

- can be used from vacuum to >5 kbar
- are extremely robust
- It is possible to incorporate efficient gas-solution mixing.

Disadvantages

- extremely complex
- expensive.

Acquisition tips

- Unless a long-term interest in such measurements exists, the sensible course is to seek a collaboration with a group that specializes in such measurements.

Gas-Liquid Mixing Cells. The simplest approach is to use a dip tube in conjunction with Roe's sapphire tube.[79] More complex designs include bubble columns,[78] and recirculating cells.[65,85] The most complex use mechanical stirring.[81,82]

Advantages

- Such cells can be used in the pressure range 1 to >200 bar.
- Designs using metal vessels are robust.
- Gas concentrations in solution are maintained.
- Experiments requiring changes in gas composition are easily performed.

Disadvantages

- Sapphire tubes require protection from chips and scratches.
- Such cells are more expensive than conventional NMR probes.

Acquisition tips

- All require specialized equipment; unless a long-term interest in such measurements exists, the sensible course is to seek a collaboration with a group that specializes in such measurements.

NMR in Supercritical/Pressurized Fluids. Any of the above systems can be easily modified to record NMR spectra of samples in supercritical/pressurized fluids (within the pressure range of the chosen device).[65,69]

3.7 *para*-Hydrogen NMR spectroscopy[a]

The inherent low sensitivity of NMR spectroscopy makes the detection and characterisation of reaction intermediates, which might be present in low concentration, difficult. One technique that can circumvent this problem is the use of *para*-enriched hydrogen.[86] Any molecule of high symmetry that contains coupled, equivalent, magnetically active nuclei can exist in isomeric forms that differ only in their nuclear spin arrangements. Thus, dihydrogen has two isomers, *ortho*-hydrogen, in which the nuclear spin wavefuntions correspond to the combinations $\alpha\alpha$, $\beta\beta$, or the linear combination $\alpha\beta + \beta\alpha$, and *para*-hydrogen ($p$-$H_2$), which exists as the antisymmetric linear combination

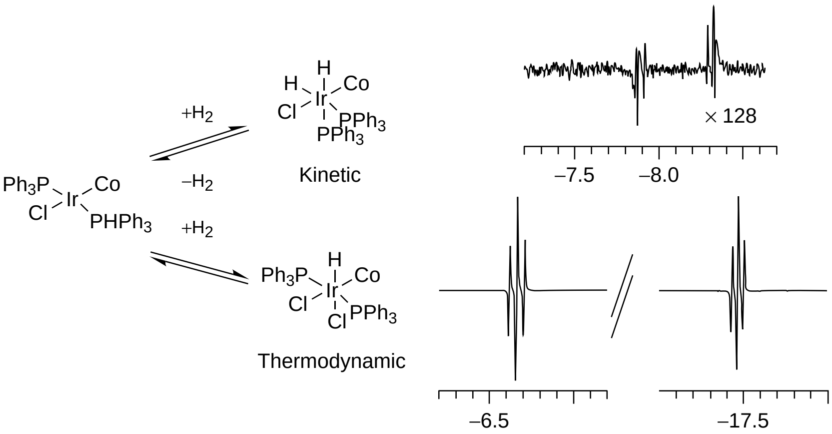

Figure 30 Hydride region of the ^1H NMR spectra for the addition of *para*-H_2 to $[Ir(PPh_3)_2(CO)Cl]$ at 295 K, showing the weak second-order resonance from *cis-cis*-$[Ir(CO)(PPh_3)_2(Cl)(H)_2]$ and the strong signal due to *trans-cis*-$[Ir(CO)(PPh_3)_2(Cl)(H)_2]$. (Figure courtesy of Prof. S. Duckett)

$(\alpha\beta - \beta\alpha)$. Enhanced ^1H NMR signals are observed on addition of H_2 in the *para* spin-state to a molecule. In the absence of an applied magnetic field this is the PASADENA (para-hydrogen and synthesis allow dramatically enhanced nuclear alignment) or PHIP (para-hydrogen induced polarization) effect. For example, on oxidative addition of p-H_2 to Vaska's complex, $[IrCl(CO)(PPh_3)_2]$, the metal dihydride complex $[IrCl(CO)(H)_2(PPh_3)_2]$, that contains two magnetically distinct hydride ligands, is obtained in which only the $\alpha\beta$ and $\beta\alpha$ spin states of the product are populated. Large population differences will exist across transitions that involve these hydride ligands, and hence signal intensities will be large. The resonances of the hydride ligands will also appear in antiphase with respect to J(HH) (Figure 30). If the reaction involving p-H_2 occurs in a weak magnetic field, a different effect, dubbed ALTADENA (adiabatic longitudinal transport after dissociation engenders net alignment), is observed. This arises because under these conditions the coupling between the nuclei is large compared to their frequency difference and hence the lower energy $\alpha\beta$ or $\beta\alpha$ level is populated. In the corresponding ^1H NMR spectrum, only two enhanced transitions are observed. When a reaction does not go to completion before the sample is placed in the NMR spectrometer both ALTADENA[87] and PASADENA[88,89] effects are observed simultaneously.

3.7.1 *para-Hydrogen Enhanced HMQC*

With suitable modification of the pulse sequences the *para*-hydrogen effect can be used to enhance the signals in many NMR experiments, for example, COSY, HMQC, HSQC, EXSY and Overhauser spectroscopy.[86]

Example Pulse Sequence

The HMQC sequence can be modified by replacing the initial 90° proton excitation pulse, p1, with a 45° pulse (Figures 31 and 32). The proton magnetisation must then evolve with respect to heteronuclear couplings prior to magnetisation transfer to heteronuclei. As in the normal HMQC experiment, this is achieved by the fixed delays d2 which must be optimised for heteronuclear magnetisation transfer. During d2 the proton spins evolve with both J(HH) and J(HX). In organometallic complexes J(HH) is typically small, corresponding to a slow evolution time; the effect of this evolution can therefore be neglected. A purge pulse p5 completes the modified HMQC sequence.

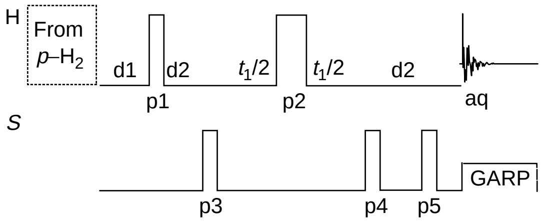

Figure 31 Modified HMQC sequence using *para*-hydrogen

Advantages

- strong enhancement (ca 15 000 times) of NMR signals
- observation of intermediates present in low concentrations
- evidence for pairwise hydrogen transfer
- polarization transfer to hetero nuclides (^{13}C, ^{31}P, etc.).

Disadvantages

- No enhancement is observed if the hydrogen nuclei are transferred to equivalent sites.
- Enhanced signals due to minor species will dominate the spectrum at the expense of signals due to major species that are not enhanced.

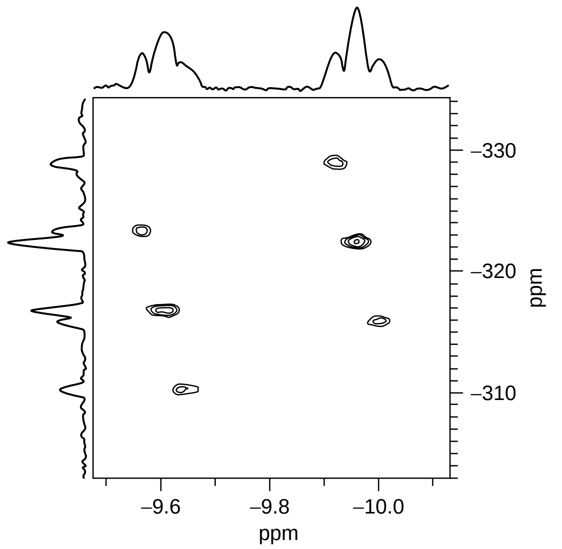

Figure 32 Selected cross peaks and projections from the ^{1}H,^{103}Rh HMQC spectrum of $Rh(PMe_3)_3Cl(H)_2$ obtained with *para*-H_2. (Figure courtesy of Prof. S. Duckett)

Acquisition tips

- Use a 45° excitation pulse for maximum signal intensity.

3.7.2 Preparation of para-Hydrogen

Often a sufficient enrichment in *para-hydrogen* can be achieved simply by storing the NMR sample, containing the complex to be studied and hydrogen gas, in liquid nitrogen for a few hours. If higher enrichment is required, *para-hydrogen* can be readily prepared by cooling hydrogen gas in the presence of a paramagnetic catalyst such as $FeCl_3$. On separation of the gas from the catalyst *at low temperature*, re-establishment of the thermodynamic equilibrium is very slow. A sample containing *para*-enriched hydrogen, in a suitable container, and in the absence of a catalyst, can be stored for several hours prior to use—remember the walls of a lecture bottle will also catalyse equilibration. A device that can produce essentially pure p-H_2 (>99.8%) by cooling H_2 to 18 K is available form Prof S. B. Duckett.

3.8 Solid-State NMR Spectroscopy

3.8.1 Cross-Polarization

The transfer of magnetization from an abundant spin (I), to a dilute one (S), by CP[90] is widely used in numerous pulse sequences in solid-state NMR. The process of CP occurs through the tendency of the magnetization to flow from highly polarized nuclei to nuclei with lower polarizations when the two are brought into contact. CP improves the signal-to-noise ratio due to the transfer of magnetization from abundant ^{1}H spins and significantly reduces recycling delays between the pulses (the relaxation is governed by the ^{1}H system with much shorter relaxation times compared to S spins). The CP relies on the heteronuclear dipolar couplings and the efficiency of CP depends on the strength of the ^{1}H–S dipolar couplings governed by the ^{1}H–S distance and mobility of the S-containing groups. This explains the non-quantitative character of CP. The application of the cross-polarization extends beyond the systems where ^{1}H act as source spins. Recent advances in the development of triple resonance probe heads enable the X → S in which protons are used to either generate X-magnetization (especially for source spins with low natural abundance) or provide ^{1}H–X or ^{1}H–S heteronuclear decoupling. Examples of such experiments include ^{31}P–^{27}Al, ^{31}P–^{29}Si, ^{51}V–^{31}P, ^{13}C–^{15}N pairs.[91–93]

Pulse Sequence. The initial ^{1}H $(\pi/2)_x$ pulse creates ^{1}H magnetization along the $-y$ axis (Figure 33). During the following on-resonance $-y$ pulse (contact pulse) applied at the spin-lock field $B_1(^{1}H)$ the ^{1}H magnetization is kept in the rotating frame of reference. This pulse is applied simultaneously with the S pulse with amplitude $B_1(S)$ (Figure 33). The transfer of magnetization from ^{1}H to S occurs when the amplitudes of the two contact pulses are set to achieve the Hartmann–Hahn matching condition (equation 5).

$$\gamma_{^1H} B_1(^{1}H) = \gamma_S B_1(S) \quad (5)$$

This condition corresponds to the situation when the energy gaps in the rotating frames of S and ^{1}H spins are equal.

Setting up the CP Experiment. CP can be used for the acquisition of the spectra of both dilute and abundant nuclei. While setting up the CP experiments for spin-1/2 nuclei is relatively straightforward, several difficulties exist for quadrupolar nuclei related to both the presence of several transitions for the quadupolar spins and usually short relaxation times, making it difficult to maintain sufficient magnetization for the time required for the transfer of magnetization. In addition, in rotating samples, strong quadrupolar interaction also

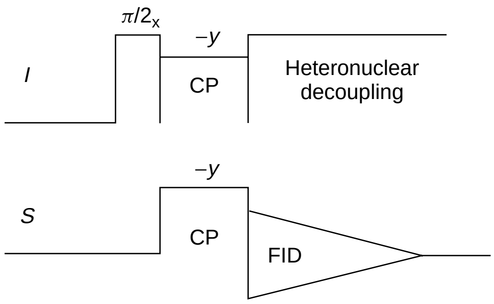

Figure 33 Pulse sequence for CP experiment

becomes time dependent and severely affects the spin-locking efficiency.[92,94,95] The crucial step in setting up the CP experiments is the optimization of the Hartmann–Hahn matching conditions. One should take into account the effect of MAS on the Hartmann–Hahn matching condition. While at relatively slow MAS rates this effect can be neglected, it should be taken into account even at moderate spinning rates. At the high MAS rates, the application of CP is particularly sensitive to the instabilities of the spinning and *rf* power since sidebands of the Hartmann–Hahn match are particularly sharp.

The usual procedure for setting up the CP is:

- Set ^{1}H offset on-resonance via recording a ^{1}H spectrum;
- Determine the ^{1}H ($\pi/2$) pulse (this is also important from the point of view of not overpowering the NMR probe);
- The Hartmann–Hahn match can be found by varying the $B_1(S)$ power level so that maximum intensity is observed. It is important to ensure that the observed spectrum results from the CP (the best indication of this is the absence of the signal after increase of the power beyond the H–H matching condition).
- The CP can be used with different decoupling sequences during the acquisition (these should also be optimized).

The cross-polarization spectra can be acquired using single or RAMP amplitude of B_1^H during the contact time. By using the RAMP amplitude CP (RAMP-CP, Figure 34), one can recover the broad Hartmann–Hahn matching profile even at fast spinning speeds.[96–99] An increase in the intensity of peaks is observed compared to both conventional CP and the originally proposed variable amplitude cross-polarization (VA-CP) pulse sequence since the inhomogeneous Hartman–Hahn conditions are matched over the whole sample volume,[97] making the quantification of the measurements much easier.

The CP step is an essential building block for pulse sequences in solid-state NMR. The easiest 1D experiments that are routinely used for characterization of organic, organometallic and hybrid solids are total suppression of spinning sidebands (TOSS), nonquaternary suppression, and so on.

Cross-Polarization Kinetics. Knowledge of the CP kinetics (dependence of the intensity of the peaks versus contact time) is essential for quantification of the CP-spectra. The CP-kinetics parameters can also provide information on the dynamic properties of the materials under study. A typical CP-kinetics curve consists of two distinct parts: at short contact times the magnetization is increased followed by the decrease

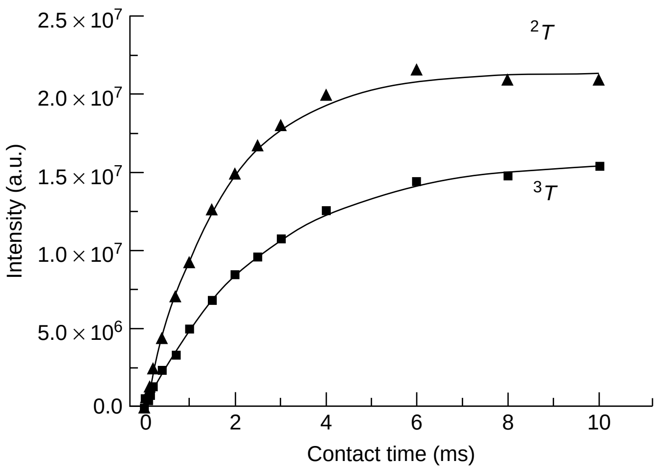

Figure 36 ^1H–^{29}Si CP/MAS kinetics curves of ^2T and ^3T sites in the –CH=CH– SiO_2 hybrids

of the intensity (due to the ^1H relaxation in the rotating frame) or a plateau (Figures 35 and 36).

Different models of CP kinetics have been developed.[100] The simplest model of CP dynamics (I–S) was derived for homogeneous solids where the I–S heteronuclear interactions are relatively weak and the I–I homonuclear dipolar interactions are sufficiently strong to provide efficient spin diffusion. For the abundant-dilute spin system, the CP dynamics can be described by equation (6):

$$I(t) = I_0\left(1 - \frac{T_{\mathrm{IS}}}{T^I_{1\rho}}\right)^{-1}\left[\exp\left(-\frac{t}{T^I_{1\rho}}\right) - \exp\left(-\frac{t}{T_{IS}}\right)\right] \quad (6)$$

Since CP is governed by the heteronuclear dipolar interactions, the T_{IS} time constant is related to the internuclear distances and molecular mobility. The $T^{\mathrm{I}}_{1\rho}$ relaxation time describes the decay of intensity for longer contact times. Relaxation is mostly ensured by the ^1H–^1H homonuclear dipolar interactions. In contrast to the T_{IS} time characteristic of the chemical group under study, $T^{\mathrm{I}}_{1\rho}$ relaxation time is a volume property averaged over the distance of ca. 2 nm.[100,101]

Whereas the I–S model is simple to understand and is widely applied, it is not sufficient to describe the CP kinetics for solids with heterogeneous populations of the source spins. The I–I^*–S model[100] takes into account the efficiency of spin diffusion, which relies on homonuclear dipolar interactions and proceeds through flip–flop spin transitions. The I–I^*–S model relies on the existence of different proton populations, denoted I^* for the protons directly bound to an S spin under study and I for the rest of the proton network. The CP proceeds in two steps. A fast rise of the intensity is observed initially due to the transfer of the magnetization to a dilute spin (I^*–S) by the abundant spins in close proximity followed by a slow rise of the intensity or damped oscillation. Several equations have been proposed to describe the CP kinetics; the simplest is shown below (equation 7).[100]

$$I(t) = I_0 \exp\left(-\frac{t}{T^I_{1\rho}}\right)\left[1 - \lambda \exp\left(-\frac{t}{T_{df}}\right) - (1-\lambda)\exp\left(-\frac{3}{2}\frac{t}{T_{df}}\right)\exp\left(-\frac{1}{2}\frac{t^2}{T_2{}^2}\right)\right] \quad (7)$$

where $T^{\mathrm{I}}_{1\rho}$ is the I spin-lattice relaxation time in the rotating frame; T_{df} is the ^1H spin-diffusion time constant describing the strength of the homonuclear dipolar interactions and the homogeneity of the I spin pool; λ is defined by the number n of I spins attached to the S spin under study ($\lambda = 1(n+1)$); T_2 is the spin–spin relaxation time. The values of absolute intensity I_0 derived from either the I–S or I–I^*–S models can be used for the quantification of the ^1H–^{13}C CP/MAS spectra.

3.8.2 Total Suppression of Spinning Sidebands (TOSS)

The spectra of organic and organometallic compounds, especially ones bearing aromatic rings in their structure, recorded at low or moderate MAS rates often display a series of spinning sidebands in addition to the isotropic peaks. While such sidebands can be used to derive important structural information (via the knowledge of CSA), they often mask other lines in the spectra which makes the assignment of the spectrum a considerable challenge. The TOSS pulse sequence[16] (Figure 37) has been designed to obtain the spectra in which the sidebands have significantly reduced intensity (Figure 38). This is particularly important for low MAS rates.

Pulse Sequence. In the TOSS pulse sequence a series of usually four (π) pulses are applied in precisely placed points with respect to the rotor cycle prior to acquisition. The TOSS experiments are designed for MAS rates below 8 kHz. The setup of this experiment is identical to the one for the CP apart from the need for an accurate determination of the S (π)-pulse. This can be difficult as a standard with relatively short T_1 relaxation time is required. The S (π)-pulse can also be set using the TOSS pulse sequence indicated by the lowest intensity of spinning sidebands.

The most significant disadvantage of this experiment is the fact that eliminated sidebands do not necessarily contribute to the central band, thus making the quantification of the spectra less reliable than a CP spectrum. The

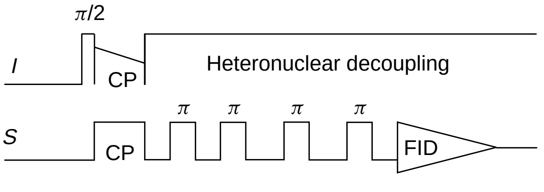

Figure 37 TOSS pulse sequence

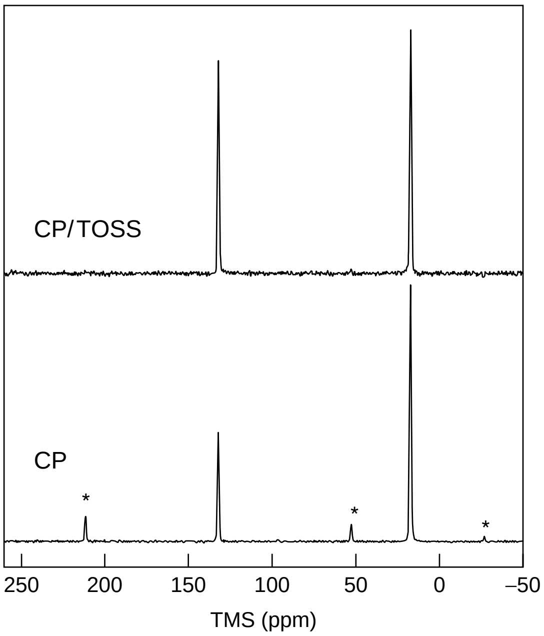

Figure 38 $^{1}H-^{13}C$ CP/MAS and $^{1}H-^{13}C$ CP/TOSS/MAS NMR spectra of hexamethylbenzene measured using MAS rate of 8.0 kHz

pulse sequence was designed for samples with cylindrical symmetry. The large number of spinning sidebands hampers the performance of the sequence. In addition, the sequence might suffer from the problems of setting up the S (π)-pulse.

3.8.3 *Nonquaternary Suppression (Dipolar Dephasing)*

The assignment of the $^{1}H-^{13}C$ CP/MAS spectra can be assisted using a simple pulse sequence which differs from the traditional CP pulse sequence only by the delay between the contact pulse and proton decoupling.[102] Such delay results in a rapid decay of transverse magnetization for carbon sites with very strong $^{1}H-^{13}C$ heteronuclear dipolar interactions. As a result, the magnetization of the protonated carbons (except CH_3 groups) decays, while that of the quaternary carbons remains in the spectra.

Pulse Sequence. The setup for this experiment is very similar to the conventional CP experiment (Figure 39). The delay times can be set in the range 10–100 μs. The dependence of the signal intensity *versus* the delay time can be used for the estimation of the strength of heteronuclear dipolar coupling and can provide information on mobility.

3.8.4 *Homonuclear Decoupling*

Elimination of homonuclear dipolar coupling is a significant challenge in solid-state NMR of nuclei with high natural abundance and large γ (particularly ^{1}H and

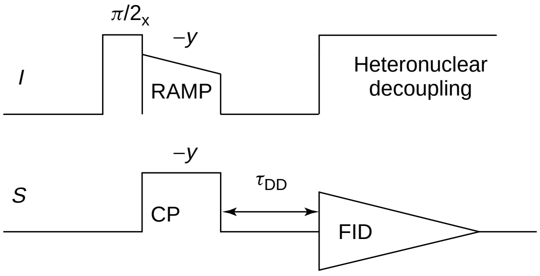

Figure 39 NQS pulse sequence

^{19}F) and can be achieved using multiple-pulse sequences (i.e., WAHUHA, Mansfield, Rhim, Elleman and Vaughan homonuclear decoupling pulse (MREV-8)).[3,4] Most of these pulse sequences are designed in such a way that at certain points in the pulse sequences the effect of the homonuclear dipolar Hamiltonian on the nuclear magnetization is zero. By recording the signal at these specific points, the effect of homonuclear dipolar coupling vanishes. These pulse sequences are far from trivial to implement. Firstly, the FID points need to be collected at a particular point between cycles of pulses. Secondly, high-power pulses are required as the pulse length must be short relative to the cycle time. Moreover, the spectral width of the resulting spectrum is the inverse of the cycle time and it must be large enough to contain all the signals; as a result, short cycle times are preferable. Finally, MAS can interfere with the decoupling sequence so that the decoupling sequence and sample spinning should be accurately synchronized. To avoid these problems, one often relies on two-dimensional (2D) experiments; the homonuclear decoupling being implemented in the indirect dimension. This has been used to generate high-resolution ^{1}H spectra from 2D experiments.[103] The main advantage of this approach over the implementation of one-dimensional (1D) homonuclear decoupling is that the homonuclear decoupling does not need to be rotor synchronized.

Frequency-Switched Lee–Goldburg Decoupling (FSLG). The frequency-switched Lee–Goldburg decoupling (FSLG) decoupling[104,105] has found numerous applications in solid-state NMR pulse sequences. The Lee–Goldburg (LG) decoupling employs off-resonance (2π) pulses (Figure 40). If the offset frequency, $\Delta\omega$, is chosen as $\Delta\omega = \omega_{RF}\sqrt{2}$, ω_{RF} corresponding to the on-resonance *rf* pulse, the effective field that the spins experience in the rotating frame is oriented at magic angle with respect to $\vec{B}_0$. Thus a (2π) pulse with such offset causes the net magnetization to precess by one turn around this effective field leading to averaging out the homonuclear dipolar coupling between the spins. To compensate errors in the averaging of the dipolar Hamiltonian, the offset is switched between $+\Delta\omega$ and $-\Delta\omega$ and its phase simultaneously changed by (π).

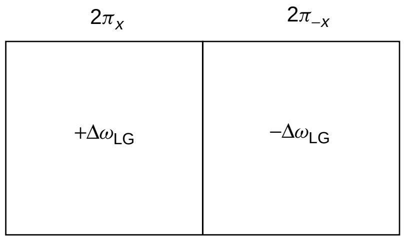

Figure 40 FS-LG Homonuclear decoupling

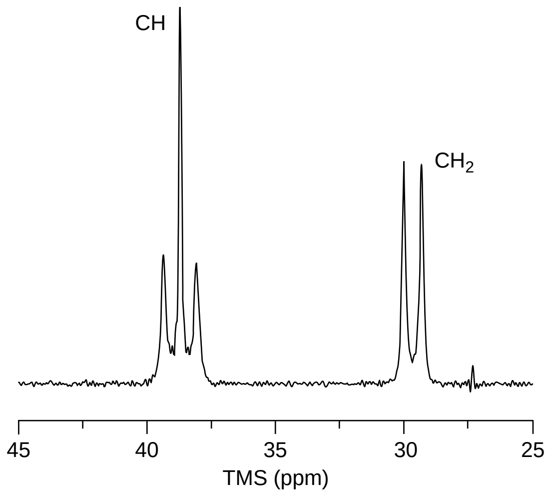

Figure 41 $^1H-^{13}C$ CP/MAS NMR spectrum of adamantane recorded using FSLG decoupling. Note the splitting of lines: the triplet corresponds to CH sites, the doublet corresponds to CH_2 sites

Setting up the FSLG is not straightforward. The pulse sequence is rotor synchronized and particular consideration should be taken when setting the ^1H offset. The FSLG decoupling can be setup using the $^1H-^{13}C$ CP/MAS spectrum of adamantane recorded at the conditions of the homonuclear decoupling (Figure 41). FSLG decoupling is correctly setup when the spectrum shows a well defined triplet and doublet corresponding to the CH and CH_2 sites respectively. The presented pulse sequence requires well set up CP and TPPM decoupling steps. The FSLG is frequently used as a building block for the pulse sequences employing homonuclear decoupling. Other recently developed pulse sequences for homonuclear decoupling include decoupling using mind-boggling optimization (DUMBO) and phase-modulated Lee–Goldburg experiment.[106]

3.9 Correlation Experiments in Solid-State NMR

3.9.1 Homonuclear Correlation

Most homonuclear correlation experiments rely on the homonuclear dipolar couplings to provide information on the spatial proximity of nuclei. Such experiments utilize the possibility of excitation of multiple-quantum transitions in the dipolar-coupled systems. The high-resolution type experiments relying on the J-couplings (i.e., incredible natural abundance double-quantum transfer experiment (INADEQUATE)) can be used. All these experiments are performed under MAS to meet the requirements of the resolution.

2D CRAMPS Spectroscopy. The measurement of ^1H solid-state NMR spectra for organic compounds is a significant challenge due to the presence of very strong homonuclear coupling. Combined rotation and multiple pulse spectroscopy (CRAMPS)[107] provides a significant improvement in the resolution of the spectra. Despite the obvious advantages, wider application of this method has been hampered by the very difficult setup procedure and its high sensitivity to the instabilities of *rf* power and MAS. Unlike its predecessor, the 2D CRAMPS method is much easier to setup due to the recent development of homonuclear decoupling sequences (i.e., FSLG or DUMBO).[103,108]

Pulse Sequence. The first $(\pi/2)$ pulse creates the proton magnetization in a plane perpendicular to the direction of the effective field present during the application of the multiple-pulse homonuclear decoupling sequence (Figure 42). During t_1, the proton magnetization evolves in this tilted transverse plane under homonuclear decoupling. At the end of the evolution time t_1 a pre-pulse of flip-angle θ is applied. This rotates the proton magnetization from the tilted transverse plane to the (x, y) plane of the rotating frame. A z-filter is then applied to allow phase-sensitive detection in t_1, before direct signal detection in t_2. As a result, a two-dimensional correlation between a high-resolution proton CRAMPS spectrum in ω_1 and the MAS spectrum in ω_2 can be observed (Figure 43). The one-dimensional CRAMPS spectrum is obtained by simply summing the ω_1 traces extracted at the various proton frequencies. This method of indirect detection of the high-resolution proton spectrum is particularly convenient since it allows the use of windowless multiple-pulse sequences which currently have a far superior performance to sequences allowing direct acquisition of the signal. The method is also less prone to artefacts.

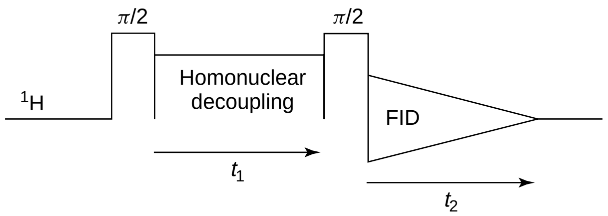

Figure 42 2D CRAMPS pulse sequence

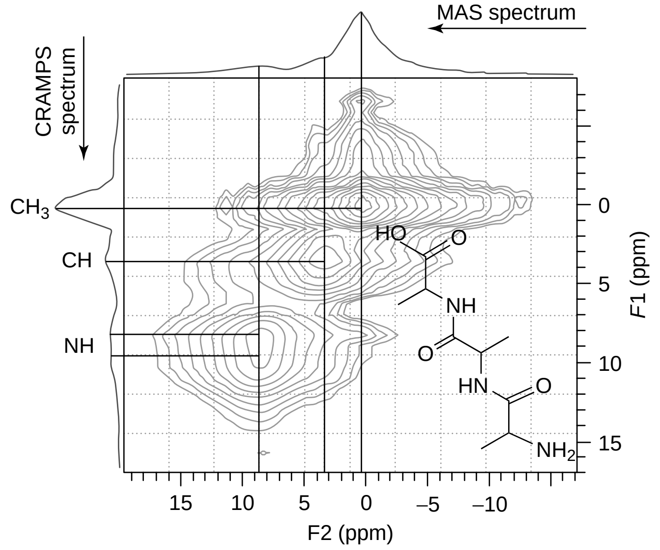

Figure 43 $^1H-^1H$ correlation spectrum of tri-L-alanine recorded using FSLG decoupling in t_1, MAS = 15 kHz

Experimental Setup. The setup of the experiment is determined by a homonuclear decoupling sequence used during t_1. For FSLG decoupling the spectra can be recorded with MAS rate up to 15 kHz (both 4 mm and 2.5 mm rotors can be used). The resolution of the spectra can be improved by using the rotors with reduced sample volume (CRAMPS rotor). FSLG decoupling needs to be optimized prior to the experiment. The performance of the pulse program can be improved by the careful optimization of the pre-pulse. Since the FSLG is used during the acquisition, the chemical shift in ω_2 is altered by a factor of $3^{-1/2}$ and rescaling of the ω_2 is required during the processing step.

Double-Quantum. (DQ) Proton Spectroscopy. Multiple-quantum (MQ) coherences are routinely used in high-resolution solution-state NMR spectroscopy. The MQ coherences cannot be observed directly and the application of two-dimensional methodology is required. The Double-Quantum (DQ) methodology is particularly useful to derive the information on the spatial proximity of different spins on the basis of the homonuclear dipolar couplings.[106]

Pulse Sequence. A typical pulse sequence for DQ experiments consists of several blocks (Figure 44). One also needs to consider the effect of MAS. The commonly used pulse sequences are designed in such a way that the excitation time is synchronized with the rotor period. The excitation of DQ coherence can be achieved by using different recoupling sequences (i.e., back-to-back recoupling sequence (BABA),[109] dipolar recovery at the magic angle (DRAMA), C7 recoupling pulse sequence (C7), homonuclear rotary resonance (HORROR)). The DQ coherence evolves

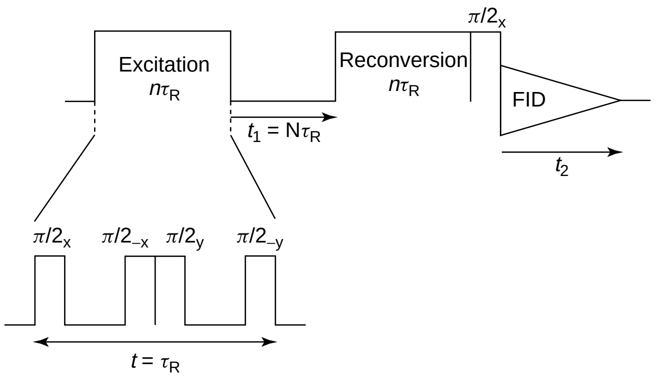

Figure 44 Double-quantum pulse program

subsequently during t_1. In the following step, the DQ coherence needs to be converted back into observable, single-quantum coherence which is detected during t_2.

In the case of very strong dipolar couplings ($^1H-^1H$) the experiment is performed using fast MAS rates (ca. 30 kHz) so that spectra with sufficient resolution can be recorded. The performance of this pulse sequence is very sensitive to the instabilities of MAS. The rotor synchronised 2D DQ NMR spectrum (the increment in t_1 set to one rotor period) provides information on the spatial proximity of different protons based on the presence of peaks in the ω_2 dimension. If the spins A (ν_A) and B (ν_B) are close in space, the peaks at $((\nu_A + \nu_B), \nu_A)$ and $((\nu_A + \nu_B), \nu_B)$ will appear in the 2Q spectrum (Figure 45). This provides semi-quantitative

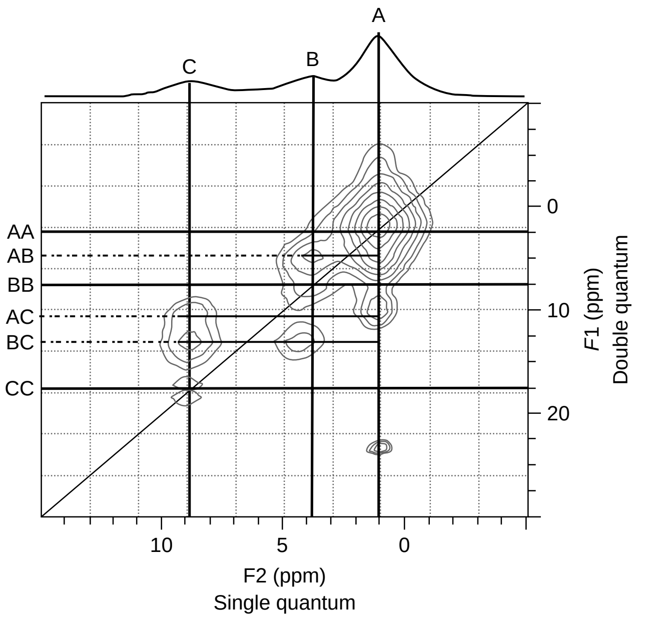

Figure 45 Rotor synchronised $^1H-^1H$ double-quantum MAS spectrum of tri-L-alanine using 1 rotor period BABA for excitation and reconversion, MAS = 30 kHz

assignment of the structures. If the increment in t_1 is reduced and a suitable recoupling sequence is used (BABA or DRAMA), the DQ MAS sideband pattern is generated from which the $^1H-^1H$ dipolar coupling constant and, hence, the $^1H-^1H$ distances can be determined.[106]

DQ spectroscopy is not limited just to $^1H-^1H$ pairs and has been applied to determine proximities between ^{13}C nuclei (in isotopically enriched systems). Recently, Levitt *et al.* developed a new $SR26_4$ homonuclear recoupling pulse sequence which was used for the determination of $^{29}Si-^{29}Si$ correlations in zeolites.[110,111] One should be aware of the important difference between the DQ and INADEQUATE experiments. While the former is based on the homonuclear dipolar couplings, the INADEQUATE relies on the J-couplings to create the DQ coherence. The DQ coherences build up much faster using the dipolar recoupling sequence in comparison with INADEQUATE experiments due to much higher $^{29}Si–O–^{29}Si$ dipolar couplings compared with the $^{29}Si–O–^{29}Si$ J-couplings.

3.9.2 Heteronuclear Correlation Methods

HETCOR. Heteronuclear correlation (HETCOR) experiments are very important in solution-state NMR spectroscopy and are used for the assignment of structure of complex organic molecules. While in high-resolution NMR spectroscopy the inverse detection (HSQC or HMQC) is a method of choice, the presence of strong $^1H–X$ ($X = {}^{13}C$, ^{15}N, ^{29}Si etc.) heteronuclear dipolar couplings, which can be used for the $^1H \rightarrow X$ transfer of magnetization in CP, is exploited further to determine the $^1H–X$ connectivities in the solid.[112] The $^1H–X$ HETCOR experiment enables the increased resolution of ^1H peaks due to the usually much higher resolution of the spectra for the heteronucleus. The HETCOR method has been applied to the determination of the structure of porous heterogeneous catalysts with limited long−range order.[6,113]

Pulse Sequence. The basic pulse sequence for the HETCOR experiment can be considered as a derivative of the pulse sequence used for the CP experiments (Figure 46). The main difference between the CP and HETCOR pulse sequences lies in the presence of the homonuclear decoupling step before the ^1H ($\pi/2$) pulse. The experiment starts with the excitation of the single-quantum coherence of the ^1H spins and its evolution during t_1. In the case of FSLG-HETCOR the ^1H magnetization is to be brought to the xy plane by an additional θ_m pulse (in the FSLG pulse sequence the ^1H magnetization is kept at θ_m). This is followed by the usual CP transfer of magnetization and detection of X FID in t_2 (under the heteronuclear decoupling, i.e., TPPM). In the basic HETCOR experiment it is important to use a very short contact time in the CP step to ensure the detection of the X peaks with ^1H in close proximity. This problem can be eliminated by the application of Lee−Goldburg CP ensuring the transfer of magnetization from directly bound protons (Figure 47).[112] It is important to note that due to the use of FSLG, the scale of the ^1H dimension in the resulting spectrum is modified by the factor $(1/3)^{1/2}$.

Since its introduction, several other coherence transfer pathways have been employed. The described FSLG-HETCOR and recently proposed MAS-J-HMQC pulse sequence[114] uses heteronuclear dipolar couplings, while the REPT-HMQC employs the rotational-echo double resonance (REDOR)[115] recoupling pulse sequence.

Wide Line Separation Spectroscopy (WISE). Wide line separation spectroscopy (WISE) has been applied to correlate the molecular structure and mobility based on the linewidths of static ^1H lines (Figure 48). In this experiment ^1H lines are separated by virtue of a much better resolved chemical shift of ^{13}C sites in their close proximity.[9,116] The linewidths of ^1H peaks provide a qualitative estimation of mobility (the wider the peak, the stronger the $^1H-^1H$ coupling and, hence, a reduced mobility), while the well-resolved ^{13}C sites provide the information on molecular structure.

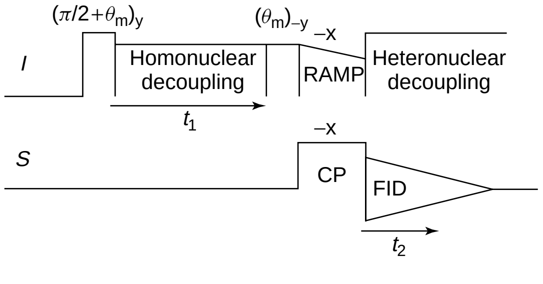

Figure 46 HETCOR pulse sequence

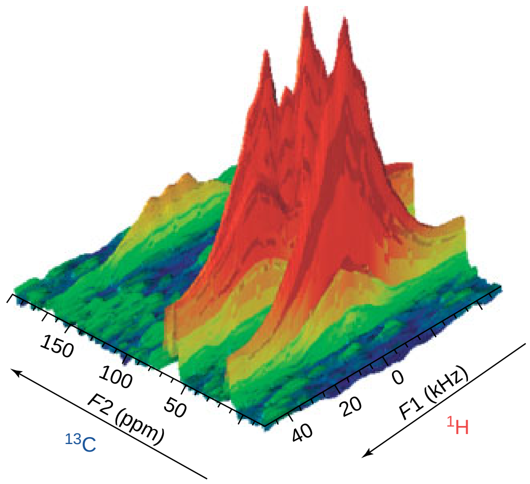

Figure 48 $^{1}H-^{13}C$ WISE NMR spectrum of poly-lactide/glycolide. The projection in F_2 corresponds to $^{1}H-^{13}C$ CP/MAS NMR spectrum ensuring site resolution; the projections in F_1 corresponds to ^{1}H wide lines: the linewidth can be correlated with molecular mobility of a particular ^{13}C site

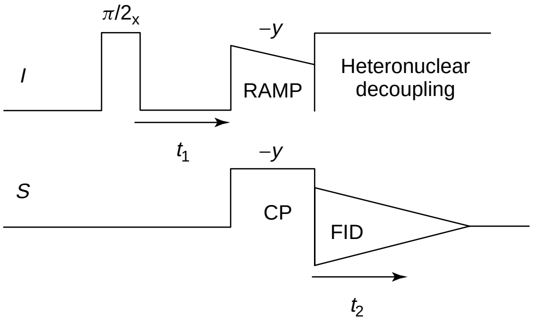

Figure 49 Pulse sequence for WISE

Pulse Sequence. The pulse sequence for WISE experiments can be considered as a derivative of the CP pulse sequence (Figure 49). After the initial ($\pi/2$) pulse, the ^{1}H magnetization is allowed to evolve during t_1. Subsequently, the remaining ^{1}H magnetization is transferred via CP to ^{13}C. The resulting ^{13}C magnetization is then recorded in t_2. The very short CP step (50–150 µs) is essential to prevent ^{1}H spin diffusion.

3.10 Measurement of Dipolar Couplings in Solid-State NMR

Measurement of the heteronuclear dipolar couplings defines the use of solid-state NMR spectroscopy for determination of internuclear distances. The main part of such experiments involves refocusing of the heteronuclear dipolar couplings. The REDOR experiment has been used extensively to determine the internuclear distances ($^{13}C-^{15}N$, $^{13}C-^{31}P$ etc.).[112,115,117]

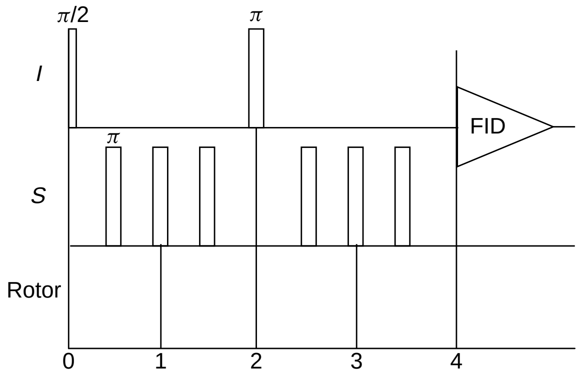

Figure 50 Pulse sequence for REDOR experiment

3.10.1 *Pulse Sequence*

The measurement of the heteronuclear dipolar coupling constant is achieved via a rotor synchronized pulse sequence in which the transverse magnetization dephases under the $I-S$ heteronuclear dipolar coupling during the first half of the rotor period and is subsequently refocused during the second half of the rotor period via the application of $S\pi$ pulse (Figure 50). The difference of spectra recorded with and without the application of $S\pi$ pulses depends on the strength of dipolar coupling. An I π pulse applied at the halfway point of dephasing period ensures refocusing of any I spin chemical shift offset.[118]

The magnitude of the $I-S$ dipolar coupling can be derived from the plot of intensity of difference spectra versus number of rotor periods. This is easily achievable for $I-S$ isolated spin pairs. Such analysis becomes significantly more difficult when I spin is coupled to several S spins so that several dipolar coupling constants are present. The dephasing effect in REDOR depends on the strength of dipolar coupling (for very strong couplings the magnetization will be totally dephased after only one or two rotor periods). The setup of the experiment depends on the rotor speed and accuracy of the used π pulses.

The REDOR experiment has been proposed for spin-1/2 pairs. For quadrupolar nuclei-spin-1/2 pairs, the use of this experiment is limited. The main reason behind this is the fact that a significant quadrupolar broadening (in order of several MHz) makes the $S\pi$ pulses inefficient for the inversion of S populations. For such systems REDOR experiments can be applied if the π pulses are applied to the spin-1/2 nucleus and only central transition is observed for a half-integer spin. The transfer of population in double resonance (TRAPDOR)[119] or rotational-echo adiabatic passage double resonance (REAPDOR)[120] experiment offer a much better choice for the measurement of quadrupolar nuclei-spin-1/2 pair dipolar couplings.

3.11 Quadrupolar Nuclei

Quadrupolar nuclei present several challenges in solid-state NMR. While for spin-1 (^2H, ^6Li) nuclei most of the solid-state NMR experiments rely on the wide lines and measurement of quadrupolar coupling constants (though significant progress in MAS methodology for ^2H has been reported recently), for half-integer quadrupolar nuclei it is possible to record high-resolution spectra. The central transition of the latter is not broadened by the first-order quadrupolar interactions ensuring its much easier detection relative to the satellite transitions. MAS can provide a significant narrowing of the lines of quadrupolar nuclei for solids. MAS will average out the first-order quadrupolar broadening of satellite transitions (in most cases not completely, due to the rate of spinning not being large enough relative to the size of the anisotropy). It is important to note that the central transition is still affected by the second-order quadrupolar interactions. Therefore, MAS does not succeed in a complete removal of anisotropic quadrupolar effects.

The theoretical background of solid-state NMR spectroscopy of quadrupolar nuclei can be found in excellent recent reviews.[4,22] In this section only the main techniques will be highlighted. Such methods achieve the averaging out of the quadrupolar anisotropy by using either a purely geometric part of the Hamiltonian (i.e., double-rotation or dynamic-angle spinning methods) or combine multiple-pulse methodology with MAS (Multiple-quantum magnetic angle spinning (MQMAS) or Satellite Transition MAS methods).

The double-rotation (DOR) method[121,122] leads to high-resolution NMR spectra of quadrupolar nuclei by spinning the sample at two different angles: the first angle is set at the magic angle, thus ensuring averaging out of the first-order quadrupolar effects; the second angle is set at either 30.6 or 70.1° so that the second-order effects are averaged out (Figure 51). Practical implementation of this method requires the use of the specifically designed NMR probe heads capable of ensuring the stable MAS of a complex sample holder consisting of two rotors spun simultaneously (much lower rate of rotation of the outer rotor results in generation of numerous sidebands). The dynamic-angle spinning (DAS) method[121,123] results in a two-dimensional spectrum, separating isotropic chemical shift and quadrupolar powder patterns. This is achieved by rotor synchronized refocusing of the quadrupolar broadening. The transition frequency is changed by the alteration of the sample spinning angle (usually, the combination of spinning angles of 37.38° and 79.19° is used). Since only rotation about one axis is required at any time in the pulse sequence, this method can employ relatively fast spinning rates. However, the need to change the spinning angle during the acquisition can only be achieved with specially designed probe heads. In addition, the DAS method does not use rotation about the magic angle. Therefore other anisotropic magnetic interactions are not averaged out.

Unlike DAS or DOR methods, the MQMAS method achieves high resolution for half-integer spins under the conditions of MAS and therefore can be used on any conventional solid-state NMR spectrometer. The resulting two-dimensional spectra correlate isotropic chemical shifts in t_1 with a quadrupolar coupling pattern in t_2. Whereas in DAS method the refocusing of the evolution period is carried out via the change of spinning angle, in MQMAS the same is achieved by changing the order of the evolving coherence. The theoretical background of MQMAS spectroscopy can be found in an excellent book by M. J. Duer.[4] Considering the practical aspects of this method, the pulse sequence consists of three main parts: excitation of the multiple-quantum coherence, transfer of multiplequantum into the single-quantum coherence, and detection during t_2 (Figure 52). The excitation of multiple-quantum coherence can be achieved by $(\pi/2) - \tau - (\pi/2)$ sequence (used in high-resolution NMR

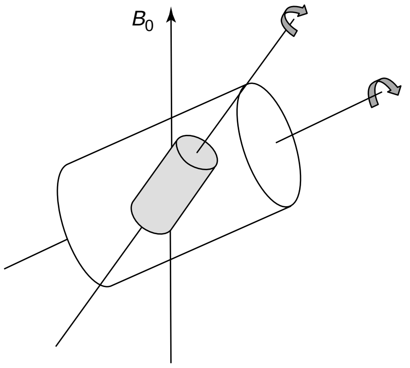

Figure 51 Set-up for double-Rotation NMR

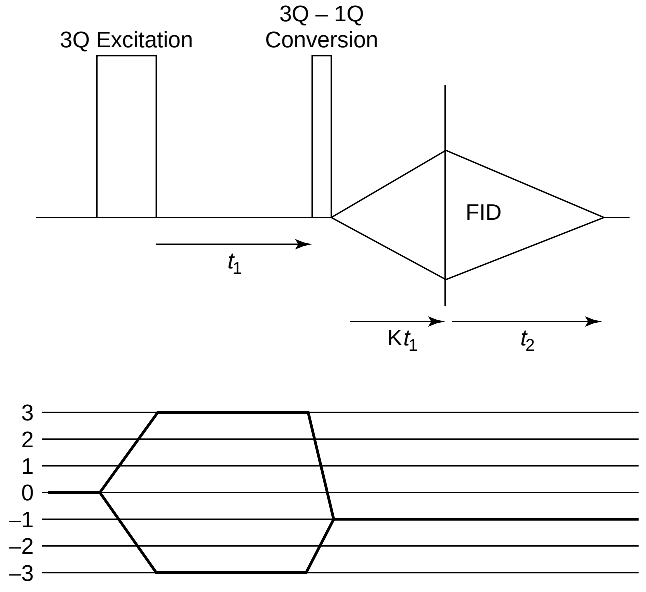

Figure 52 MQMAS pulse sequence

spectroscopy) and its selection is ensured by the specific phase cycling. The high-power of the pulse is needed for effective excitation. It is important to note that the efficiency of this step depends on the magnitude of quadrupolar coupling constant. The MQ-SQ transfer is also dependent on the quadrupolar coupling constant and, hence, on the pulse power.

The MQMAS has now become the most widespread method for the acquisition of high-resolution solid-state NMR spectra of quadrupolar nuclei. The MQMAS step has been incorporated into the other pulse sequences focusing on achieving the correlation between the quadrupolar and spin-1/2 nuclei (i.e., HETCOR-MQMAS).[124]

The recently proposed Satellite Transition Magic-Angle Spinning (ST-MAS)[22] is similar to the MQMAS, apart from the fact that the central transition is correlated with satellite transition rather than MQ transitions. The use of only single-quantum coherences in ST-MAS is advantageous (compared with the MQMAS method where MQ coherences are used) from the point of view of better signal-to-noise. The satellite transitions show a much weaker dependence on the quadrupolar coupling constant in comparison with the MQ coherences. The main disadvantage of ST-MAS method is in its very high sensitivity to the setting of the magic angle to prevent the reintroduction of first- and second-order quadrupolar couplings into the satellite transition coherence. The very accurate setting of magic angle can be achieved using the Rb NMR and ensures a satisfactory resolution of the resulting 2D spectrum.

4 END NOTE

METHOD SUMMARY

Acronyms, Synonyms

- Nuclear Magnetic Resonance

Measured physical quantities

- nuclear spin transition frequency (chemical shift, ppm)
- relative numbers of equivalent spins (signal area)
- nuclear relaxation rates (R_1, R_2, s^{-1})
- dipole–dipole and scalar couplings (Hz).

Information available

- high-resolution three-dimensional solution structure (in favorable cases)
- dipolar and scalar couplings between nuclei, and between unpaired electrons and nuclei
- rates of conformational and chemical exchange processes
- magnetic anisotropy and orientation of magnetic axes in paramagnetic molecules.

Information not available, limitations

- Only nuclei with spin $I \neq 0$ can be observed.
- Detailed information is difficult to obtain on molecules that are insoluble, very large, or highly disordered.

Examples of questions that can be answered

- Is this protein or RNA folded?
- What amino acid residues bind the cofactor?
- What is this paramagnetic transition metal oxidation and spin state?
- Does ligand or cofactor binding to this biomolecule induce a change in conformation or in dynamics?

Major advantages

- Spatially resolved high-resolution information on structure and dynamics across the entire molecule may be discerned in favorable cases.
- Effects of ligand binding, pH, temperature, denaturant, and so on, are readily studied.
- For molecules that bind paramagnetic metals, spectra contain information on metal electronic structure.

Major disadvantages

- Low sensitivity is a major disadvantage and requires relatively large amounts of sample.
- Spectral crowding decreases resolution for larger biomolecules.
- Isotopic labeling of sample may be required.
- Linebroadening resulting from paramagnetism, nuclear spin $>1/2$, or large molecular weight (MW) decreases resolution and may severely limit analysis.
- Specialized approaches are required for molecules of high molecular weight or low solubility.

Sample constraints

- The volume of sample is restricted to 300–500 μL (using a conventional 5 mm probe), or a few microliters (using a microprobe).
- Liquid sample is preferred for high-resolution studies; nuclear magnetic resonance (NMR) of solids requires specialized methodologies.
- Concentration should optimally be at or above 1 mM; considerably lower values are possible with state-of-the art probes and/or experiments.
- High sample purity is needed if a detailed study is to be undertaken.

1 INTRODUCTION

Life has evolved making use of a wide range of elements, including metals.[1] It is estimated that ∼25% of known proteins bind one or more metal ions,[2] and the majority of catalytic nucleic acids require divalent metal ions for function.[3] As metal ions play key functional or structural roles in biological systems, the metals and the portions of the biomolecule with which they interact are a natural focus of structural and spectroscopic studies. In the application of nuclear magnetic resonance (NMR) spectroscopy, the presence of metal ions in biomolecules raises both opportunities and challenges. In paramagnetic biomolecules, the interaction of unpaired electron spins with nuclear spins perturbs both chemical shifts and line widths in NMR spectra. These effects complicate the interpretation of spectra, but in favorable cases they allow the metal to act as a ''beacon'' to light up the metal-binding site, which is frequently the biomolecule active site. Because the perturbations to NMR spectra by paramagnetic ions depend on the metal spin state and coordination geometry, the NMR spectra provide a means by which the metal coordination environment and electronic structure may be characterized. Even for metals typically thought of as spectroscopically silent, the changes in biomolecule chemical shifts upon metal binding provide a probe of the active site.

The application of NMR to metallobiomolecules, and metalloproteins in particular, has a long history. In fact, paramagnetic cytochrome *c* is among the first proteins for which multiple well-resolved NMR signals were observed (in 1962).[4] The field of biological NMR has developed rapidly since that time; the first solution structure of a protein was reported in 1985,[5] and the first NMR structure of a paramagnetic protein was reported only nine years later.[6] Soon thereafter, it was demonstrated that the effect of the paramagnetic center on proton chemical shifts can be utilized to refine metalloprotein solution structures[7,8]; such restraints are now included in standard software packages for biomolecule structure refinement. The utility of paramagnetic restraints is such that extrinsic paramagnetic centers are being introduced to allow the spectroscopist to take advantage of paramagnetic effects on NMR spectra for characterizing biomolecules that do not bind metals.[9]

Among the metallobiomolecules, small (MW $<$ 30 kDa), soluble metalloproteins are the most amenable to study by NMR, and thus many studies of soluble heme proteins

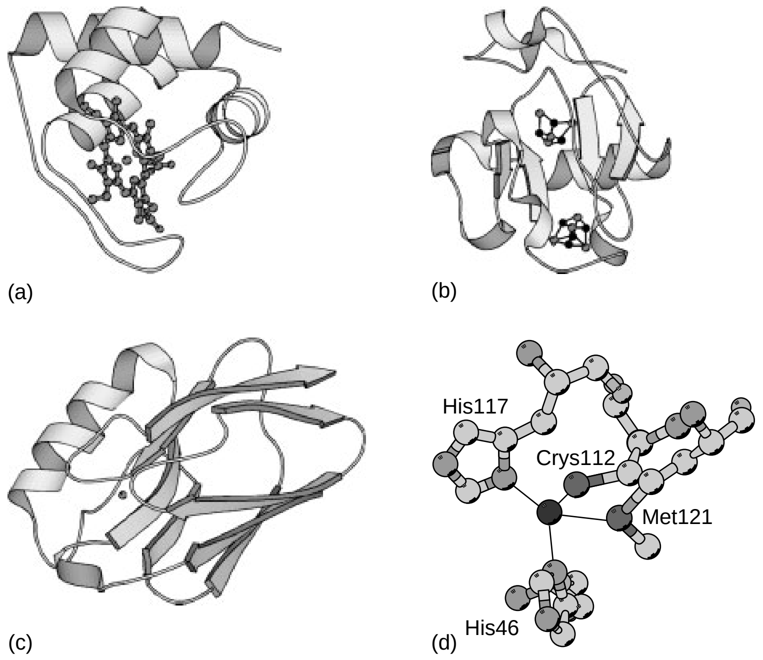

Figure 1 Three-dimensional structures of metalloproteins illustrating examples of metal-binding sites probed in NMR studies. (a) *Hydrogenobacter thermophilus* cytochrome c_{552} (PDB:1YNR), a heme protein. (b) *Azotobacter vinelandii* ferredoxin (PDB:1FDA), an iron–sulfur cluster protein (with one Fe_3S_4 and one Fe_4S_4 cluster). (c) *Pseudomonas aeruginosa* azurin (PDB:1AZU), a blue copper protein. The Cu ion is shown as a sphere in (c), and the copper-binding residues in azurin are enlarged in (d). Biomolecule figures prepared using Molscript[13]

(cytochromes, globins),[10] iron–sulfur proteins (ferredoxins, high-potential iron proteins (HiPIPs)),[11] and copper proteins (cupredoxins)[12] have been reported (Figure 1). As many small, soluble metalloproteins are electron transfer proteins, our understanding of biological electron transfer has benefited greatly from NMR. Metalloenzymes tend to have larger molecular masses and thus have been studied less by NMR, although enzymes such as peroxidases and superoxide dismutases have been studied extensively, whereas larger enzymes such as cytochrome P-450 are being tackled in detail only recently. Whereas most NMR studies in the area of metallobiomolecule NMR have focused on metalloproteins, NMR also has provided vital information on binding of metals to RNAs. As our understanding of the varied activities and roles of RNA in biology continues to grow, so will the interest in obtaining detailed information on metal sites in RNA.

Advances in NMR spectrometer and probe technology and in solid-state NMR methods, along with development of new pulse sequences have opened up the biomolecular NMR field to the study of membrane-bound proteins and large molecular weight (MW $>$ 50 kDa) systems. In addition, studies of low-sensitivity nuclei are expected to gain in popularity as the appropriate technical and experimental expertise is developed and refined. Another important area concerns developments in protein engineering that allow preparation of biomolecules isotopically labeled either uniformly or at particular sites. The rapid and continuing development of these methodologies suggests that the footprint of NMR on the metallobiomolecule field will continue to grow into the future.

This article will concentrate on topics most likely to be of interest to inorganic and bioinorganic chemists, and not requiring highly specialized equipment or training. Thus, the focus will be on NMR of soluble metallobiomolecules, as studies of biomolecules in the solid-state and/or bound to membranes are typically reserved for specialists. One exception is that solid-state NMR studies that allow interpretation of data on low-sensitivity quadrupolar metal nuclei (^{25}Mg, ^{67}Zn) will be described briefly because of the direct relevance to inorganic chemistry and the difficulty in characterizing such sites using other spectroscopic methods. Most of the examples and applications will utilize metalloproteins, as the preponderance of NMR studies on metallobiomolecules is on proteins. The application of NMR to metal-binding RNAs will be described in a separate Section 8 as metal binding to nucleic acids is addressed using approaches that are distinct from those usually applied to proteins. In summary, NMR encompasses a broad range of approaches to characterize not only structure but also dynamics and reactivity of metallobiomolecules. Technical developments in the NMR field have been exceedingly rapid, resulting in its application to biomolecules that were considered as recently as the year 2000 to be inaccessible to detailed NMR study. NMR is expected to grow in its importance in the metallobiomolecule field for years to come.

2 TECHNICAL BACKGROUND

NMR spectroscopy probes transitions between nuclear spin states. The transition frequencies and relaxation times contain a wealth of information related to molecular structure and dynamics. Transition frequencies also reveal couplings between nuclear spins, and between electron and nuclear spins. The primary experimental observables in NMR are the chemical shift, which is related to the transition frequency, and the line width, which is related to the relaxation time. In paramagnetic systems, both of these parameters have the potential to be affected significantly by the unpaired electron, requiring special interpretation of data but also revealing information on the nature of the metal site. To make full use of NMR to study complex systems such as metallobiomolecules, it is important to understand the factors that influence observables in NMR.

2.1 The NMR Transition

Nuclei of certain isotopes possess angular momentum, or spin, with an associated quantum number, I. Nuclei with $I \neq 0$ have a nonzero magnetic moment, μ. In the presence of a magnetic field, there are $2I + 1$ possible orientations for the nucleus relative to the applied field, each associated with a different energy described by

$$E_{\mathrm{m}} = \frac{-m\mu B_0}{I} \tag{1}$$

where B_0 is the magnetic field strength and m is a quantum number, which can take on the values of $I, I-1, I-2, \ldots, -I$. In the most familiar case, a nucleus with $I = 1/2$ has m values of $+1/2$ and $-1/2$ and thus two possible energies E_{m}. NMR probes transitions between these states (Figure 2), which are governed by the selection rule $\Delta m = \pm 1$, giving the expression for transition energy

$$\Delta E = \frac{\mu B_0}{I} \tag{2}$$

This expression is often written in terms of the magnetogyric ratio, which is the ratio of the magnetic moment (μ) and the maximum value of the spin angular momentum ($hI/2\pi$):

$$\gamma = \frac{2\pi\mu}{hI} \tag{3}$$

Substituting into equation (2) yields

$$\Delta E = \frac{h\gamma B_0}{2\pi} \tag{4}$$

As $\Delta E = h\nu$, the frequency of the associated electromagnetic radiation is given by the Larmor equation

$$2\pi\nu_0 = \omega_0 = \gamma B_0 \tag{5}$$

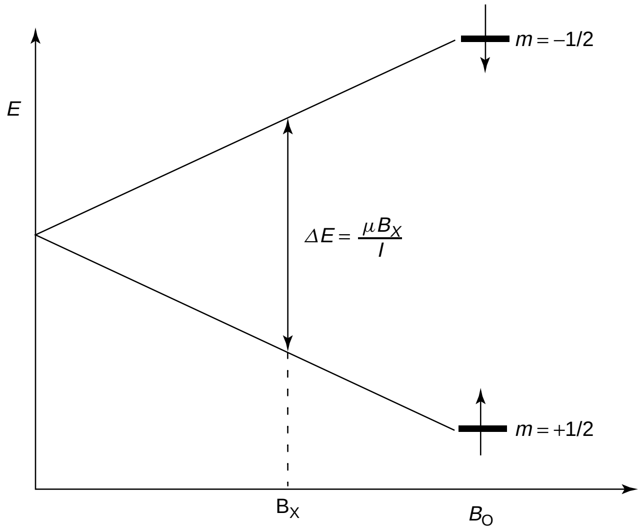

Figure 2 Illustration of the splitting of the $m = +1/2$ and $m = -1/2$ states for a spin-1/2 nucleus by applied magnetic field with strength B_x. The ΔE between these states increases in proportion to field strength

Thus, the frequency of the nuclear spin transition depends on the strength of the applied magnetic field and magnitude of γ for the nucleus. The transition frequency of a particular nucleus is one of the important parameters in NMR and is related to the chemical shift as explained in the next section. The value of γ also determines sensitivity of a given isotope, as ΔE (equation 4) determines the ratio of the number of spins in the upper (n_1) and lower (n_2) energy levels according to the Boltzmann relationship:

$$\frac{n_1}{n_2} = \exp\left(\frac{-\Delta E}{k_{\mathrm{b}}T}\right) \tag{6}$$

Because ΔE is small in NMR compared to many other spectroscopic methods, there exists only a small excess of spins in the lower energy state, giving rise to low sensitivity. This becomes a greater problem for nuclei with low γ values including many that are of interest to bioinorganic chemists (Table 1).

2.2 The Chemical Shift in Diamagnetic Molecules

NMR is a powerful technique for probing the chemical environments of nuclei. Even in large molecules such as metallobiomolecules, signals from individual nuclei can be distinguished from each other as a result of differences in transition frequency. This is expressed as the chemical shift (δ), which relates the transition frequency of the nucleus being examined (ω) to that of a reference nucleus (ω_{ref}):

$$\delta(\mathrm{ppm}) = \frac{10^6(\omega - \omega_{\mathrm{ref}})}{\omega_{\mathrm{ref}}} \tag{7}$$

Table 1 Properties of selected NMR-active nuclei

Nucleus	Spin (I)	γ (10^7 rad s^{-1} T^{-1})	Natural abundance (%)	Larmor frequency at 11.744 T (MHz)	Q (10^{-28} m^2)	Chemical shift range (ppm)[a]
^{1}H	1/2	26.7519	99.98	500	0	50[b]

^{205}Tl	1/2	15.589	70.5	288.54	0	7000

[a] In the absence of unpaired electrons.
[b] Including metal hydrides.

The interpretation of the chemical shift depends on the identity of the nucleus and whether it interacts with unpaired electrons. In general, the immediate chemical environment plays a central role in determining chemical shift. This is a result of the fact that the electrons near the nucleus affect the local magnetic field such that the magnetic field at a nucleus, B_{eff}, is slightly different from the applied magnetic field, B_0. This effect is known as *screening* and is described by a proportionality constant σ:

$$B_{\text{eff}} = B_0(1 - \sigma) \tag{8}$$

As a result, a particular nucleus experiences a transition frequency ω determined by B_{eff} that is slightly different from the Larmor frequency (equation 5), giving rise to chemical shift.

$$\omega = \gamma B_{\text{eff}} \tag{9}$$

The screening constant σ is the trace of a second-rank tensor, the components of which can be observed in solid-state NMR. In high-resolution solution NMR, however, an average value, σ, is measured as a result of rapid reorientation of the molecule in the magnetic field. The screening constant has two components, diamagnetic (σ_{d}) and paramagnetic (σ_{p}):

$$\sigma = \sigma_{\text{d}} + \sigma_{\text{p}} \tag{10}$$

The diamagnetic screening constant describes the circulation of electrons around the nucleus, whereas the paramagnetic screening constant is related to bond orders, internuclear distances, and the energy difference between filled and empty orbitals. For ^{1}H, σ_{d} dominates, but for heavier atoms, σ_{p} becomes the dominant factor. Thus, ^{1}H has a small chemical shift range relative to heavier atoms, but ^{1}H shifts are straightforward to interpret in terms of chemical environment. The complexity of factors contributing to σ_{p} means that, unlike for ^{1}H, heavy atom chemical shifts cannot be interpreted using concepts of local electron density, and chemical shifts for different heavy elements are interpreted differently from each other with significant reliance on comparison to known compounds.

In biomolecular NMR, the nuclei most often utilized are ^{1}H, ^{13}C, and ^{15}N. Each of these nuclei has distinct factors determining chemical shift values. Chemical shifts of ^{1}H can be interpreted in a straightforward manner in the context of local chemical environment, ^{13}C shifts (particularly of backbone Cα nuclei) are an indicator of protein secondary structure, and ^{15}N shifts are determined largely by local bonding interactions. ^{13}C and ^{15}N show greater dispersion than ^{1}H, greatly aiding the obtainment of assignments in biomolecules of larger molecular weight, or that show disorder or poor dispersion in ^{1}H resonances. Factors determining ^{1}H, ^{13}C, and ^{15}N chemical shifts in proteins have been analyzed in detail.[14,15]

2.3 The Chemical Shift in Paramagnetic Molecules

Paramagnetic centers can exert dramatic effects on the chemical shifts of nuclei with which they interact. The observed shift of a nucleus in a paramagnetic molecule is the sum of its hypothetical shift in an isostructural diamagnetic molecule (δ_{dia}) and its shift due to the electron–nucleus (hyperfine) interaction (δ_{hf}), which in turn has dipolar (pseudocontact, δ_{pc}) and scalar (contact, δ_{con}) contributions[16,17]:

$$\delta_{\text{obs}} = \delta_{\text{dia}} + \delta_{\text{hf}} \tag{11}$$

$$\delta_{\text{hf}} = \delta_{\text{pc}} + \delta_{\text{con}} \tag{12}$$

The contributions of δ_{hf} and δ_{dia} to δ_{obs} can be estimated by comparing the chemical shift of a nucleus in the paramagnetic

molecule to its shift in a structurally homologous diamagnetic form. This is most commonly achieved by utilizing a different metal oxidation state within the molecule (i.e., reducing Cu^{II} to Cu^{I}), or substituting with a diamagnetic metal (i.e., Zn^{II} or low-spin Co^{III}). Alternatively, the δ_{dia} values may be estimated using chemical shift prediction programs.

2.3.1 The Fermi Contact Shift

The Fermi contact shift describes the influence of the unpaired electron spin on nuclear chemical shifts as a result of through-bond hyperfine coupling. The contact shift is caused by the presence of unpaired electron spin density at the observed nucleus.**[18,19]** Thus, spin density must be transferred to an s orbital of the nucleus of interest, which is typically achieved through spin polarization. In the case of a single, isolated spin state for a molecule in solution, contact shift can be described by

$$\delta_{con} = \left(\frac{2\pi A}{h}\right)\left[\frac{(g\mu_B S(S+1))}{3\gamma k_B T}\right] \quad (13)$$

where $2\pi A/h$ is the coupling constant for the scalar interaction between the unpaired electron and nucleus, g is the average g value, μ_B is the Bohr magneton, and S is the total electron spin. The $1/T$ temperature dependence of δ_{con}, known as *Curie behavior*, may be utilized to identify contact-shifted nuclei, although deviations from Curie behavior are common. Note that a dependence on magnetogyric ratio is not observed as γ cancels out with a component of A. The hyperfine coupling constant is the key variable determining δ_{con}, and falls off rapidly as the number of bonds between the paramagnetic metal and the nucleus being examined increases. The magnitude of δ_{con} may be assumed to be negligible if the number of bonds between the paramagnetic metal and the nucleus is greater than four, and there are no π bonds. For nuclei in π-bonded systems such as substituents on hemes, δ_{con} can be substantial four or more bonds from the metal.

2.3.2 The Pseudocontact (Dipolar) Shift

The pseudocontact shift results from a through-space interaction between the magnetic moments of the unpaired electron and nucleus as modulated by molecular rotation.**[20,21]** It is described by

$$\delta_{pc} = (24\pi r^3)^{-1}\left[2\Delta\chi_{ax}(3\cos^2\theta - 1) + 3\Delta\chi_{rh}\sin^2\theta\cos 2\phi\right] \quad (14)$$

where $\Delta\chi_{ax}$ and $\Delta\chi_{rh}$ are the axial and rhombic components of the paramagnetic susceptibility tensor χ^{para}, and r, θ, ϕ are the polar coordinates of the nucleus in the metal-centered reference frame of χ^{para}. Thus, δ_{pc} requires an anisotropic magnetic susceptibility tensor, and can be positive, negative, or zero depending on the angular position of the nucleus within this reference frame (Figure 3). Pseudocontact shifts are largest in magnitude for nuclei in molecules with highly anisotropic χ^{para}, such as low-spin Fe^{III} and some of the trivalent lanthanides (Table 2). The dependence of δ_{pc} on the position of the nucleus within χ^{para} makes it a valuable parameter in structure determination and refinement for paramagnetic biomolecules.

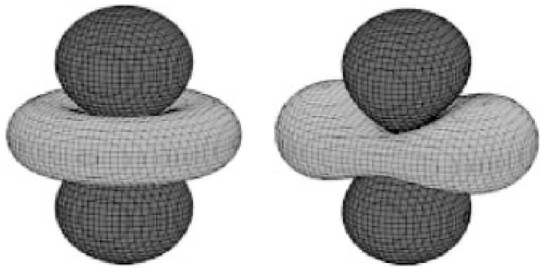

Figure 3 Isopseudocontact shift surfaces calculated from equation (14) with $\Delta\chi_{rh} = 0$ (a) and $\Delta\chi_{rh} = 1/3\Delta\chi_{ax}$ (b). Positive shifts are in dark gray, negative in light gray. (Adapted from Bertini, Luchinat, Parigi and Pierattelli.**[22]** © 2005 Wiley-VCH)

2.4 Nuclear Relaxation

Relaxation is the establishment of the equilibrium distribution of spins after perturbation. For nuclear spins, relaxation is induced by coupling to fluctuating magnetic fields, described by rate constants ($R_1 = 1/T_1$) and ($R_2 = 1/T_2$). T_1 is the spin-lattice relaxation time and is modulated by high-frequency fluctuations, whereas T_2 describes spin–spin relaxation, which in addition to high-frequency fluctuations is also modulated by low-frequency processes such as chemical exchange. T_2 determines line widths according to

Table 2 Magnetic susceptibility anisotropies of selected paramagnetic metal ions[(a)]

[(c)]Assuming $\Delta\chi_{rh} = 0$ and nucleus in axial position relative to χ tensor ($\theta = 0°$).

the following:

$$W_0 = (\pi T_2)^{-1} \quad (15)$$

where W_0 is the homogeneous line width in hertz. The coupling of the nuclear spin to fluctuating magnetic fields is characterized by a correlation time, τ_c, which has contributions from time constants for molecular tumbling (τ_r) and chemical exchange (τ_m) if present, and electron relaxation in paramagnetic systems (τ_s):

$$\tau_c^{-1} = \tau_s^{-1} + \tau_r^{-1} + \tau_m^{-1} \quad (16)$$

Values for τ_s for paramagnetic metals range from 10^{-13} to 10^{-8} s (Table 3), and values for τ_r depend on the size of the molecule and can be roughly approximated by equating τ_r in picoseconds to the molecular weight. Thus τ_r is $\sim 10^{-11}$ s for small molecules, and 10^{-8} to 10^{-7} s for most proteins. In paramagnetic metalloproteins, τ_c is typically determined by τ_s as this is usually the fastest among these three processes in equation (16).[23] The value of τ_c along with transition frequency ω (equation 5) determines the spectral density function $J(\omega)$, which describes the frequencies sampled by a system described by τ_c (Figure 4). This function in turn relates to T_1 and T_2 as shown in Figure 5.

As in the case of the hyperfine shift, both contact and dipolar contributions to nuclear relaxation induced by the unpaired electron are present. In paramagnetic metalloproteins, the primary contribution to relaxation induced by the unpaired electron for most nuclei is the dipolar term, which is described in the fast motion limit ($\omega^2\tau_c^2 \ll 1$) by[23,25]

$$R_{1p,2p} = \frac{4}{3}\left(\frac{\mu_0}{4\pi}\right)^2 \gamma^2 g_e^2 \mu_B^2 S(S+1) r^{-6} \tau_c \quad (17)$$

Table 3 Relaxation properties of selected paramagnetic metal ions[(a)]

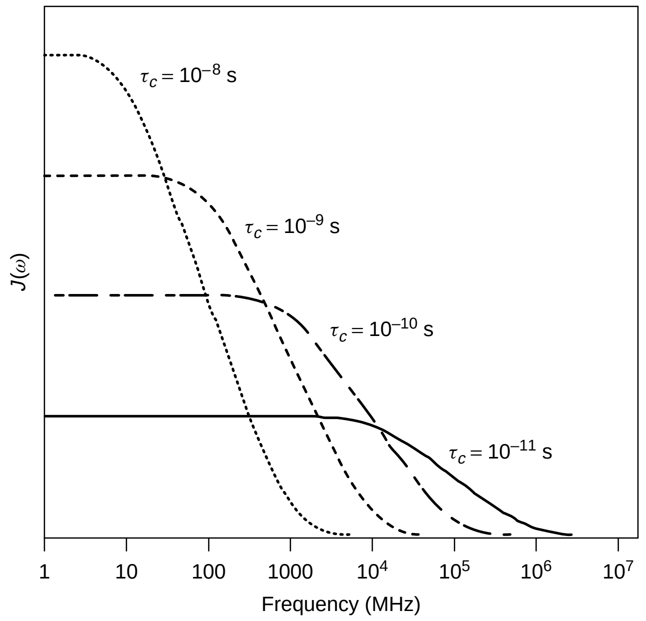

Figure 4 Spectral density function $J(\omega)$ as a function of frequency on a log scale. The functions are calculated for the different τ_c values indicated on the plot. The inflection points occur at $\omega\tau_c = 1$. Note that the vertical scale is not the same for the four curves

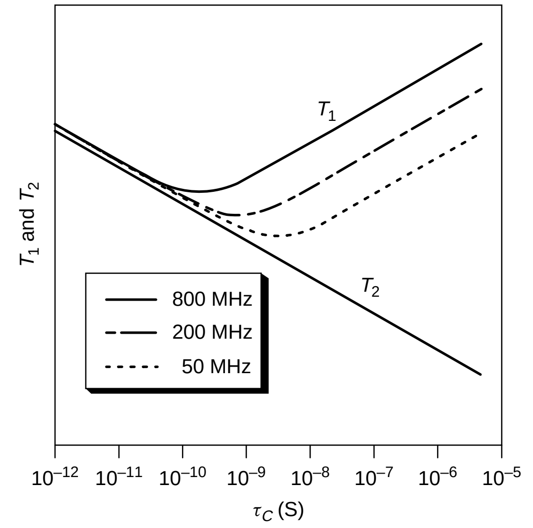

Figure 5 Plot of T_1 and T_2 as a function of τ_c at three different Larmor frequencies. The region where T_1 and T_2 diverge is the slow-motion regime and characterizes relaxation properties of most biomolecules

where the subscript p indicates paramagnetic contribution to relaxation. Although the fast motion limit does not apply to molecules the size of biomolecules (Figure 5), equation (17) provides an approximation of behavior that is helpful for understanding how the properties of the paramagnetic center impact relaxation rates and thus line widths. Relaxation enhancement increases with τ_c, which is usually equal to τ_s in paramagnetic macromolecules. Values for τ_s range over many orders of magnitude (Table 3) and therefore τ_s is key for determining the extent of linebroadening induced by the paramagnetic center. For example, obtaining high-resolution NMR spectra of molecules containing low-spin Fe^{III} is straightforward, as it has a short τ_s and thus induces minimal linebroadening. In contrast, Cu^{II}-containing molecules generally display severe linebroadening as a result of the long τ_s. The dependence of relaxation enhancement on r^{-6} means that information on electron–nucleus distance can be obtained from relaxation measurements, as described in Section 3.4.3.

For macromolecules, the fast motion limit does not apply and T_1 and T_2 diverge (Figure 5). The decreasing value of T_2 with τ_c is the reason large proteins exhibit broad lines (equation 15). Studies of large proteins (MW $>$ 50 kDa) by NMR is thus assisted by transverse relaxation-optimized NMR spectroscopy (TROSY) experiments that yield narrower resonances by optimizing transverse relaxation.[26,27] The increase in T_1 at long τ_c values results in efficient nuclear cross-relaxation, which allows, for example, observation of transfer nuclear Overhauser effects (NOEs) in studies of intermolecular interactions (see Section 6).

An additional relaxation mechanism, Curie relaxation, can become a significant contributor to R_2 and thus line widths when $\tau_s \ll \tau_r$, in other words, for large paramagnetic molecules. Curie relaxation increases with B_0^2 and T^{-2} and thus its presence can be deduced by identifying this magnetic field and temperature dependence.[23,28] Curie relaxation can be a limiting factor in obtaining high-resolution spectra of large paramagnetic biomolecules.

The quadrupole moment (Q) exhibited by nuclei with $I > 1/2$ (Table 1) is an efficient source of nuclear relaxation and depends on the quadrupole coupling constant Cq, which contains nuclear quadrupole moment Q and the electric field gradient at the nucleus. As a result of the dependence on electric field gradient, quadrupole relaxation is highly sensitive to the symmetry of the nuclear environment, making it a valuable observable when it can be determined and interpreted (see Section 7). Quadrupole relaxation can lead to significant linebroadening that makes signal detection difficult, but depends on the nucleus and its environment. For example, Cq of ^{14}N is usually a few megahertz and T_1 values are ∼10 to 20 ms, giving quite broad lines. The situation is more severe for Cl and Br in asymmetric bonds for which Cq may be 100 MHz, giving T_1 values of microseconds. In contrast, Cq is typically small for ^{2}H such that it displays relatively narrow lines.

2.5 Dynamics and Exchange Phenomena

NMR is a powerful tool for the characterization of chemical exchange phenomena and has been widely used for monitoring reactions of metallobiomolecules such as ligand binding and electron transfer. When two or more species interchange to perturb the magnetic environment of one or more nuclei, this process will impact chemical shifts and/or line widths in NMR spectra provided that the process occurs on a timescale to which the experiment is sensitive. The exquisite sensitivity of chemical shifts to environment means that even subtle changes in conformation may be detected. A variety of experiments probing a range of timescales are available; for example, kinetics ranging from $\sim 10^{-2}$ to 10^8 s^{-1} may be probed by ^{1}H NMR. Importantly, timescales directly relevant to chemical reactivity (microseconds to milliseconds) are often accessible.

Depending on the timescale of the process, exchange rates can be measured or estimated, and characteristics of the species in exchange may be discerned. The timescale regime of the process is defined by comparing the time constant for exchange ($\tau_{ex} = 1/k_{ex}$) to the reciprocal of the difference in frequency for the nucleus observed in the two forms A and B in exchange ($|\nu_A - \nu_B| = \Delta\nu$). It is important to consider the rate of the process relative to the experimental timescale in order to select informative experiments and interpret data correctly. The exchange process is commonly described as slow, intermediate, or fast on the NMR timescale (Figure 6). For very slow exchange, the lifetime at each site is long such

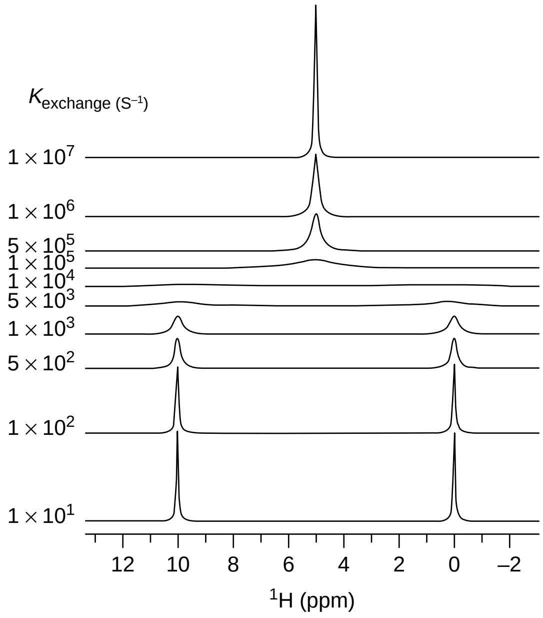

Figure 6 Simulation of ^{1}H NMR spectrum for exchange of a nucleus with $\Delta\nu = 5000$ Hz (10 ppm at 500 MHz) at different exchange rates, showing exchange rates slow, intermediate, and fast on the experimental timescale. Simulation performed using WinDNMR[29]

that sharp lines at ν_A and ν_B are observed, as if no exchange was occurring. For slow exchange causing linebroadening but not coalescence, the first-order rate constant can be related to the observed line width at half height ($W_{1/2}$) according to

$$W_{1/2} = \frac{k_{ex}}{\pi} + \frac{1}{\pi T_2} \tag{18}$$

provided there is minimal overlap between the two peaks. T_2 may be estimated from the line width W_0 in the absence of exchange (equation 15). In the intermediate exchange regime, a highly broadened resonance is observed and if the natural line width is small compared to the observed line ($W_0 \ll W_{1/2}$) the exchange rate can be determined from the following expression:

$$k_{ex} = \left[\frac{\pi(\Delta\nu)}{2}\right]\left[\left(\frac{\Delta\nu}{W_{1/2}}\right)^2 - \left(\frac{W_{1/2}}{\Delta\nu}\right)^2 + 2\right]^{1/2} \tag{19}$$

Under fast exchange ($W_{1/2}/\Delta\nu \ll 1$), a Lorentzian line is observed at the population-weighted mean of ν_A and ν_B, and an approximate expression for the rate constant based on the observed line width can be used:

$$k_{ex} = \frac{\pi(\Delta\nu)^2}{[2(W_{1/2} - W_0)]} \tag{20}$$

In addition to evaluation of line widths and peak separations, analysis of T_1 values and spin saturation transfer can be performed to access a wide range of timescales. Under conditions of slow exchange between forms A and B and upon irradiation at ν_B, the time constant associated with state A (τ_A) can be determined from the measured T_1 of nucleus A in the presence of exchange and the T_1 of nucleus A in the absence of exchange:

$$(T_{1,A}^{app})^{-1} = (T_{1,A})^{-1} + \tau_A^{-1} \tag{21}$$

Equation (21) is applicable in the slow-exchange regime provided resonances A and B do not overlap.

Saturation transfer experiments are useful in the slow-exchange case in which resolved resonances of the two states can be observed simultaneously and the exchange rate is on the same order as the relaxation rates. In this experiment, a resolved resonance at ν_B is saturated, and a change in the corresponding resonance at ν_A is observed. If ν_B is saturated for a period long enough to reach steady state, the ratio of the signal intensity of signal A upon saturation of B (I_{on}) and in the absence of saturation (I_{off}) is related to lifetime τ_A according to

$$\frac{I_{on}}{I_{off}} = \frac{\tau_A}{(\tau_A + T_{1A})} \tag{22}$$

In addition to providing exchange rates, saturation transfer experiments have been useful for assigning resonances in one form of a metalloprotein by obtaining correlations with previously assigned resonances of another form with which it is in exchange. An example of this application is shown in Figure 7.

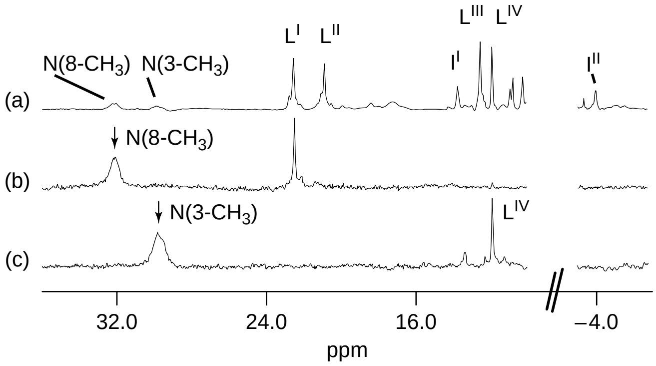

Figure 7 Illustration of the use of saturation transfer to assign ^{1}H NMR resonances of one form of a metalloprotein based on known assignments of another form of the protein. Here, heme methyl ^{1}H NMR resonances of a folding intermediate of horse ferricytochrome *c* in exchange with the native form are assigned. (a) Reference 500-MHz ^{1}H NMR spectrum, 90% H_2O:10% D_2O, 55 °C, 5.4 M urea. (b, c) Difference spectra showing saturation transfer observed (90% H_2O:10% D_2O, 55 °C, 5.4 M urea) upon irradiating the native protein resonances at (b) 32.1 ppm (native 8-CH_3) and (c) 29.8 ppm (native 3-CH_3), allowing assignment of L^I and L^{IV} in species L to heme 8-CH_3 and 3-CH_3, respectively. (Adapted from Russell, Melenkivitz and Bren[30])

2-D exchange spectroscopy (EXSY) is a convenient method for correlating resonances for two species in slow exchange. In theory, the integrations of the cross peaks can be related to the exchange rate; however, 1-D methods provide more precise rate determinations. In the case of paramagnetic proteins, 1-D methods are preferred as the resonance with the shorter T_1, which is often well resolved, can be saturated selectively, in which case the magnetization transfer is under the control of the species with the longer T_1.

Another means by which chemical exchange can be monitored is through isotope exchange. This is most commonly done to determine rates of exchange with solvent for exchangeable protons in biomolecules by transferring the molecule into deuterated buffer and observing the decrease in exchangeable ^{1}H signal intensity with time. Relatively slowly exchanging protons ($k_{obs} < 5 \times 10^{-2}\,s^{-1}$) can be monitored this way. These experiments provide site-specific information on conformational fluctuations in proteins that control local solvent exposure and also probe hydrogen bonding interactions. The application of hydrogen exchange (HX) methods to metalloproteins is discussed further in Section 5.2.

The reader is referred to the monograph by Sandström for a detailed treatment of the subject of dynamic NMR.[31] A helpful tool in evaluating NMR spectra of species in chemical exchange is to perform simulations of spectra, which

can be assisted by the available software.[29] The application of dynamic NMR techniques to study chemical exchange and intermolecular interactions involving metalloproteins is described in Sections 5 and 6.

2.6 Residual Dipolar Couplings

Dipolar couplings result from the dipole moment of one nucleus affecting the dipole moment of another. Dipolar couplings depend on the distance between the spins and the orientation of the vector between the spins with respect to the external magnetic field B_0. In isotropic solution, this effect averages to zero because the molecular reorientation in the magnetic field is fast relative to the reciprocal of the dipolar interaction (i.e., $<$ms for a ^{1}H and a ^{15}N nucleus separated by 1 Å). In a solid sample, in contrast, coupling of each nucleus to many other nuclei is observed, but the result is a spectrum showing severe overlap. The most useful case for obtaining information related to structure is an intermediate case in which partial alignment of a sample relative to B_0 is achieved. In other words, the sample is prepared in such a way that not all orientations of the molecules have equal probabilities. In this case, residual dipolar couplings (RDCs) that provide angular restraints for internuclear vectors (usually bond vectors) relative to the orientation of the applied field can be observed. RDCs (D^{res}, Hz) between nuclei i and j separated by distance r_{ij} are given by[32,33]

$$D^{\mathrm{res}} = -\left[\frac{\left(B_0^2\gamma_i\gamma_j h\right)}{\left(240k_{\mathrm{B}}T\pi^3 r_{ij}^3\right)}\right]\left[\Delta\chi_{\mathrm{ax}}^{\mathrm{mol}}(3\cos^2\theta - 1) + 1.5\Delta\chi_{\mathrm{rh}}^{\mathrm{mol}}\sin^2\theta\cos 2\phi\right] \quad (23)$$

where θ is the angle between the vector connecting i and j (usually bonded ^{15}N–^{1}H) and the z axis of the χ^{mol} tensor, and ϕ is the angle describing the projection of the internuclear vector on the xy plane of the χ^{mol} tensor axes, relative to the x axis. Note that the molecular magnetic anisotropy $\Delta\chi^{\mathrm{mol}}$ has two components, magnetic anisotropy arising from the paramagnetic center, which also gives rise to pseudocontact shifts (equation 14), and the magnetic anisotropy of the diamagnetic protein frame. Such bond orientation restrictions have become important restraints in determinations of biomolecule structure in solution.[34] RDCs are useful for defining long-range order within a molecule because they constrain bond orientations within the frame of the applied field. Because the restraints most used in structure determination by NMR (NOEs, which are usually observed for internuclear distances <5 Å, and J couplings, which are observed only through a few bonds) are local in nature, dipolar couplings provide an important complementary restraint for structure determination. This information is particularly valuable for elongated molecules, and for molecules with multiple domains. Experiments making use of RDCs also can provide insight into biomolecule motions on timescales from picoseconds to milliseconds.[35]

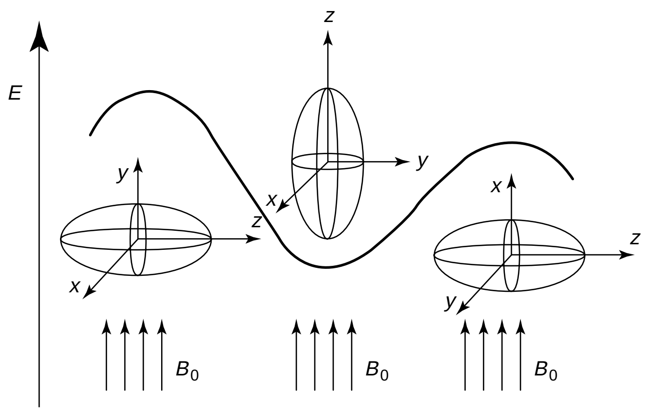

Figure 8 Illustration of a magnetically anisotropic molecule. Its energy depends on its orientation relative to the applied magnetic field, B_0. Thus, it will preferentially adapt orientations with lower energies. (Adapted from Bertini, Luchinat, Parigi and Pierattelli.[22] © 2005 Wiley-VCH)

Metalloproteins have played an important role in the development of RDCs as a tool for structure determination. Pioneering work on RDCs was performed by Prestegard, who showed RDCs could be measured in paramagnetic cyanometmyoglobin.[32] Partial alignment yielding observable RDCs resulted from the interaction of the highly anisotropic paramagnetic susceptibility tensor of cyanometmyoglobin with a strong applied magnetic field (Figure 8). Partial alignment also can be achieved by obtaining NMR data in the presence of a medium that imposes a weak degree of order on the molecule. Bicelles, bacteriophage, and anisotropic gels have been commonly used for this purpose.[34] There has been increased interest in taking advantage of the interaction between an anisotropic paramagnetic metal and B_0 to induce partial alignment, which can be employed on paramagnetic metallobiomolecules or on biomolecules tagged with paramagnetic moieties.[9] The ability of paramagnetic samples to achieve partial alignment is a valuable tool available to the bioinorganic chemist interested in characterizing metallobiomolecule structure and dynamics.

3 APPLICATION TO METALLOPROTEIN STRUCTURE DETERMINATION

NMR has become an important tool for determination of high-resolution three-dimensional structures of biomolecules. As of the end of 2006, over 14% of all structures deposited in the protein data bank (PDB) were determined using NMR,[36] a trend showing tremendous growth since the first NMR structure of a protein was reported in

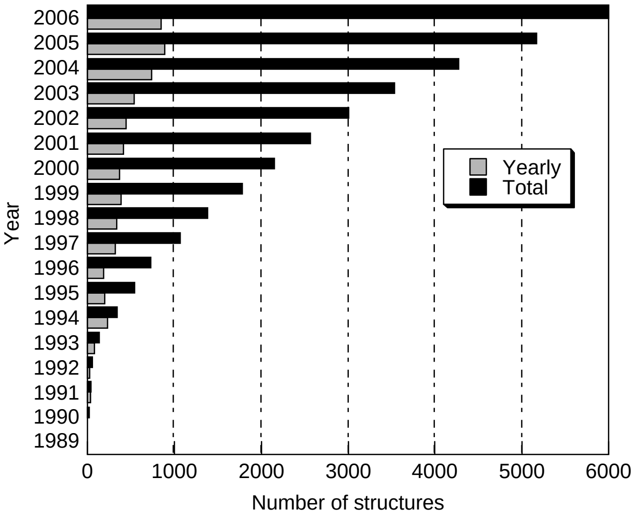

Figure 9 Growth in the number of biomolecule (protein and RNA) structures solved by NMR by year. Data from the Protein Data Bank[36]

1985 (Figure 9).[5] Initially, paramagnetic proteins were considered intractable targets for structure determination because of the challenge of making assignments and identifying NOEs involving nuclei experiencing paramagnetic relaxation enhancement. Today, not only are solution structures of paramagnetic metalloproteins being determined by NMR on a routine basis, but employing paramagnetism-based restraints in structure determinations has been shown to improve structure quality.[8,24,37] The utility of paramagnetic restraints is such that efforts are being put forth to devise paramagnetic tags for nonmetalloproteins for this purpose.[9]

NMR analysis of metalloprotein structure does not necessarily mean performing a complete structure determination, as in some cases this effort is not required to answer the salient questions. Many of the observables in NMR experiments (chemical shifts, NOEs, coupling constants) can be related to specific structural properties of a particular site within a biomolecule. Thus, NMR can provide an efficient means to answer a specific question requiring structural data without performing a complete structure determination. This focused approach is particularly attractive in paramagnetic metalloproteins, as the paramagnetic center endows characteristic properties on nuclei with which it interacts that can allow resonances from these nuclei to be observed and analyzed selectively. Paramagnetic effects on NMR spectra also make it possible to study metal sites in proteins for which a full structure determination is problematic because of size or disorder. Paramagnetic metalloproteins thus have moved beyond being just tractable to being attractive targets for NMR studies. Meeting the challenges of characterizing paramagnetic biomolecule structure has provided new tools useful for NMR studies of all biomolecules.

3.1 Protein Sample Preparation

As a result of the small energies involved in nuclear spin transitions, sensitivity of NMR is inherently low (equation 6), and relatively large amounts of sample are needed, with a typical sample having a minimum of 1 mM biomolecule in 300–500 µL volume. Whereas this amount of sample is usually not limiting in studies of small molecules, it can present a significant impediment to studies of biological samples. If this amount of sample is not available, obtaining a greater number of scans can compensate for low signal-to-noise, but only to a point, as signal-to-noise increases by a factor of $N^{1/2}$ where N is the factor by which the number of scans is increased. Advances in pulse sequences and in probe technology have significantly eased sample requirements. The availability of cryoprobes and microprobes has made NMR studies on significantly lower concentrations and volumes of biomolecule possible; however, these technologies are not always available to the routine user.

The need for large amounts of sample for NMR often requires that the protein be overexpressed, although in some cases sufficient amounts of sample are available from the native source. Overexpression is most conveniently done using *Escherichia coli* as a host. A major advantage of expressing the target protein in *E. coli* is that this often provides a means to prepare isotopically labeled protein. Uniformly labeled (^{15}N and/or ^{13}C) protein can be prepared by growth of *E. coli* containing the appropriate expression plasmid on medium in which the sole source of nitrogen or carbon is labeled with the desired isotope. Minimal medium containing $^{15}NH_4^+$ and/or ^{13}C-glucose is typically used for this purpose, although rich media are available commercially for producing labeled proteins.

Metalloproteins that have been overexpressed may need to be reconstituted with their native metal(s). For example, overexpression of the blue copper protein azurin results in a mixture of apo- and Zn^{II} forms. When a gene of an uncharacterized metalloprotein is expressed, care must be taken to assure that the identity of the native metal is determined through studies of native protein. Overexpression of heme proteins typically requires reconstitution with hemin. In the case of *c*-type heme, the heme must be attached covalently to the polypeptide with the assistance of cellular machinery. Wide success in expressing a range of *c*-heme containing proteins has been achieved by expression of both the structural cytochrome gene and the apparatus for protein maturation.[38,39]

Solution conditions (buffer, ionic strength, pH, and temperature) of the NMR sample should be optimized by monitoring 1-D ^{1}H or 2-D ^{1}H–^{15}N heteronuclear single quantum correlation (HSQC) spectra as a function of conditions to assure the protein is folded as seen by the expected peak dispersion (Figure 10). HSQC data correlate ^{15}N with directly bound ^{1}H and thus provide a probe of each nonproline amino acid. Because pH has a significant effect on exchange rates of exchangeable protons, slightly acidic

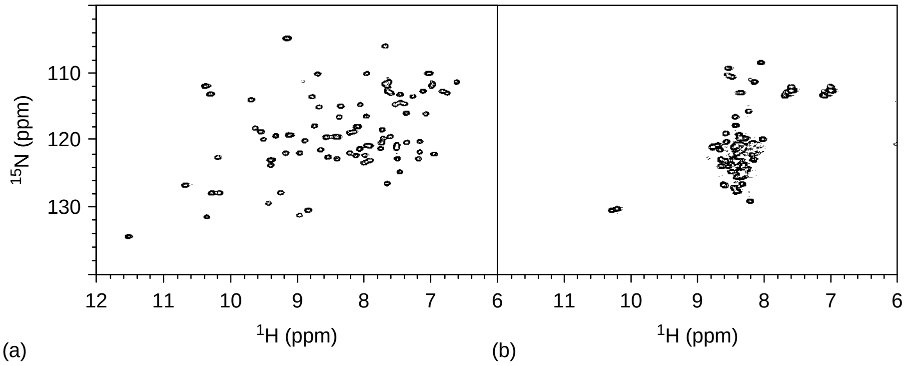

Figure 10 ^{1}H–^{15}N HSQC spectra of 0.5 mM ^{15}N-labeled *Pseudomonas aeruginosa* ferricytochrome c_{551} illustrating effect of protein unfolding on spectral dispersion. (a) Folded protein; note excellent dispersion in both the ^{1}H and ^{15}N dimensions. (b) Unfolded protein (in 8 M urea); note loss of dispersion particularly in the ^{1}H dimension. Proteins displaying partial unfolding or disordered regions will show spectra with properties between these extreme cases

pH values (pH 4 to 6) are often preferred as amide proton exchange rates are minimized at lower pH values, enhancing their detection.

3.2 Data Collection and Analysis for Protein Structure Determination

The experiments required to do a detailed analysis of protein structure are now standard in the case of well-behaved proteins (i.e., well structured, soluble, and relatively small size). What is required are enough experimental restraints (in addition to ''intrinsic'' restraints on bond lengths and angles, van der Waals distances, etc.) to allow a calculation of the structure. Experimental restraints include internuclear distances, dihedral angles, and positions of nuclei or angles of bond vectors within some reference frame. For small proteins (MW $<$ 10 kDa), 2-D homonuclear data alone are often enough to yield assignments of ^{1}H chemical shifts throughout the protein. The most useful experiments for this purpose are nuclear overhauser effect spectroscopy (NOESY), which provides information on through-space connectivities, and total correlated spectroscopy (TOCSY), which provides through-bond correlations over many bonds and thus aids in identification of amino acid side chain spin systems. The key experimental input for 3-D structure determination is the NOE, which scales with internuclear distance in a r^{-6} fashion and thus provides distances between protons relatively close in space (usually $<$5 Å). Coupling constants and, in partially ordered systems, RDCs provide additional restraints. Larger proteins require ^{15}N and/or ^{13}C labeling and use of a suite of multidimensional experiments to obtain sufficient chemical shift assignments and structural restraints because of increased spectral crowding, which is a particular problem for ^{1}H resonances. Compounding this problem for larger proteins is the increase in line widths resulting from efficient R_2 relaxation at long τ_c (Figure 5). The introduction of TROSY methods that optimize transverse relaxation has been a breakthrough for obtaining high-quality spectra of large proteins and has opened up the possibility of determining high-resolution structures of larger proteins, up to 100 kDa.[26,27]

Significant structural information can also be obtained without performing a full structure calculation. For example, chemical shifts of backbone nuclei are sensitive to secondary structure and can be utilized to determine locations of α and β structures within a polypeptide.[14] It also is possible to use protein engineering to incorporate specific amino acid probes, for example, ^{13}C–Leu, or a fluorinated amino acid, for a targeted study. In the case of paramagnetic metalloproteins, the hyperfine interaction allows for application of methods that enhance detection of nuclei in the vicinity of the paramagnetic metal, as explained in more detail in the following sections. This allows detailed information on metalloprotein active site structure to be obtained without determining a full three-dimensional structure.

3.3 Experiments Optimized for Paramagnetic Systems

NMR analysis of a paramagnetic biomolecule may require modifications to the standard experiments. In some cases, this is to compensate for deleterious line broadening caused by unpaired electrons, which interferes with detection of resonances and NOEs. In other cases, modifications are made to take advantage of the effects of unpaired electrons to selectively observe nuclei in the vicinity of the paramagnetic metal. The effects of the metal on the NMR spectrum depend largely on the τ_s value, which determines amount of linebroadening (equations 16 and 17). For systems with relatively short τ_s, few, if any, modifications need to be made, whereas study of systems with long τ_s require specially tailored experiments to obtain any information on nuclei in the vicinity of the metal site.[40]

Enhanced nuclear relaxation leads not only to broad lines, but also to less efficient magnetization and coherence transfer. This has an important impact on the NOE since this

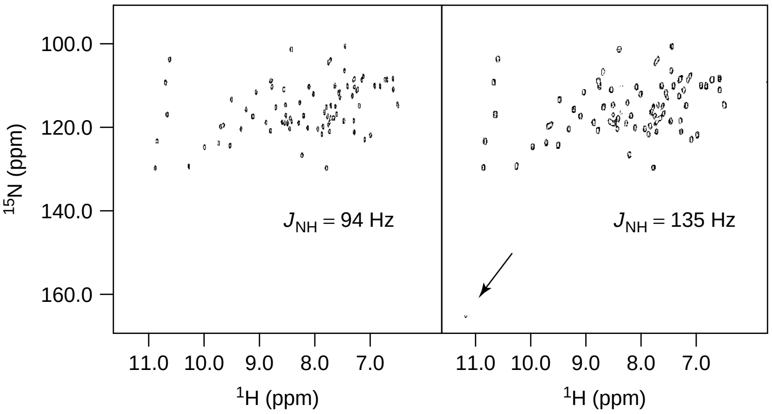

Figure 11 $^1H-^{15}N$ HSQC spectra of 1 mM ^{15}N-labeled *Hydrogenobacter thermophilus* ferricytochrome c_{552} showing the effect of a decreased INEPT delay on intensity of the peak correlating the heme axial His δHN nuclei. The input J_{NH} value is 94 Hz in (a), and 135 Hz in (b). The axial His δHN is readily observed in spectrum (b) (indicated with arrow), but is not detected under conditions used in (a)

effect is dependent on dipole–dipole relaxation. For nuclei with short T_1 values, detection of NOEs is aided by using a 1-D steady state NOE experiment rather than a transient NOE experiment (including the 2-D NOESY). In the steady state 1-D NOE, if the rapidly relaxing nucleus is saturated, the observation of the NOE depends only on the T_1 of the more slowly relaxing nucleus, aiding NOE detection. In 2-D NOESY and TOCSY experiments, mixing and spin-lock times may need to be adjusted to account for these effects. Often, collection of a spectrum with a shorter mixing or spin-lock time relative to standard values will reveal cross peaks involving rapidly relaxing nuclei. Similarly, decreasing the insensitive nuclei enhanced by polarization transfer (INEPT) delay times in an HSQC experiment will enhance peaks for nuclei with short T_1 values (Figure 11). Applying these methods can afford the advantage of identifying resonances from nuclei near the metal, even if they do not have unusual chemical shifts. In addition, experiments optimized to detect nuclei with short T_1 values can be performed with significantly faster repetition rates, thus allowing more scans to be acquired in a given amount of time. A detailed account of optimization of NMR data collection and processes for paramagnetic biomolecules has been provided by La Mar.[40]

Nuclei with low magnetogyric ratios experience weaker dipolar coupling with unpaired electrons because the coupling energy depends on γ^2. For example, for ^{13}C the line width enhancement from dipolar relaxation will be 1/16 of that seen for ^1H (equation 17). Thus for heteronuclei hyperfine coupling information is lost far from the paramagnetic center, but the decreased paramagnetic linebroadening may allow detection of residues not observable in ^1H NMR experiments. Detailed studies of nuclei near metal sites with long τ_s values thus benefit from detection of heteronuclei. ^{13}C is attractive as it provides a balance between a γ that is smaller than that of ^1H to decrease relaxation enhancement, but not so small that sensitivity becomes a limiting factor. A number of experiments have been designed to take advantage of this effect (e.g., see Figure 12).[41]

3.4 Characterization and Refinement of Metalloprotein Structure Using Paramagnetic Effects

The effects of the hyperfine interaction on NMR properties of nuclei can be exploited to obtain information on molecular structure beyond what is available using ‘‘traditional’’ restraints such as NOEs and coupling constants.

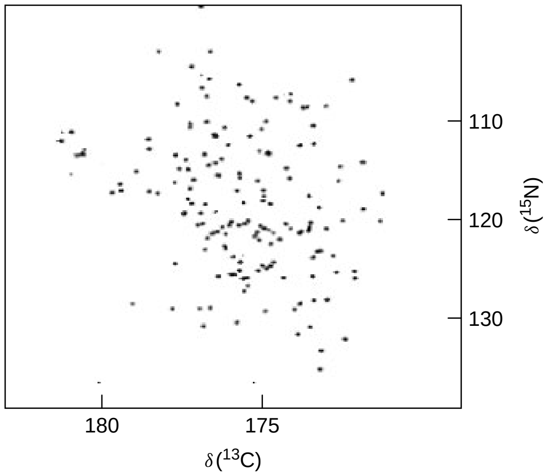

Figure 12 2-D in-phase–antiphase spectrum correlating backbone ^{13}C and ^{15}N nuclei, with detection of ^{13}C (CON-in-phase-antiphase (CON-IPAP) experiment). Data were acquired on a 1.5 mM sample of ^{13}C, ^{15}N labeled reduced monomeric superoxide dismutase with a 14.1 T Bruker Avance spectrometer equipped with a cryogenically cooled probehead optimized for ^{13}C detection at 298 K. (Reprinted from Bermel, Bertini, Felli, Piccioli and Pierattelli.[42] © 2006, with permission from Elsevier)

Through-space (dipolar) and through-bond (contact) interactions can be employed to perform a focused study of the structure of a paramagnetic metal-binding site in a protein, or to obtain additional structural restraints for determination of a full solution structure. This section is dedicated to the analysis of global molecular structure. Examples of focused studies of metal site structure are given in Section 4.

3.4.1 Pseudocontact (Dipolar) Shifts

Metal sites with anisotropic paramagnetic susceptibility tensors (χ^{para}) will induce pseudocontact shifts, δ_{pc}, on nuclei. The magnitude and sign of δ_{pc} are determined by the position of the nucleus relative to the principal axes of χ^{para}, centered at the metal, according to equation (14). The pseudocontact shift has both a distance and angular dependence, making it a valuable structural restraint for molecules in which the orientation of χ^{para} can be defined relative to the molecular frame. The value of δ_{pc} for a nucleus may be estimated experimentally by comparing the observed chemical shift in a paramagnetic system δ_{obs} with the chemical shift of the same nucleus in a diamagnetic reference system (which gives an estimate of δ_{dia}, equations (11), (12), and (14)). For example, a reduced, low-spin Fe^{II} heme protein may be used as a diamagnetic reference for the paramagnetic oxidized form, provided no significant structure change occurs with redox state change. The δ_{pc} values may then be obtained by subtraction ($\delta_{obs} - \delta_{dia}$), provided there is no contact contribution to the shifts, which will be the case for any nuclei not on moieties bound directly to the paramagnetic metal. The values defining the magnetic axes may then be calculated using equation (14) as was originally described by La Mar.[43] If one knows the axes and anisotropy of χ^{para}, a δ_{pc} value for a nucleus restrains its position within that frame of reference.

Pseudocontact shifts serve as a link between molecular and electronic structure, allowing the magnetic axes to be defined relative to the molecular frame. This interrelationship has been put to use in an iterative procedure for calculating χ^{para} tensor axes and anisotropies and refining molecular structure based on initial input data (Figure 13).[8] In addition, the pseudocontact shifts can be related to the heme axial ligand orientations as illustrated in Figure 14. Most pseudocontact shift refinements of structure have been on low-spin Fe^{III} heme proteins, although trivalent lanthanides also have been used for this purpose. Because the δ_{pc} values are greatest near the metal center, the additional structural restraints are identified in a region of the protein that frequently lacks restraints due to loss of NOE intensities. By including pseudocontact shift restraints, the structure near the paramagnetic center can be much more well defined than when solely traditional restraints are relied upon. Standard structure calculation programs now routinely provide means to incorporate pseudocontact shift restraints.[44]

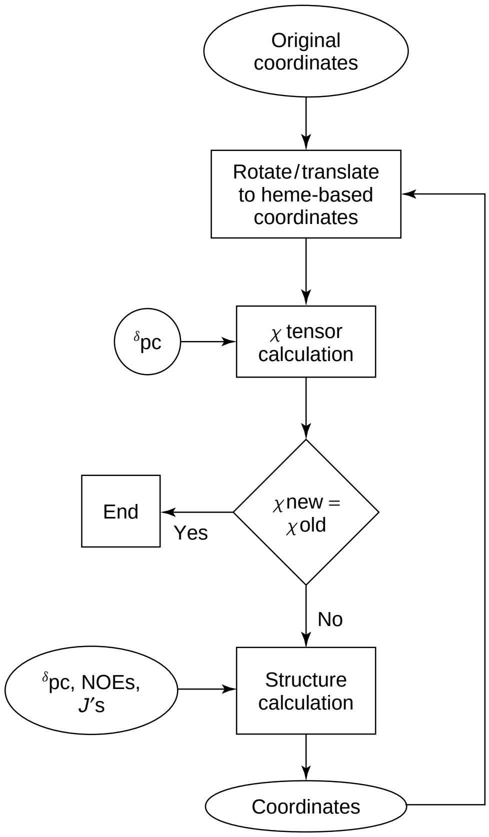

Figure 13 Flowchart for refinement of NMR solution structures and the parameters defining χ[8]

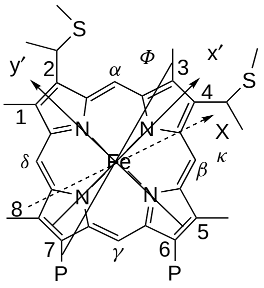

Figure 14 Relationship between orientation of magnetic axes and heme ligand orientation. The coordinates x and x' indicate the x axis in the magnetic and molecular coordinate systems, respectively. The solid line indicates the axial ligand orientation angle Φ (i.e., the plane of an imidazole ring), and the dashed line indicates κ, which is the orientation of χ_{xx}. The ligand orientation determines magnetic axes orientation according to $\kappa = -\Phi$. The orientation of axial ligands to the heme also determine contact shifts, as the ligand orientation determines which heme π orbital contains the largest unpaired electron spin density

3.4.2 Contact Shifts

Contact shifts are determined by unpaired electron spin density at the nucleus being observed (equation 13) and

provide structural restraints for a limited number of nuclei as this effect becomes minimal more than a few bonds from the metal in most cases. Nevertheless, nuclei connected to a paramagnetic metal through bonds may lack observable NOEs such that obtaining a few contact shift restraints on their positions may provide a significant improvement on structure of the metal coordination environment. Contact shifts can be determined by subtracting the reference diamagnetic shift from the observed shift in the paramagnetic system, provided the pseudocontact shift does not contribute, or the pseudocontact shift contribution is determined and subtracted (equations 11, 12 and 14).

Contact shifts for nuclei three bonds from the metal are dependent on dihedral angle θ through a Karplus-type relationship:

$$\delta_{\text{con}} = a\cos^2\theta + b\cos\theta + c \tag{24}$$

where the coefficients depend on the nature of the bonds and atoms between the metal and nucleus in question and have been determined heuristically.[45] This analysis has been applied to the definition of dihedral angles between iron and βCH_2 protons of coordinated Cys residues in iron–sulfur proteins. Nuclei near iron–sulfur sites typically exhibit severe linebroadening, and incorporating these restraints can play an important role in defining metal site structure.

There have been extensive studies relating heme substituent shifts, some of which are dominated by the contact contribution, to the type and orientation of the heme ligands.[46] Thus, the chemical shifts for the heme substituents provide information on heme ligand type and orientation.

3.4.3 Dipolar Relaxation Enhancement

Paramagnetic enhancement of R_1 in macromolecules (R_{1p}) primarily depends on dipolar coupling between the electron and nuclei and is proportional to r^{-6} (equation 17). Thus, relaxation enhancement contains electron–nucleus distance information, although the enhancement diminishes sharply as distance increases. The metal-centered sphere in which this effect can be measured depends on the molecule studied and the properties of the metal, especially the τ_s; metals with longer τ_s will exert greater effects on relaxation. To use relaxation enhancement as a restraint on structure, a reference R_1 value from a diamagnetic system is needed. This may be determined on a diamagnetic homolog, or estimated from R_1 values of nuclei within the molecule at a distance far from the paramagnetic center. R_{1p} is taken as the difference between the observed and reference R_1 values. This approach has been used, for example, to refine the structure of a Fe_4S_4 ferredoxin. Inclusion of relaxation constraints led to a substantial improvement of the structure near the iron–sulfur cluster relative to the structure obtained using conventional constraints in particular, because of the difficulty of observing NOEs near the cluster.[22] Caution is called for in interpretation as nonlinear dependence on r^{-6} has been observed at longer distances, which may result from effects of spin delocalization.[41] Similarly, R_{2p} values, which contribute to R_2 and thus line widths, may be employed as constraints. When interpreting R_2 values, contributions from Curie spin relaxation and chemical exchange must be considered. Relaxation enhancement has also been applied to NMR studies of RNAs as described in Section 8.

3.4.4 Residual Dipolar Couplings

RDCs provide information on angular orientations of bond vectors relative to the applied magnetic field (Section 2.6). For measurement of RDCs it is required that the molecule take a preferred orientation relative to the external magnetic field, which is usually achieved by including an alignment medium in the sample.[34] In principle, all biomolecules in solution will take on a preferred orientation relative to B_0 as a result of magnetic susceptibility anisotropy, but in practice RDCs will be observable only at high B_0 and highly anisotropic $\Delta\chi^{para}$. Prestegard's seminal study on cyanometmyoglobin demonstrated paramagnetic-induced alignment and also the ability to determine relative orientations of helices within the protein through analysis of RDCs.[32]

With their typically high magnetic anisotropies, low-spin ferric heme proteins are attractive candidates for structure analysis using RDCs, as they may achieve a degree of orientational preference within the applied field significant enough to allow observation of RDCs. Low-spin ferric heme proteins that have been analyzed in this way include the alkaline form of a cytochrome *c* mutant, cytochrome b_5, and *E. coli* cytochrome b_{562}.[37,47,48] Proteins that bind the paramagnetic lanthanide ions with high magnetic anisotropies are also attractive candidates for self-orientation (Table 2). Substitution of trivalent lanthanides for calcium in calcium-binding proteins has been a useful approach as the lanthanides are known to substitute for Ca^{II} and typically maintain a nativelike coordination environment. For example, the calcium-binding protein calbindin D_{9k} substituted with trivalent lanthanides was shown to self-orient to yield observable dipolar couplings to aid solution structure determination.[49] A means of preparing self-orienting samples of diamagnetic proteins and even proteins that do not bind metals is to attach a lanthanide-binding tag or to prepare a fusion protein with a lanthanide-binding domain such as an EF-hand.[9]

RDC restraints can be incorporated into structure calculations using modules available in standard structure determination software as well as programs developed specifically for RDC analysis.[37,50] They are expected to be particularly helpful for determining structures of large proteins or any system for which obtaining sufficient restraints is difficult. RDCs also are valuable for characterizing elongated, multidomain, or other nonglobular proteins as they define relative orientations of distant bond vectors. For example, in a two-domain protein, few NOEs may be observed between the domains, making the determination of their relative

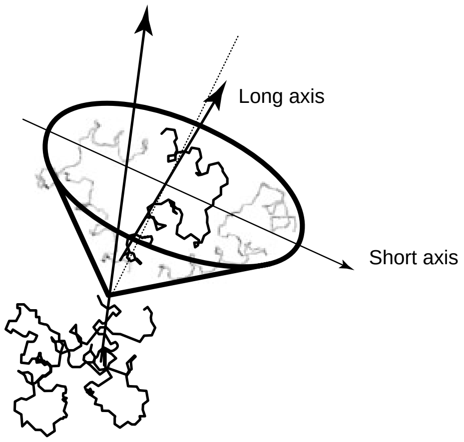

Figure 15 Cone containing three conformations of the C-terminal domain of calmodulin providing pseudocontact shifts and residual dipolar couplings consistent with experimental data. (Adapted from I. Bertini *et al.* (2004) *Proc. Natl. Acad. Sci. U. S. A.*, **101**:6841–6846. © 2004 National Academy of Sciences, USA)

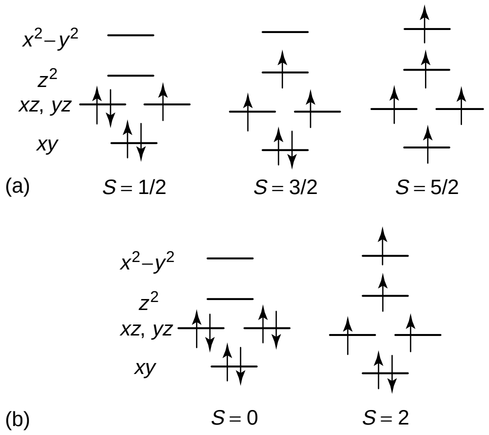

Figure 16 Spin states displayed by ferric (a) and ferrous (b) heme

orientations difficult. Measuring RDCs for the two domains however, allows the definition of the orientation of each domain relative to a common external frame of reference, and thus relative to each other (Figure 15). The increased availability of high-field spectrometers and methods for creating self-aligning samples, coupled with ongoing efforts to push the size limit of biomolecules for which NMR structures can be determined, is expected to result in increased use of RDCs in the future.

4 APPLICATION TO CHARACTERIZATION OF METAL SITES IN METALLOPROTEINS

The goal of many biomolecular NMR studies is characterization of global molecular structure. In metallobiomolecules, and in particular, for paramagnetic species, it is sometimes preferable to use NMR to perform a more focused study of the metal ion coordination environment and the metal electronic structure. Metal sites show great variation in the effects on chemical shifts and line widths and thus often call for tailored approaches. In this section, characteristics of some of the metalloproteins metal sites most frequently studied by NMR are summarized. Examples have been selected to illustrate approaches described in this chapter such as metal substitution, use of pseudocontact shifts, RDCs, relaxation enhancement, and detection of nuclei other than ^{1}H.

4.1 Heme

Heme is found in proteins and enzymes and performs a wide range of biological functions. Heme also exhibits a range of oxidation and spin states, with the ferric and ferrous states usually being the most stable. Low-spin Fe^{II} heme has filled t_{2g} orbitals and is diamagnetic, whereas high-spin Fe^{II} heme has spin state $S = 2$. Ferric heme is paramagnetic but can be found in low- ($S = 1/2$), intermediate- ($S = 3/2$), or high-spin ($S = 5/2$) states, depending on heme ligation (Figure 16).

Heme proteins containing low-spin Fe^{III} have played important roles in the development of NMR techniques for paramagnetic proteins. Low-spin ferric heme proteins are popular targets for NMR study because they display minimal linebroadening (due to short τ_s) and large pseudocontact shifts (due to large χ anisotropy). Other than using a larger than usual spectral width, few accommodations need to be made for the paramagnetism to obtain high-resolution spectra, and in fact the large chemical shift range increases dispersion, in particular, for ^{1}H. Early studies related chemical shifts of heme substituents of paramagnetic cytochromes *c* to the heme axial methionine orientation; this has evolved to a detailed understanding of how heme axial ligand orientations determine contact and pseudocontact shifts of heme substituents.[43,46] Cyanometmyoglobin was the first protein for which magnetic axes were calculated on the basis of pseudocontact shifts,[43] and was the subject of an early study of RDCs.[32] The favorable properties of low-spin ferric heme also allows direct analysis of axial ligand resonances, providing vital information on how hydrogen bonding to axial ligands tunes heme electronic structure and redox potential.[10]

High-spin ferrous heme has functional importance as an intermediate of several heme enzymes. Deoxy-hemoglobin and deoxy-myoglobin also have high-spin ferrous heme. Nevertheless, there are relatively few NMR studies of $S = 2$ heme because of the high amount of linebroadening exacerbated by Curie spin relaxation, which results in poorer resolution at high magnetic fields. High-spin ferric heme is the resting state of many heme enzymes. Linebroadening is less severe than for high-spin ferrous heme as a result

of a faster electron spin relaxation time. Despite the ^6A symmetry of the high-spin heme ground state, zero field splitting introduces anisotropy that induces pseudocontact shifts; this is also the mechanism through which electronic relaxation is made relatively efficient. Proteins containing high-spin ferric heme nevertheless, display a substantial amount of linebroadening that often calls for specially tailored experiments. An example is the study of the hemophore HasA (proposed to exhibit a mixture of $S = 5/2$ and $S = 1/2$ states) using ^{13}C- and ^{15}N-detection, including specially tailored 2-D experiments in which ^{13}C is detected. Ferric HasA (His/Tyr$^-$ axial ligation) has extremely short T_1 values for residues near the heme, hindering ^1H NMR approaches. ^{15}N and ^{13}C-detected experiments, however, yielded assignments for heme axial ligands, which in turn allowed characterization of a functionally relevant hydrogen bond to the axial Tyr ligand.[51] Another important development has been preparation of selectively labeled hemes by Rivera and coworkers. Chemical shifts of ^{13}C resonances of high- and intermediate-spin ferric hemes have been related to porphyrin conformations relevant to the function of the heme-degrading enzyme heme oxygenase.[52]

4.2 Iron–sulfur centers

Iron–sulfur proteins are challenging targets for NMR because of the significant linebroadening they typically display. At the same time, NMR is a valuable approach for the study of iron–sulfur proteins as it provides a way to probe properties of the ligands to the individual iron ions within the cluster, thus allowing the electronic coupling among the iron ions to be examined in detail. Mononuclear iron protons such as rubredoxin display extremely broad lines, especially in the ferric state. Many NMR studies have thus utilized proteins substituted with diamagnetic metals (Zn^{II} or Ga^{III}). Detection of low-γ nuclei, however, has provided a means to directly study mononuclear Fe^{II} and Fe^{III} sites. For example, in *Clostridium pasteurianum* rubredoxin containing a single Fe^{II} or Fe^{III} ion, ^{15}N hyperfine shifts of amide ^{15}NH groups that hydrogen bond with Cys γS ligands to iron (Fe–S–H–N) in a series of mutants have been analyzed to determine electron spin density delocalized to the ^{15}N, which in turn was related to redox potential tuning.[53] Iron–sulfur cluster proteins (Figure 17) are more tractable for NMR than the mononuclear systems because coupling between the iron ions enhances electron relaxation. The Fe_4S_4 and Fe_3S_4 proteins in particular display narrower lines than the mono and dinuclear iron–sulfur proteins and can be studied directly using ^1H NMR methods.

4.3 Copper

Copper ions are found in electron transfer proteins such as the cupredoxins and in enzymes such as Cu–Zn superoxide dismutase. Cu^{II} has a long τ_s and is thus effective

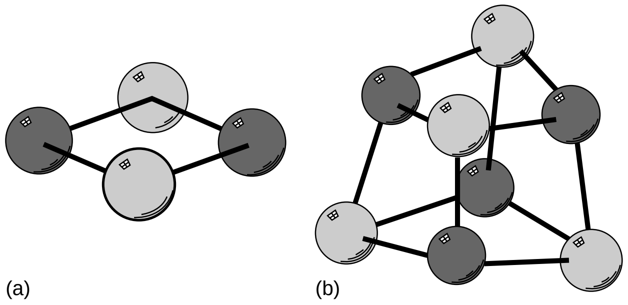

Figure 17 Structure of a Fe_2S_2 (a) and Fe_4S_4 (b) cluster, with the Fe atoms in dark gray. Cys are the most common ligands to Fe, but other amino acids such as Asp and His also bind Fe in clusters

in enhancing nuclear relaxation. As a result, ^1H resonances of ligands to Cu^{II} are typically broadened beyond detection. NMR studies of mononuclear Cu^{II} proteins such as the cupredoxins have usually made use of variants substituted with diamagnetic Zn^{II}, or paramagnetic ions with shorter τ_s values such as Co^{II} or Ni^{II}. New methodologies have now provided means to directly study mononuclear Cu^{II} proteins. An example is the use of specialized experiments to observe the extremely broad ^1H resonances for Cu^{II} ligands in *Anabaena variabilis* plastocyanin. Relaxation rates of rapidly relaxing contact-shifted signals have been measured using the signal eliminating relaxation filter (SERF) experiment. This experiment involves substituting the 180° inversion pulse of the conventional inversion-recovery sequence with a SERF consisting of three 180° pulses separated by two variable delays. The SERF experiment allows a selective suppression of signals with relaxation rates below a given limit while monitoring the relaxation of faster relaxing signals. Secondly, a saturation transfer experiment was used to detect broadened signals not actually observed in the NMR spectrum. Employing these methods allowed the measurement of paramagnetic relaxation enhancement of protons close to the metal site and the distribution of the unpaired electron spin onto the ligand atoms. These paramagnetic restraints supplemented conventional restraints to allow determination of geometric metal site structure directly on the Cu^{II} protein.[54]

As with iron-containing systems, coupling between copper ions results in longer electron spin relaxation times and thus narrower NMR lines. This was first demonstrated in a protein in the study of the soluble Cu_A fragment of cytochrome *c* oxidase (Figure 18).[55] Whereas ligand ^1H nuclei are not directly observable in mononuclear Cu^{II} systems, in oxidized (Cu^{II}–Cu^{I}) Cu_A, many ligand ^1H resonances are readily assignable. Strong Cu–Cu coupling is evident both in the relatively long nuclear T_1 values (reflecting a short τ_s) and in the similar hyperfine shifts of the ligands to the two coppers, indicating that the Cu^{II}–Cu^{I} site behaves as a $Cu^{+1.5}$–$Cu^{+1.5}$ site. In addition, the high (100–300 ppm) chemical shifts of βH_2 protons of the bridging Cys residues, dominated by the contact shift, reveal a high amount of electron

spin delocalization onto the ligands. It is suggested that this delocalized nature enhances electron transfer by reducing reorganization energy and increasing electronic coupling.

4.4 Zinc

Zinc plays an essential role as a cofactor in many metalloproteins and as a regulatory agent in cell homeostasis.[1] Zn^{II} has a preference for tetrahedral geometry and can thus serve a structural role, for example, templating the folding of ubiquitous zinc finger domains.[56] Zn^{II} also plays catalytic roles, for example, activating water through polarization or ionization in hydrolytic enzymes.[57] Although Zn^{II} displays a wide range of functions in nature, it has been subjected to fewer spectroscopic studies than many other metals because its closed-shell nature makes its direct study difficult. One approach is to perform ^{67}Zn NMR using solid-state NMR experiments, described in Section 7, although this is a highly specialized approach. Other NMR studies of Zn^{II} proteins performed to probe active site properties have made use of variants substituted with paramagnetic metals. Co^{II} exhibits coordination properties similar to Zn^{II}, and also has properties favorable for NMR as it induces hyperfine shifts on active site nuclei and does not induce excessive broadening. NMR studies of Zn^{II} proteins substituted with Co^{II} have been performed on Zn^{II} enzymes as well as on zinc finger proteins.

4.5 Calcium

Ca^{II} plays diverse roles in biology, displaying structural, catalytic, and regulatory functions. The importance of Ca^{II} in signal transduction has piqued great interest in its interactions with proteins. NMR has been extremely valuable for probing the effects of Ca^{II} binding on protein structure and dynamics, providing vital information on the regulatory role of calcium. A large superfamily of calcium-binding proteins, the EF-hand proteins, have been most studied by NMR. The EF-hand motif itself is small, and may be studied in isolation from other EF-hand domains as these domains are often connected by flexible linkers. However, the flexibility of such linkers introduces challenges in NMR study of multidomain EF-hand proteins as it reduces interdomain NOEs, making it difficult to determine relative orientations of the domains.

As Ca^{II} is diamagnetic, substitution is necessary to take advantage of paramagnetic effects on NMR spectra. Trivalent lanthanides have been shown to substitute for Ca^{II} without significantly altering protein structure, and are an attractive paramagnetic probe because of their short τ_s values and large paramagnetic anisotropies (Table 2). Thus, they do not cause significant linebroadening, but do induce pseudocontact shifts. In addition, they may be used to achieve partial alignment in the magnetic field so that RDCs may be observed. This approach is particularly helpful for obtaining restraints of EF-hand domains relative to each other. An example of the use of lanthanide substitution is di-Ce^{III} substituted calmodulin, a protein with two EF-hand motifs. The addition of T_1 and pseudocontact shift restraints was shown to significantly improve the solution structure.[58] In another example, the ability to observe RDCs in calbindin D_{9k} substituted with a range of lanthanide ions was also reported. In addition to characterizing structure, it is possible to assess mobility of domains through RDC analysis.[49]

5 APPLICATION TO CHARACTERIZATION OF INTERNAL METALLOPROTEIN DYNAMICS

It is now appreciated that a full description of the physicochemical basis for biomolecular function must consider the thermally accessible motions of the biomolecule in addition to the average structure. Protein flexibility has been invoked in a wide range of biological processes including folding and assembly, ligand binding and catalysis, and regulation and signal transduction.[59–61] NMR has proved to be a particularly powerful tool for analysis of biomolecule motions, as it provides probes of motions in solution occurring on timescales ranging from picoseconds to milliseconds and longer. In addition, NMR provides site-specific information on polypeptide motion, aiding elucidation of the relationship between dynamics and function.[62,63]

5.1 Nuclear Relaxation Studies of Backbone Dynamics

Molecular motions modulate fluctuating magnetic fields that induce nuclear spin relaxation. Nuclear relaxation properties thus contain information on these motions. A majority of relaxation studies of protein dynamics have

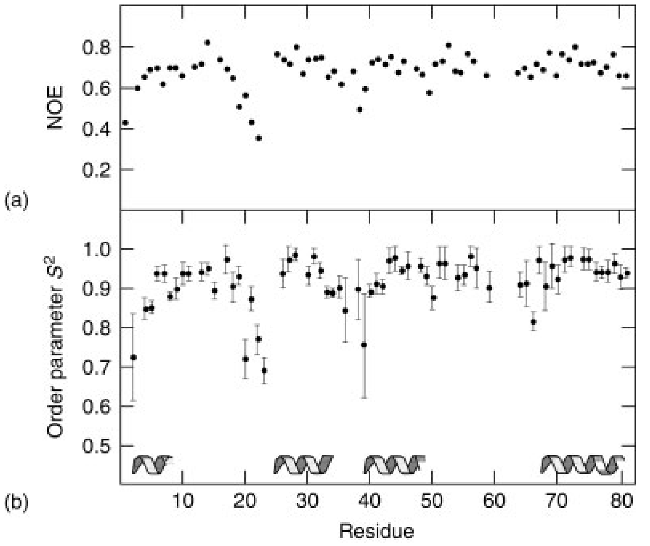

Figure 19 Results of ^{15}N relaxation experiments on *Pseudomonas aeruginosa* ferricytochrome c_{551}, collected at 298 K on a 500-MHz spectrometer. Values for (a) $\{^1H\}-^{15}N$ NOE and (b) order parameter S^2 are shown. Order parameters are calculated from relaxation data and reflect the magnitude of picosecond–nanosecond timescale motions of backbone N–H bond vectors. S^2 ranges from 0 to 1 with 1 indicating a rigid bond vector in the molecular frame. Helices at the bottom of the figure indicate α-helical regions of the protein; the helices are connected by loops. (Figure prepared from data published in Russell, Zhong, Bigotti, Cutruzzolà and Bren[65])

focused on the polypeptide backbone ^{15}N nuclei. One reason for this is convenience; ^{15}N labeling of metalloproteins is economical and also provides one probe of backbone motion per amino acid residue. Methods for collecting and analyzing ^{15}N relaxation data are well established.[62] Analyzing backbone amide ^{15}N relaxation properties also yields a general picture of dynamics, as backbone conformation defines secondary structure and the overall fold. Relaxation of protonated nitrogen nuclei is typically described by their R_1 and R_2 values as well as the heteronuclear $\{^1H\}-^{15}N$ NOE, measured using standard $^1H-^{15}N$ correlation spectra.[64] Of these parameters, the heteronuclear NOE is the most straightforward to interpret directly; its magnitude is determined by rapid ($\tau < \tau_r$) internal motions. R_1 and R_2 are also influenced by rapid motions, but slower motions provide an additional contribution to R_2. Other relaxation parameters also may be measured, in particular, to characterize slower motions (microseconds). The R_1, R_2, and NOE may be interpreted using the Lipari–Szabo model-free treatment, which yields magnitudes of N–H bond vector motions (order parameters, S^2) from relaxation data. An example of these results is shown in Figure 19. In nuclear relaxation studies of paramagnetic metalloproteins, care needs to be taken to account for enhanced relaxation imparted by the paramagnetic center, as otherwise interpretation of data cannot be made simply on the basis of dynamics. This is not a significant problem for ^{15}N nuclei because the effect is attenuated 100-fold in comparison with ^{1}H nuclei, according to equation (17), as $(\gamma_H/\gamma_N)^2 \sim 100$.

Relaxation studies of metalloproteins have revealed effects of metal binding and metal redox state on backbone dynamics.[66] Calcium-binding proteins have been a favorite subject of dynamics studies and show significant changes in flexibility induced by metal binding. For example, backbone dynamics changes upon metal binding have been correlated with cooperativity of Ca^{II}-binding in EF-hand proteins. Dynamics of electron transfer proteins have also been characterized, although the direct functional significance is less clear. Some electron transfer proteins have been shown to display enhanced mobility in regions of the protein proposed to interact with redox partners. For example, a surface hydrophobic patch of *Pseudomonas aeruginosa* cytochrome c_{551} with particularly high mobility is the site of interaction with its physiological electron acceptor, nitrite reductase.[65] Similarly, in the blue copper protein azurin, the hydrophobic patch proposed to be the port of entry for electrons is characterized by large magnitude nanosecond timescale mobility. In addition, longer timescale motions of active site residues are proposed to play a role in a gated electron transfer mechanism.[67]

5.2 Hydrogen Exchange Experiments

Whereas relaxation experiments to probe biomolecule dynamics have become popular only within the past 10 years, HX experiments have been performed on proteins for many decades. Provided that the experiment is carried out under conditions favoring the native protein state, thermodynamics of conformational fluctuations that lead to exchange of protons with solvent (ΔG_{HX}) can be determined using the following expression:

$$\Delta G_{HX} = RT \log\left(\frac{k_{int}}{k_{obs}}\right) \tag{25}$$

where k_{obs} is the observed exchange rate and k_{int} is the intrinsic chemical exchange rate, which is sequence-dependent.[68–70] The values of ΔG_{HX} obtained provide site-specific information on thermodynamics of conformational fluctuations leading to exchange, and modeling studies suggest these energies of structural fluctuations reflect magnitude of motions on the micro to millisecond timescale.[71] HX experiments are best performed on ^{15}N-labeled proteins in which HX can be followed by the decrease in HSQC peak intensity as a function of time after exchange of the protein into D_2O, as HSQC spectra yield one peak for each $^1H-^{15}N$ bond and can be collected in a period of minutes. An example is shown in Figure 20. HX rates are dependent on the oxidation state of metalloproteins and in some cases this dependence has been subscribed functional significance. An interesting example is in putidaredoxin, a Fe_2S_2 protein that is the

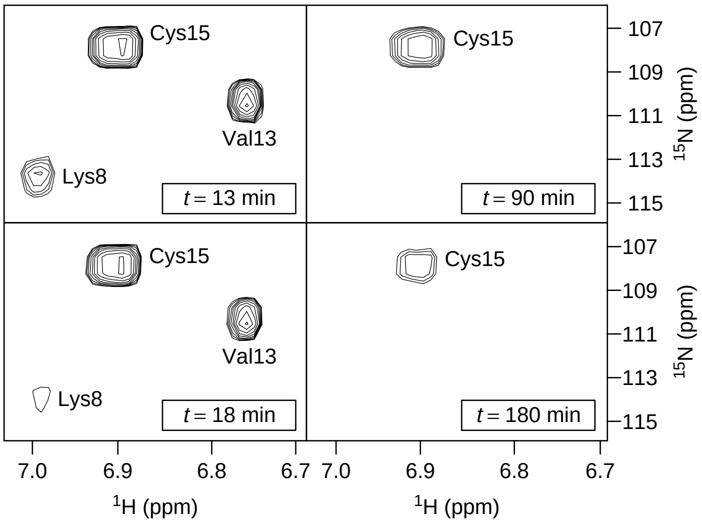

Figure 20 Example of hydrogen–deuterium exchange experiment monitored by HSQC. A portion of the ^{1}H–^{15}N HSQC spectrum of *Pseudomonas aeruginosa* ferricytochrome c_{551} is shown with time after exchange into D_2O indicated. Note the different rates of change in NH peak intensity for the residues shown

electron donor to *Pseudomonas putida* cytochrome P-450. Redox-dependent dynamics in putidaredoxin are inferred from differential HX rates, with the largest differences being near the metal center. This change is proposed to play a role in controlling redox-dependent affinity of putidaredoxin for cytochrome P-450.[72]

5.3 Side Chain Dynamics

Relaxation studies can be performed to analyze side chain dynamics, usually using ^{13}C or ^{2}H nuclei. Whereas analysis of backbone relaxation relies on a limited number of bond vectors to sample the protein, side chains present a wider array of possible probes of dynamics. Relaxation studies of amino acid side chains require specialized isotope enrichment schemes to yield interpretable relaxation behavior.[73] An example of an application to a metalloprotein is the study of *Rhodobacter capsulatus* cytochrome c_2 in the reduced (diamagnetic) state in which ^{2}H relaxation of amino acid side chain methyl groups was analyzed. Relative to other proteins, methyl side chains were found to have very limited mobility, which was attributed to interactions with the hydrophobic heme group for many of the hydrophobic amino acids. This high rigidity is proposed to enhance electron transfer by minimizing reorganization energy.[74]

Line shape analysis has been utilized to detect and elucidate dynamics of ligands bound to metals. For iron porphyrin models of metalloproteins, axial imidazole ligands may rotate relative to the heme axes; linebroadening of heme substituents resulting from this process can be observed at low temperature.[75] Such ligand motion is not commonly observed within metalloproteins because of constraints of the protein structure and metal–ligand bonding. NMR studies of some metalloproteins, however, have revealed linebroadening of active site nuclei interpreted to indicate amino acid side chain dynamics.[67] For example, in some cytochromes *c*, the heme axial methionine ligand has been shown to undergo inversion at sulfur on the microsecond time scale. This process results in averaging of the heme methyl proton chemical shifts of the two conformations in exchange. Heme methyl resonance linebroadening is evident as the exchange process approaches the intermediate timescale regime at low temperatures (Figure 21).[76]

6 APPLICATION TO ANALYSIS OF INTERMOLECULAR INTERACTIONS

NMR is a powerful tool for characterizing intermolecular interactions such as ligand binding to proteins, or protein–protein interactions. Under favorable conditions, dissociation constants (K_d) and dissociation rates (k_{off}) can be determined, as can the binding site(s) on the protein. In addition, changes in protein structure and dynamics resulting from protein or ligand binding may be determined. The utility of NMR for characterizing in detail even weak ($K_d \sim$ mM) intermolecular complexes sets it apart from other methods used to analyze intermolecular interactions involving biomolecules.

When characterizing an intermolecular interaction by NMR, the experimenter is examining a system in dynamic exchange. Considering this to be a simple two-state process exchanging the two unbound molecules (A and B) with the complex (AB),

$$A + B = AB \tag{26}$$

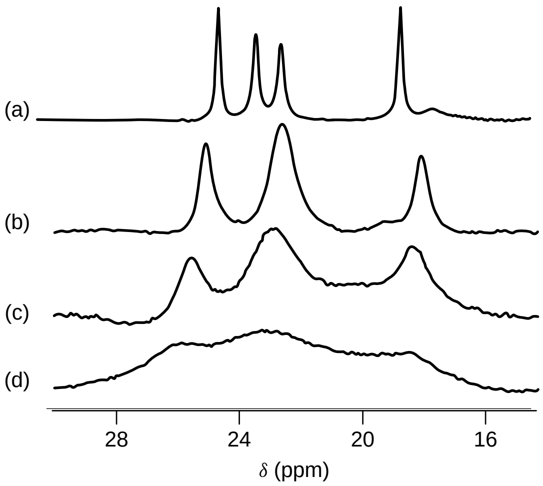

Figure 21 ^{1}H resonances of heme methyl groups of *Hydrogenobacter thermophilus* ferricytochrome c_{552} at (a) 26, (b), 11 (c) 1, (d) −6 °C. The chemical shifts observed are an average of shifts for two different axial methionine orientations in fast exchange on the NMR timescale. Upon lowering the temperature, the exchange process is slowed so that resonance broadening is evident as the process approaches the intermediate exchange regime. Samples for (b)–(d) are in 20% methanol

the dissociation constant (K_d, M^{-1}) is described by the ratio of the rate constants for binding (k_{on}, $M^{-1}\,s^{-1}$) and dissociation (k_{off}, s^{-1}):

$$K_d = \frac{k_{on}}{k_{off}} \tag{27}$$

Thus, it becomes important to consider the rate-limiting process (k_{off}) when designing experiments to characterize the complex, as dissociation may be slow, intermediate, or fast relative to the NMR time scale. The reader is referred to Section 2.5 for a summary of dynamic NMR methods. This section will present an application of these methods to study binding of molecules to metalloproteins.

6.1 Ligand Binding to Metalloproteins

Small molecules that bind to biological macromolecules are referred to as *ligands*. In bioinorganic chemistry, the term ligand also has the more specific meaning of a small molecule, ion or other moiety that binds to a metal site to form a coordination complex. NMR is readily employed to characterize both kinds of ligand binding to metalloproteins. A simple and effective general approach to studying ligand–protein interactions is to monitor chemical shift changes in the ^{15}N–^{1}H HSQC spectrum of the target protein as a function of added ligand. This is effective for proteins with molecular weights up to about 40 kDa. For larger proteins, protein deuteration and use of TROSY is needed to obtain sufficient resolution. In addition, ^{13}C-methyl labeling of specific residues (i.e., Ile, Leu, and Val) may help in studying larger proteins. An alternative method for monitoring protein–ligand binding is saturation transfer. If the ligand's off rate is fast relative to T_1, its signal will be reduced in the unbound form upon saturation of the bound form. This method is particularly useful when applied to a large biomolecule because of effective spin diffusion. Also useful for detecting binding to relatively large proteins (>50 kDa) is the transfer NOE, which can reveal the bound-state conformation of the ligand. These and other methods for NMR characterization of protein–ligand interactions have been reviewed recently.[77]

The above methods may be applied to binding of ligands either at or away from a metal site in a metalloprotein. In the case that a ligand binds a metal site, particularly when that metal is paramagnetic, significant changes in chemical shifts and/or line widths of the ligand and metal often result. The spectral changes observed depend on the differences in the electronic structure of the metal caused by binding and are particularly dramatic when ligand binding induces a spin-state change, as commonly occurs in heme proteins, for example.[10] As large shift differences between bound and unbound forms may be seen, application of 1-D methods to monitor ligand binding are greatly facilitated.

6.2 Protein–Protein Interactions

Protein–protein interactions play key roles in all areas of biology. The dissociation constant (K_d) for these interactions ranges over many orders of magnitude, from subpicomolar to millimolar. For weakly associating complexes ($K_d > \mu$M) in particular, structural information on complexes between proteins is scarce. This lack of structural information results from the difficulty of crystallizing these complexes, which by nature are transient and not characterized by a single specific set of interactions. Rather, weak protein–protein complexes may be considered a collection of complexes with a fluctuating interface. The topic of weak protein–protein complexes is of particular relevance in bioinorganic chemistry as metalloproteins that function in electron transfer tend to bind weakly to their redox partners, with K_d values ranging from millimolar to micromolar. Association rates (k_{on}) for electron transfer partners are usually high (10^7 to $10^9\,M^{-1}\,s^{-1}$),[78] and dissociation rates often fall in the range of 10^3 to $10^6\,s^{-1}$. Thus, from the NMR perspective, interactions between redox proteins are dynamic phenomena spanning multiple rate regimes on the experimental timescale. There are a number of recent reviews on the topic of NMR characterization of redox protein complexes providing excellent summaries of recent work in this active field.[78–81]

The most straightforward means to characterize binding of redox partner proteins is by monitoring chemical shift changes upon complex formation. This is most conveniently performed by observing ^{1}H–^{15}N HSQC resonances of a uniformly ^{15}N-labeled protein as a function of added concentration of the partner protein. Complex formation

causes changes in chemical shifts, which are expected to be largest at the protein–protein interface. Under the typical case of fast exchange, a change in chemical shift between the values characteristic of the unbound and bound forms of the protein is observed. Plotting the change in chemical shift as a function of ratio of the partner proteins yields binding curves that may be fitted to obtain a K_d value. In addition, the resonances showing the largest chemical shift changes provide a ''chemical shift map'' of the binding interface. Chemical shift changes are not confined to binding interface residues. Binding may cause alterations in structure reflected by changes in chemical shifts, although this is not commonly seen in the case of weak complexes. Detecting structural changes remote from the binding interface is facilitated in paramagnetic proteins because of the higher sensitivity of chemical shifts to structure.

Chemical shift mapping is the most common method of analyzing interactions between metalloproteins, but other approaches similar to those outlined above for ligand binding (Section 6.1) can be applied. The most relevant methods for studying weak protein–protein interactions are transferred NOEs that may be observed in protein–protein complexes in the case that one of the target proteins has a large molecular weight (>50 kDa) and the complex is under fast exchange. In addition, RDCs can aid in characterization of weak protein–protein complexes, for which relative orientations of the two proteins may be discerned.

Utilizing these methods, the past decade has seen an explosion of structural information on weak complexes of metalloproteins that have revealed important fundamental information relevant to understanding biological electron transfer. For one, the typically weak and transient nature of binding of redox partner proteins is a substantial deviation from the ''lock and key'' hypothesis of biomolecular recognition. At the same time, the binding interface arranges the protein partners so as to minimize separation of the redox metal sites. The interface may be hydrophobic in nature, or electrostatic, with one partner having a positive and the other a negative electrostatic potential at the binding site. The experimental determination that interfaces between electron transfer partners are fluctuating and mobile has provided information vital to the advancement of experimental and theoretical studies of biological electron transfer.

6.3 Self-exchange Electron Transfer

The electron self-exchange (ESE) reaction is the interconversion of oxidized and reduced forms of a redox-active molecule, with a rate described by a second-order rate constant (k_{11}):

$$A_{ox} + A'_{red} = A_{red} + A'_{ox} \qquad (28)$$

The ESE reaction is both convenient and informative to study because it has a driving force of 0, such that the Marcus equation describing electron transfer rates takes the simple form

$$k_{11} = \nu_n \kappa S \exp\left(\frac{\lambda}{4RT}\right) \qquad (29)$$

where the nuclear factor ν_n is $10^{13}\ s^{-1}$, κ is the transmission coefficient (=1 when the donor and acceptor are in close contact), S is a steric factor reflecting the fraction of complexes formed that are competent for electron transfer, and λ is reorganization energy.[82] If the ESE rates for two redox partners (k_{11}, k_{22}) are known, the rate for the cross-reaction (k_{12}) can be estimated using the Marcus cross-relation:

$$k_{12} = (k_{11}k_{22}K_{12}f_{12})^{1/2} \qquad (30)$$

where f_{12} is ~1 and K_{12} is the equilibrium binding constant.[82]

The ESE rate is conventionally used as an indication of intrinsic electron transfer reactivity. In the case of a strongly coupled system (close contact between partners), this rate reflects reorganization energy and the formation of the productive complex for electron transfer. NMR has proven convenient for analyzing ESE as measurements can be made on a system at equilibrium through a range of temperature and solution conditions. ESE rates for metalloproteins range from ~10^2 to $10^8\ M^{-1}s^{-1}$, and in some cases depend strongly on solution conditions. Thus ESE can be slow or fast on the NMR timescale. For slow exchange, saturation transfer and T_1 methods can be used to determine k_{11}, whereas for fast exchange, line width analysis can be utilized (see Section 2.5) (Figure 22). ESE experiments not only provide information on electron transfer rates, but can also be used to obtain assignments of one oxidation state of a protein based on known assignments of the other oxidation state. This method was used to determine the first assignments of hyperfine-shifted resonances of paramagnetic horse ferricytochrome *c*.[83]

Information on the nature of the binding site for the ESE reaction can be obtained by varying solution conditions, in particular, ionic strength. If the binding interface

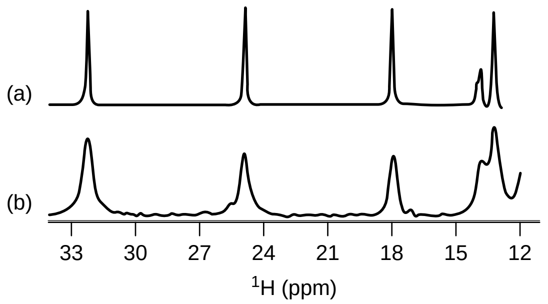

Figure 22 Effect of electron self-exchange reaction (Fe^{II}/Fe^{III}) on oxidized heme methyl resonance line widths of *Pseudomonas aeruginosa* ferricytochrome c_{551}, 25 °C. (a) 100% Fe^{III}, (b) 98% Fe^{III}. This ESE reaction is fast on the NMR timescale (~$10^7\ s^{-1}$)

is hydrophobic, little dependence on ionic strength will be observed, whereas protein complexes binding through a charged interface will display marked ionic strength dependence. Another approach to characterizing the binding interface in an ESE reaction is to observe effects on ESE rates of mutations targeting residues proposed to be involved in protein–protein binding.

7 APPLICATION TO QUADRUPOLAR METAL NUCLEI

Despite their abundance in nature and varied roles in biology, Zn^{II} and Mg^{II} have received less attention from spectroscopists in the bioinorganic field than most other metals. This is a result of these ions having closed-shell configurations, which renders them silent to conventional spectroscopic methods. Studies of the effects of Zn^{II} or Mg^{II} binding on protein structure and dynamics can be accomplished by titrations of the metal ion monitored by the protein resonances; however, such studies do not provide direct information on the nature of the metal ion itself. Substitutions of Zn^{II} by similar ions as spectroscopic probes have been informative, but again fail to provide direct information on the Zn^{II} ion. Mg^{II} is even more difficult to probe; its electron density is similar to that of water, making its identification in X-ray crystal structures problematic. In addition, Mg^{II} tends to bind weakly to proteins, so that Mg^{II} enzymes may not be isolated as an active holo-enzyme. As a result, the role of Mg^{II} in bioinorganic chemistry of proteins is underappreciated. For example, Mg^{II} plays an important role in many metabolic enzymes in mammals, but Mg^{II} binding to these enzymes is not well characterized.**[84]** Directly probing Mg^{II} and Zn^{II} sites remains a major challenge in bioinorganic chemistry.

A method of directly probing Zn^{II} and Mg^{II} sites in enzymes is by the use of ^{67}Zn and ^{25}Mg NMR. These nuclei are demanding targets for NMR, as both have low values of γ and thus low sensitivities. In addition, both nuclei have large quadrupole moments, which can lead to extremely broad NMR lineshapes (Table 1). An approach for directly studying these nuclei, put forth by Ellis and coworkers,**[85]** is to detect ^{67}Zn and ^{25}Mg in the solid-state at low temperature (~10 to 25 K) and high magnetic field (i.e., 18.8 T). The low temperature provides the important advantage needed for detecting these low-sensitivity nuclei of enhancing signal-to-noise ratio via the Boltzmann distribution (equation 6), and also providing for lower noise of the receiver coil. A challenge with solid-state NMR is that orientation-dependent phenomena that in liquid samples are averaged out by molecular tumbling remain in place, yielding extreme resonance overlap. In these experiments, a pulse sequence that transforms the powder lineshape into a manifold of side bands, and also utilizes cross-polarization to reduce consequences of long T_1 values, is employed to yield a detectable signal retaining valuable lineshape information. Comparison of experimental data to calculated spectra allows extraction of the key observable in the experiments, which is the quadrupole coupling constant, Cq:

$$\mathrm{Cq} = q_{zz}\left[\frac{e^2}{a_0^3 h}\right] Q \qquad (31)$$

where Q is the quadrupole moment of the nucleus and q_{zz} is the *zz* element of the field gradient tensor. Cq is thus directly proportional to the electric field gradient at the nucleus, which in turn is determined by the details of the metal coordination environment. Because Cq depends on charges of ligands, water versus anionic hydroxide ligation is readily distinguished. This provides a route to answer questions about Zn^{II} and Mg^{II} enzyme active site structure and mechanism that are extremely difficult to answer using other methods.

An example of the application of this method is a study of human carbonic anhydrase (CAII), a zinc enzyme that catalyzes the reaction

$$CO_2 + H_2O = HCO_3^- + H^+ \qquad (32)$$

which, despite extensive study, remains poorly characterized from a mechanistic standpoint. CAII contains Zn^{II} coordinated by three His residues and a fourth ligand presumed to be water, which undergoes deprotonation with a pK_a near 7. The measured values of Cq for CAII, however, fit a model with a hydroxide fourth ligand present at pH values ranging from 5 to 8.5, calling for reconsideration of the previously accepted mechanism (Figure 23).**[86]** Although low-temperature solid-state NMR is not a technique accessible to many bioinorganic chemists, it holds the potential to fill a significant gap in our knowledge about the biology of Zn^{II} and Mg^{II}.

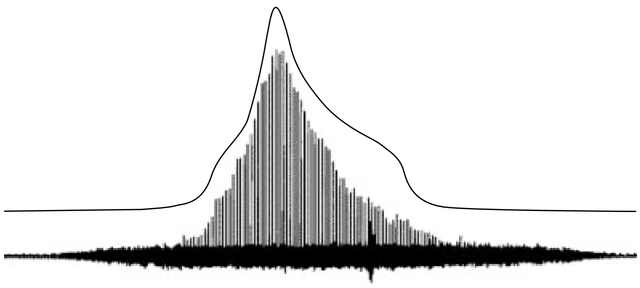

Figure 23 Low-temperature (10 K) solid-state ^{67}Zn NMR spectrum of CAII at pH 5. Above the experimental spectrum is a simulation of the spikelet envelope. The extracted value of Cq is 9.6 MHz, whereas at pH 8.5 the value is 10 MHz; the results are consistent with hydroxide ligation to Zn^{II} at both pH values. 8 APPLICATION TO NUCLEIC ACIDS

NMR has been a crucial tool for structural characterization of small nucleic acids, including both DNAs and RNAs. RNAs have been of particular interest since the discovery of catalytically active RNAs (ribozymes) in the 1980s. In the intervening decades, our understanding of the rich and versatile reactivity of nucleic acids has continued to grow, with the development if in vitro selection methodology for RNA engineering, and the discoveries of new RNA functions such as RNA interference. The expansion of the nucleic acid field has thus called for studies relating high-resolution structure to function, including understanding of the role of metal ions in stability and reactivity. Metal ions frequently play important roles in ribozyme function; RNA will thus be the focus of this section because of the particular interest the bioinorganic chemist has in it.[3,87]

The growth of available high-resolution structures of nucleic acids has relied largely on NMR. In contrast with proteins for which X-ray crystallography is the dominant method for structure determination, NMR is the leading technique for solving RNA structures,[36] in part because of the difficulty of obtaining suitable crystals. As a result of the polyanionic nature of nucleic acids, metal ion binding is ubiquitous, although often less specific than is metal binding to proteins. Detection of the binding of the metals to nucleic acids is complicated by the fact that the metal ions most often found associated with nucleic acids (Na^{I}, K^{I}, Mg^{II}) are extremely difficult to detect directly by NMR, and do not exert characteristic paramagnetic effects on NMR spectra. For these reasons, NMR studies of metal sites in nucleic acids are limited in comparison with the number and variety of studies on metalloproteins. Here, a brief overview of the methods used to address the challenges of NMR studies of metallo-nucleic acids, with a focus on RNAs, is presented.

8.1 Sample Preparation

Despite the considerable success in using NMR to determine nucleic acid structure, these biopolymers offer particular challenges to the NMR spectroscopist. The building blocks of nucleic acids are larger than those of proteins, and as a result one encounters the complications that arise with performing NMR on high molecular mass molecules for relatively short nucleic acids. Compounding this difficulty is the inherent heavy resonance overlap in ^{1}H NMR spectra even for small nucleic acids, a problem particularly severe for ribose protons. In addition, nucleic acids do not display as many NOEs between nucleotide units as do proteins between amino acid units, as most proteins are more globular in structure than RNAs, and there are fewer protons in RNA per mass unit. Thus, only small RNAs (less than ∼20 nucleotides) can be studied with routine homonuclear (^{1}H) methods, with larger molecules requiring isotopic (^{13}C and/or ^{15}N) labeling. As a result of severe chemical shift degeneracy and linebroadening, studies of RNAs ∼ 50–60 nucleotides and larger are extremely challenging and reserved for the specialist.

In contrast with proteins, suitable amounts of RNA are rarely available from a native source. Thus, expression or synthesis is necessary to obtain amounts appropriate for NMR studies. Mitigating some of the challenges of NMR of RNA is that large RNAs can often be divided into functionally significant segments that fold independently. This allows the researcher to prepare and study relatively small RNAs and obtain information relevant to understanding structure and function of the larger RNA. In addition, the ability to chemically synthesize small nucleic acids for specific labeling, or to insert labeled segments into larger RNAs, allows one to readily obtain samples tractable for NMR study. The key to preparation of isotopically labeled RNA samples is availability of labeled nucleotide triphosphates (NTPs), which have typically been prepared from ribosomal RNA of bacterial cells grown on ^{13}C and/or ^{15}N-labeled media. The reader is referred to the literature for details on preparation of nucleic acid samples for NMR using chemical and molecular biological techniques.[88]

8.2 Data Collection for Structure Determination

NMR spectra of RNAs are quite sensitive to solution conditions, and thus pH, temperature, and type and concentration of cations in RNA samples should be optimized to obtain optimal signal detection and dispersion. Sequential ^{1}H assignments for small RNAs are obtained through 2-D NOESY spectra for through-space ^{1}H–^{1}H correlation. Use of NOESY spectra is particularly useful not only for assigning imino and amino protons, but also for ribose 2′-OH protons in some cases. A double quantum filtered-correlation spectroscopy (DQF-COSY) spectrum is typically used to identify through-bond correlations and in combination with NOESY aids with assignments of base protons. In ^{15}N-labeled nucleic acids, imino proton assignments are assisted by ^{1}H–^{15}N HSQC or heteronuclear multiple quantum correlation (HMQC) data. Multidimensional experiments on ^{13}C labeled samples are helpful with making assignments of ribose ^{1}H and ^{13}C resonances. ^{31}P chemical shifts are poorly dispersed, but correlations with ribose nuclei can be used to assist assignments. As with proteins, the key parameter input for structure calculation is the ^{1}H–^{1}H NOE. In addition, coupling constants (i.e., $^{3}J_{HH}$ in ribose sugars) can reveal torsion angles. RDCs that reveal angular restraints for bond vector orientations in weakly aligned samples are also useful.

8.3 Studies of Native Metal Sites

The metal ions that most commonly bind nucleic acids, Na^{I}, K^{I}, and Mg^{II}, have closed-shell configuration and do not impart the broadening or shifting caused by

paramagnetic ions that can serve as clear signs of binding. None of these metal nuclei has a spin-1/2 isotope, and thus direct NMR measurements are challenging. In addition, these metals tend to bind nonspecifically as they have poorly defined coordination environments and high lability. Nevertheless, NMR has an important role to play in identifying metal-binding sites in nucleic acids. In particular, detection of Na^{I} and Mg^{II} binding by X-ray crystallography is complicated by the similarity of the electron density of these cations to that of water. Another concern is that the particular conditions (pH, salt, etc.) required to crystallize a nucleic acid may alter cation binding relative to what is seen in solution or in the cell.

A simple means to discern binding sites for cations is by monitoring chemical shift and/or line width changes of nucleic acid nuclei as a function of metal ion concentration. Interpretation does require that changes detected are not a result of nucleic acid conformational changes caused by altered ionic strength. Metal ion titration data can often be obtained using 1-D NMR spectra. Generally, in titrations with diamagnetic metal ions, chemical shift and line width changes will be small. The magnitude of any changes observed will depend on the change in the environment of the nucleus being observed upon metal binding including any metal-binding-induced conformational changes, and the exchange regime of binding (the off rate) relative to the NMR timescale (see Section 2.5). Metal binding to RNA is typically weak, so that the exchange rate is in the fast exchange regime. In this case, the rate of exchange and the residence lifetime cannot be calculated, although the equilibrium binding constant may be determined by monitoring the change in chemical shift as a function of added metal.

8.4 Metal Substitutions

Monitoring chemical shift changes as a function of added diamagnetic metal, such as Mg^{II}, may not reveal weak binding sites or any sites that show a very small chemical shift change upon metal binding. Mimics that bind in a similar manner but more strongly than native metals, however, may be used as probes of native metal-binding sites. Some such probes can themselves be detected directly by NMR, or they may induce nucleic acid resonance shifting or linebroadening. Monitoring binding of nonnative metals can also be used to confirm results obtained on native metals.

8.4.1 Diamagnetic metal probes

Monovalent ions (K^{I}, Na^{I}) tend to bind weakly and are particularly difficult to probe. Thus, mimics have been an important tool for probing monovalent ion binding sites. Ammonium ion has an ionic radius similar to K^{I}, and is a useful NMR probe as its protons can give rise to NOEs to nucleic acid protons. In addition, the nitrogen of $^{15}NH_4^+$ may be detected directly. An example is the detection of $^{15}NH_4^+$ binding to the DNA quadruple $[d(G_4T_4G_4)]_2$; use of ^{15}N filtering aids in identification of $^{15}NH_4^+$ ions.[89] A drawback to use of NH_4^+ is that it is most effective at low pH values at which its resonances are relatively narrow.

Divalent metals bind more strongly to nucleic acids but also may not bind strongly enough to be readily detectable, in particular, when binding through an outer-sphere mechanism. A useful mimic of $[Mg(H_2O)_6]^{2+}$ is $[Co(NH_3)_6]^{3+}$, as it has a comparable ionic radius and contains protons from which NOEs may be observed. $[Co(NH_3)_6]^{3+}$ typically binds $\sim 10\times$ more tightly to nucleic acids as a result of its higher charge, which may aid in detection of weak binding sites. As a substitution-inert complex, $[Co(NH_3)_6]^{3+}$ will specifically probe binding sites for hydrated $[Mg(H_2O)_6]^{2+}$ (outer-sphere binding) over sites requiring loss of ligands (inner-sphere binding). An example of the use of $[Co(NH_3)_6]^{3+}$ as a probe of metal-binding sites to an RNA is shown in Figure 24.

Metal ions that can be observed directly by NMR also are attractive probes of metal-binding sites in RNA. For example, direct ^{113}Cd NMR has been used to demonstrate Cd^{II} binding to a small ribozyme.[91] With an ionic radius similar to K^{I} and a nuclear spin of 1/2, $^{205}Tl^{I}$ is an attractive probe of K^{I} binding sites.[89] The NMR signal of $^{205}Tl^{I}$ bound to the G-quadruple, $d(G_4T_4G_4)_2$ from the telomeric sequence of *Oxytricha nova* has been detected to demonstrate monovalent ion binding to this structure. In addition, the exchange rate of $^{205}Tl^{I}$ was determined using magnetization transfer experiments.[92]

8.4.2 Paramagnetic metal probes

The dramatic effects paramagnetic centers may have on NMR spectra can aid in observing metal-binding sites that are difficult to detect otherwise. In studies of RNA, the most commonly used paramagnetic metal ion for this purpose is Mn^{II}, which provides highly efficient pathways for nuclear relaxation enhancement, causing significant linebroadening

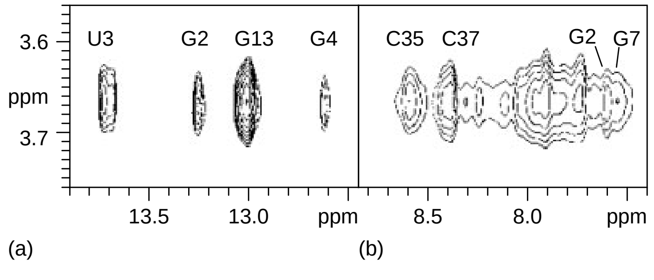

Figure 24 Portion of a 500-MHz 2-D NOESY spectrum in 90% H_2O/10% D_2O, 10 °C, of the hairpin ribozyme B domain in the presence of 1 mM cobalt hexamine, which resonates at 3.65 ppm. NOEs could be unambiguously assigned to the imino protons of nucleotides G2, U3, and G4 (a) and the amino protons of C35 and C37 and the H8 protons of G2 and G7 (b). NOEs with imino (a) and amino (b) protons are shown. (Adapted from Butcher, Allain and Feigon.[90] © 2000 American Chemical Society)

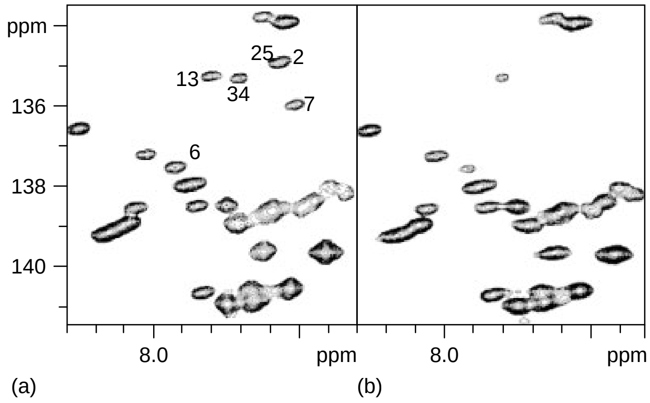

Figure 25 Five hundred megahertz ^{1}H, ^{13}C ct-HSQC spectra (aromatic region) of the hairpin ribozyme B domain, 30 °C, without (a) and with (b) the addition of 20 µM $MnCl_2$. Resonances that are broadened as a result of Mn^{2+} binding are labeled with their corresponding numbers in the spectrum without Mn^{2+}. (Adapted from Butcher, Allain and Feigon.[90] © 2000 American Chemical Society)

for nuclei in its vicinity (within about 10 Å) in a distance-dependent (r^{-6}) manner (equation 17). As it has an ionic radius similar to Mg^{II}, Mn^{II} is a reasonable probe of magnesium binding sites, which is achieved by titration of low (micromolar) concentrations of $MnCl_2$ into millimolar RNA samples. Using substoichiometric Mn^{II} will lead to significant linebroadening of nucleic acid nuclei in the vicinity of specific binding sites; higher amounts will begin to broaden resonances in a nonspecific manner. An example is the use of Mn^{II}-induced linebroadening to identify Mg^{II} binding sites in B domain RNA of the hairpin ribozyme (Figure 25).[89] Notably, the paramagnetic linebroadening data are in agreement with results obtained by diamagnetic ion titrations. Electron paramagnetic resonance (EPR) is used to identify Mn^{II} binding sites in RNA, and is in more common use for this purpose than NMR.[93]

In principle, paramagnetic ions also may be used to induce hyperfine shifts in nucleic acids to aid detection of binding sites. Ions with high relative magnetic anisotropy and short unpaired electron relaxation times (i.e., Co^{II}, Fe^{II}, and trivalent lanthanide ions except for Gd^{III}) are candidates for such studies. Indeed, Tb^{III} and Eu^{III} ions have been used as fluorescent probes of nucleic acid structures; it is expected that NMR studies also would be informative.[94]

METHOD SUMMARY

Acronyms, Synonyms

- Nuclear Quadrupole Resonance Spectroscopy
- Quadrupole Resonance
- Zero-Field Nuclear Magnetic Resonance Spectroscopy.

Measured physical quantities

- NQR Frequency(ies) (ν) of quadrupolar nucleus ($I \geq 1$)
- temperature dependence of NQR frequency
- linewidths and relaxation times for NQR signals.

Information available

- *nuclear quadrupole coupling constant* (e^2Qq_{zz}) of the quadrupolar nucleus, which reflects the deviation of the electron distribution around quadrupolar nucleus from spherical symmetry, but includes the asymmetry of the nucleus itself;
- *asymmetry parameter* ($\eta = e^2Q_{xx} - e^2Qq_{yy})/(e^2Qq_{zz})$ of the quadrupolar nucleus, which reflects the deviation of the electron distribution from axial symmetry;
- *electric field gradient* (*EFG*, q_{zz}) of the electron distribution around an atom, which measures its deviation from spherical symmetry, and does not include any asymmetry of the nucleus;
- approximate *populations of valence orbitals* of quadrupolar atom;
- approximate fractional *covalent* (σ) versus *ionic* (i) *character* of a bond, or multiple bond order, of bond(s) to quadrupolar atom; *number of electrons transferred* to or from quadrupolar atom; *partial charge* δ of the quadrupolar atom;
- number of chemically and crystallographically distinct quadrupolar nuclei in asymmetric unit of unit cell;
- presence of *weak* (*secondary*, *noncovalent*) *bonding interactions* to quadrupolar atom.

Information not available, limitations

- Very large frequency ranges may need to be searched (*see* Table 1, Column E), which may exceed the capabilities of a given NQR spectrometer.
- Unfavorable relaxation times, disorder, and paramagnetism at or near quadrupolar nucleus may cause the spectrum to be unobservable.
- Radio waves used for detection cannot penetrate deep within a metallic sample.

Examples of questions that can be answered

- Is there really a covalent bond of this quadrupolar atom to a nearby atom, even one in a neighboring molecule?
- What is the energy barrier to hindered rotation or fluxional behavior of a functional group bearing a quadrupolar atom?
- Is there a bomb in this suitcase?
- Is there a bomb under the clothing of, or inside the body of this passenger?
- Is there a landmine buried in this field?
- Does this package contain a significant amount of an illicit drug?
- Do we have the right crystalline modification of this compound?
- Is strain building up in this material?

Major advantages

- a nondestructive technique: all of the sample can be recovered
- extremely sensitive to weak (noncovalent, secondary) bonding interactions, which cause easily measured chemical shifts.

Major disadvantages

- Very large chemical shifts are possible, which require long times to scan (hours to days), and may require retuning circuitry or changing radio-frequency coils.

Sample constraints

- Usually the sample must be a microcrystalline solid, without any major disorder.
- The sample size requirements are large: at least about 0.5 g for heavy nuclei with high frequencies (100–1000 MHz, such as $^{79,81}Br$ and ^{127}I), but as much as 25 g for light nuclei with low frequencies (1–5 MHz, such as ^{14}N).

1 INTRODUCTION

Nuclear quadrupole resonance (NQR) spectroscopy is a method of sensitively characterizing the electronic environment of nuclei with nuclear spins $I \geq 1$. Such nuclei are nonspherical in shape and have electric quadrupole moments; commonly studied nuclei are confined to odd-numbered groups of the periodic table (Table 1). NQR spectra, unlike nuclear magnetic resonance (NMR) spectra (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Inorganic/Organometallic Molecules***), are measured without external magnetic fields (hence its synonym of zero-field NMR), because the energy levels of quadrupolar nuclei are principally determined not by their magnetic environments, but by their electronic environments. Samples are studied, not in solution, but mainly in the form of microcrystalline solids.

Since more nuclei have spins $I \geq 1$ than have $I = 1/2$ (all but 17 of the naturally occurring elements through uranium have at least one such isotope), and since inorganic chemists commonly are more interested in the electronic rather than the magnetic environment of a nucleus, the technique of NQR became popular soon after its discovery around 1950. Continuous-wave (CW) superregenerative NQR spectrometers (analogous to older NMR spectrometers) were used, which could search fairly wide frequency ranges automatically.

During the 1950s through 1970s many inorganic chemists used the technique to characterize the structure and bonding in polar covalent and covalent molecules and network solids, coordination compounds, and organometallic compounds. Many types of bonding were studied: ionic, covalent, coordinate covalent, and weaker interactions such as hydrogen bonding and lattice forces. NQR proved much more sensitive to weak bonding interactions than did NMR or infrared (IR) spectroscopy, for example, although NQR required much larger samples.

NQR also offered another way of determining elements of crystal structure, such as the presence of bridging versus terminal atoms, number of crystallographically inequivalent molecules in the unit cell, and so on. However, X-ray crystallography subsequently improved vastly in quickness and ease of use, and supplanted this use of NQR.

NQR has its drawbacks. One fails to observe expected NQR signals much more frequently than expected NMR signals, since NQR relaxation times can be either too long or too short for effective detection of signals, especially using CW-NQR spectrometers, and especially for transition-metal nuclei and nuclei in ionic compounds. The search for an unknown NQR signal can take much longer than the search for an NMR signal: in NMR, one deals with chemical shifts and coupling constants of hertz, while in NQR, the frequency ranges (shifts) one needs to scan for a given nucleus may be many *megahertz*. Thus it is easy to see why NQR is much less frequently used than NMR.

Now pulse-Fourier Transform (pulse-FT) NQR instruments are commercially available, which allow signal averaging and improved sensitivity. They strongly resemble

Table 1 Abundant nuclei most commonly studied by NQR spectroscopy[a]

pulse-FT NMR spectrometers without the magnets, so they are much less expensive than modern NMR spectrometers. Indeed, some pulse-FT NMR spectrometers can be used as pulse-FT NQR spectrometers by disconnecting the magnets and making other adjustments. But pulse-FT NQR spectrometers (the only kind currently available) have some disadvantages as well as advantages as compared to continuous wave NQR (CW-NQR) spectrometers. Because of the large range of chemical shifts found in NQR, single pulses cannot be wide enough to cover the entire frequency range that needs to be scanned, so the circuit must then be retuned (normally manually) and run again in the new frequency range; CW-NQR spectrometer can cover broader frequency ranges without adjustments. Thus pulse-FT NQR spectrometers, which can accumulate spectra far more easily, in the end, may not give spectra any more quickly.

However, only pulse instruments can deal with the aforementioned difficulties associated with broad signals and unfavorable relaxation times. Therefore, some of the problems that inorganic chemists gave up on using CW-NQR to solve after the 1970s could now be solved with FT-NQR, especially using its new pulse sequences and enhanced data acquisition ability. Modern applications of pulse-FT NQR include studies of glasses, nondestructive characterization of materials, studies of host-guest interactions and probes of host cavity symmetry and size in supramolecular chemistry,[1] and (using the great temperature sensitivity of NQR frequencies and linewidths) the studies of activation energies for hindered rotations and fluxional behavior of NQR-active groups such as *monohapto*-C_5Cl_5.[2] In certain situations NQR can provide information not easily obtained by other methods. In this review we try to highlight opportunities of this type, particularly for research problems for which one needs sensitive information on weak bonding or even noncovalent interactions involving quadrupolar nuclei.

2 TECHNICAL BACKGROUND

2.1 Direct Uses of NQR Frequencies

Like NMR, NQR spectra[3,4] are detected by flipping nuclei using MHz-range radio-frequency waves; NQR frequencies can readily be measured to within a few kHz. Since NQR frequencies are *extremely* sensitive to small changes in the electronic environment of quadrupolar nuclei, they are

shifted by their environment over a range of a few or many MHz (Table 1, Column E). Thus virtually every compound has a unique set of NQR frequencies.

NQR frequencies are so sensitive to electronic environments that they are affected by charges in neighboring functional groups, neighboring molecules, and (especially) neighboring ions. Therefore, different polymorphs of compounds have different NQR frequencies, and phase transitions between polymorphs can be detected. Within a given crystalline modification of a compound, NQR spectra include distinct frequencies for each crystallographically distinct atom: as an extreme example, CCl_4(s) adopts a complex lattice with 16 crystallographically inequivalent chlorine sites. CCl_4(s) has 16 ^{35}Cl NQR frequencies averaging 40.64 MHz, with a *spectral width* between the highest and lowest frequency of 0.351 MHz. Spectral widths in covalent organochlorine compounds normally are limited to about 0.8 MHz. However, in a study of 11 clathrate compounds in which CCl_4 is the guest, the spectral widths exceeded this amount in three, being as large as 1.3 MHz in one case.[5] Quadrupolar nuclei are very sensitive both to their electronic environments and to the polarizing effects of lattice ionic charges, so spectral widths can be larger in ionic compounds: we estimate up to at least 1.4 MHz in salts of chlorinated organic anions.[6] These differences have historically been termed ''crystal field effects'',[7] although they have nothing to do with the crystal field theory in inorganic chemistry.

Consequently, NQR frequencies are useful for detecting and quantifying extremely weak noncovalent (secondary-bonding) interactions between molecules or ions (such as the host-guest interactions in CCl_4 clathrates). These weak secondary interactions will be a main emphasis of this article. However, since mere crystallographic inequivalence produces quite substantial spectral widths, one must use caution in concluding that small frequency shifts are due to what one chooses to call ''noncovalent'' or ''secondary-bonding'' interactions. (One might argue that NQR frequencies are too sensitive to their environment for their own good!)

2.2 Quantities Derived from NQR Frequencies

The number of NQR frequencies observed per crystallographically and chemically inequivalent atom depends on the spin I of the nucleus: each inequivalent $I = 3/2$ nucleus gives only one NQR frequency, while each $I = 1$ or $I > 3/2$ nucleus gives two or more frequencies. With two or more NQR frequencies, it is possible to calculate the two intermediate physical properties of interest. One is the *nuclear quadrupole coupling constant* e^2Qq_{zz} (or, removing the effect of the *quadrupole moment* Q of the nucleus, the *electric field gradient EFG or* eq_{zz}) which measures the deviation of the electronic environment from *spherical* (in practice, from a higher-order point group) symmetry. This depends on the *number of unbalanced electrons* around the nucleus (the number of electrons in the z direction minus the average of the numbers in the x and y directions). (Thus, e^2Qq_{zz} for a chloride ion in an octahedral environment in the NaCl lattice is zero.) The other is the *asymmetry parameter* η, which falls between zero and one, and measures the deviation of the electronic environment from *axial* symmetry (in practice, threefold or higher symmetry), and relates to the difference in the numbers of electrons in the x and in the y directions. For the many spin-3/2 nuclei (Table 1, Column F) calculating these quantities requires additional data from single-crystal or other specialized measurements, or requires certainty that η is close to zero, as is normally found to be the case in covalent compounds in which the quadrupolar atom is a terminal atom, singly bonded to one other atom. Values of the e^2Qq_{zz} and η can also be determined experimentally in appropriate cases using microwave (*see* ***Microwave Rotational Spectroscopy***), EPR (*see* ***Electron Paramagnetic Resonance (EPR) Spectroscopy***), NMR (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Inorganic/Organometallic Molecules***), and Mössbauer (*see* ***Mössbauer Spectroscopy***) spectroscopy, and using the perturbed angular correlation (PAC) method (*see* ***Perturbed Angular Correlations of*** $\boldsymbol{\gamma}$***-rays (PAC) Spectroscopy***).

From atomic spectral or atomic beam measurements it is possible, in favorable cases, to measure the quadrupole coupling constants e^2Qq_0 of atoms in which there is one valence electron, or one hole in the valence-electron shell (Column J of Table 1). From this one can obtain the number of unbalanced electrons, and ultimately, the *populations of the valence orbitals* of the quadrupolar atom and its *partial charge,* δ.

Therefore, there is a more direct connection between valence orbital populations and NQR frequencies than there is with NMR frequencies, and indeed the Gaussian computational program allows for straightforward calculations of the electric field gradient.[8] However, the *EFG* is especially sensitive to any nonsphericity of the core electrons (or inner lobes of the valence orbitals), which normal molecular-orbital computations tend to neglect or approximate, so that such computations seriously miss producing the experimental *EFG* values. More successful calculations have been obtained by using density functional theory (DFT) and by avoiding the pseudopotential method, which simplifies the core electron wave functions.[9] These calculations give values of the *EFG* that correlate very well with the experimental ones for nitrogen and halogen atoms in a variety of bonding situations.

Often the Townes–Dailey approximation[10] is used rather successfully. This approximation assumes that contributions to the *EFG* from nonsphericity of core electron and from lattice charge distributions offset each other. Then the *EFG* results from imbalances in valence electron populations. The calculations also show that the errors introduced by the approximations of the Townes–Dailey theory do not exceed 5%. Thus Townes–Dailey calculations generally do well in showing *trends* in quadrupole coupling constants or NQR frequencies.

Using the Townes–Dailey theory, a relationship of the NQR frequency of a single-bonded terminal unhybridized ^{35}Cl atom can be derived to the ionic character, i, of the bond to the chlorine atom, or to the partial charge of the chlorine atom, δ_{Cl}.

$$\nu(^{35}\text{Cl}) = -\frac{1}{2}(1-i)e^2Qq_o = -\frac{1}{2}(1-i)(109.746\,\text{MHz}) = 54.873(1+\delta_{Cl}) \quad (1)$$

$$\delta_{Cl} = -1 + \frac{\nu(^{35}\text{Cl})}{54.873} \quad (2)$$

Hence the chlorine NQR frequency is very sensitive to the ionic character of its single bond. In close agreement with the prediction from equation (1), the NQR frequency of Cl_2(s) is 54.247 MHz, while NQR frequencies for solid Group I halides are zero, expected both from their virtually complete ionic character and their high solid-state symmetry.

In Gordy's approach[11] the ionic character of a single bond to chlorine equals one-half of the difference in electronegativities of the chlorine, 3.16, and the atom to which it is bonded. Thus the NQR frequency of this chlorine atom is a strong function of the Pauling electronegativity, X_P, of the atom M bonded to chlorine:

$$\text{Theoretical } \nu(^{35}\text{Cl}) = 27.436\,(X_P - 1.16) \quad (3)$$

$$\text{Empirical best fit } \nu(^{35}\text{Cl}) = 24.500\,(X_P - 1.07) \quad (4)$$

Figure 1 shows the fit of predicted and observed NQR frequencies for other solid binary chlorides in which the chlorine is terminal and singly bonded; similar results can be obtained for bromine and iodine. For chlorine bonded to carbon ($X_P = 2.55$) these equations predict a frequency of 38.14 or 36.26 MHz, respectively. The observed NQR frequencies of $R_1R_2R_3C$–Cl compounds span a wider range of about 33–42 MHz: they are strongly influenced by the inductive (electron-withdrawing) effects of the R groups and on any other interactions that may be present with those groups.

If the terminal atom is multiply bonded to its neighbor, slightly different equations result. The π bonding results in a reduction of population(s) of the chlorine p_π orbitals below 2.00 electrons, to a value closer to the population of the chlorine p_σ orbital. Therefore the quadrupole coupling constant and the NQR frequency of the chlorine atom are reduced.

If the atom is doubly bonded, a nonzero asymmetry parameter η also results; if the atom is triply bonded, there is axial symmetry and η returns to zero. For the case of doubly bonding the π bond order can be calculated if η can be determined:

$$\pi = \left(\frac{2}{3}\right)\eta\left(\frac{e^2Qq_{zz}}{e^2Qq_0}\right) \quad (5)$$

In practice double bonding is appreciable for chlorines bonded to aromatic rings ($\eta > 0$), and partial triple

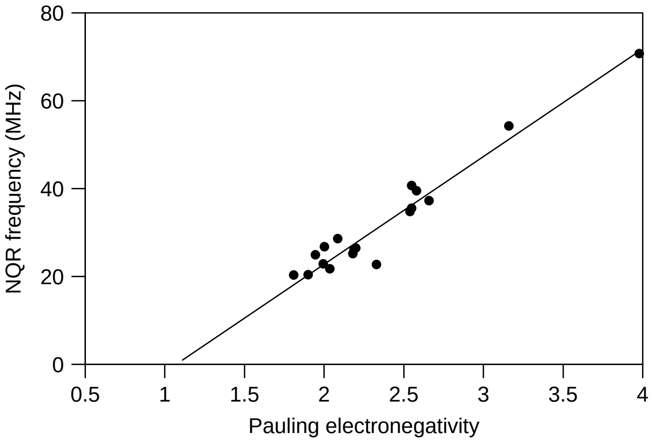

Figure 1 Average ^{35}Cl NQR frequencies (MHz) of terminal singly bonded binary element chlorides, measured in the solid state at 77 K, as a function of the Pauling electronegativity of the element

bonding is quite substantial for the chlorides of early transition metals having vacant d orbitals to which the p_π electrons are donated.[12] Thus such chlorides have been deleted from the correlation of Figure 1. For example, the electronegativity of Ti, 1.54, leads us to expect a ^{35}Cl NQR frequency of 10.42 MHz (equation 3) or 11.51 MHz (equation 4). In practice, the average frequency for $TiCl_4$ is 6.052 MHz. The cyclopentadienide anion, $C_5H_5^-$, is a much better π-donor than chloride, however, so that when it is substituted for Cl^- the π-donating ability of Cl^- is suppressed. Consequently the average frequencies[13] grow closer to the predicted values: $(C_5H_5)TiCl_3$, 8.076 MHz, and $(C_5H_5)_2TiCl_2$, 11.971 MHz.

If the quadrupolar atom is bonded to more than one other atom (i.e., it is bridging or even central to the complex), the Townes–Dailey theory can be applied to give a different equation for each geometry at the bridging or central atom; a nonzero η generally results. We will consider in detail only two-coordinate bridging quadrupolar atoms. In this case, the two bonds to the bridge can be equivalent (symmetrical bridging): the NQR frequency then depends sensitively on the interbond angle at the quadrupolar atom.

Or (in the case we will emphasize), one of the two bonds may be a normal covalent bond (with a high covalent bond order) and the other ''bond'' is a weak (secondary) Lewis base donation of an electron pair to a nearby Lewis acid. Then NQR can be used to estimate the number of electrons that are transferred from the halogen lone pair in the valence p_y orbital to (or polarized toward) the site of Lewis acidity; we can also refer to this quantity as the secondary covalent bond order σ_{B2}. If the asymmetry parameter η is known, σ_{B2} can be calculated from it using an equation analogous to equation (5):

$$\sigma_{B2} = \left(\frac{2}{3}\right)\eta\left(\frac{e^2Qq_{zz}}{e^2Qq_0}\right) \quad (6)$$

More frequently η is not known. However, it is still possible to proceed if the NQR frequency of the donor atom is known both for the terminal halogen in the free ligand and for the otherwise-equivalent bridged halogen atom in the complexed ligand. For the terminal (one-coordinate) halogen atom we designate its NQR frequency as ν_T and its covalent bond order as σ_T; for the bridged halogen atom we designate its NQR frequency as ν_B and its primary covalent bond order as σ_{B1}. For ^{35}Cl the approximate Townes–Dailey equation that results is:

$$\frac{(\nu_T - \nu_B)}{54.873} = (\sigma_T - \sigma_{B1}) + \frac{1}{2}\sigma_{B2} \quad (7)$$

To solve this equation for σ_{B2} we need to know the relationship of σ_T and σ_{B1}, that is, whether the primary covalent bond order is altered upon coordination. For halocarbons as ligands there is generally no detectable lengthening of the bond noted by X-ray crystallography, which might justify the conclusion that $\sigma_T \approx \sigma_{B1}$. If so, we have:

$$\sigma_{B2} = \frac{2(\nu_T - \nu_B)}{54.873} \quad (8)$$

In some secondary-bonding situations the primary bond is lengthened and therefore, σ_T and σ_{B1} are presumably not equal. This case will be considered in Section 3.2.

3 APPLICATIONS

There have been several modern developments in pulse-FT NQR spectrometry dealing with important practical applications which are not necessarily considered to be inorganic:

1. $^{63,65}Cu$ and ^{139}La NQR have been extensively used to study high-temperature superconductors while they are in the superconducting state, and the magnetic fields needed for NMR are being excluded.[14]
2. ^{14}N NQR is used to detect, identify, and quantify amounts of illicit drugs hidden in suitcases, packages, or the body, without having to open the container.
3. ^{14}N NQR is used to detect, identify, and quantify amounts of explosives hidden in suitcases, packages, on the body, or in buried landmines, without having to put the sample inside the instrument.[15]
4. NQR (a proprietary type) is being investigated for use to detect strains that may develop in aerospace composite structures before these structures can fail and lead to crashes.
5. ^{14}N and ^{35}Cl NQR are being investigated for uses in the pharmaceutical industry for measuring quantities of medicines in containers without opening them, and for determining whether, during the manufacturing process, the proper polymorph of the pharmaceutical is being produced.[16] (Different polymorphs of drugs can have different stabilities and bioavailabilities.)

In this article we emphasize modern uses of NQR spectroscopy in inorganic chemistry, particularly those involved with characterizing relatively weak bonding and noncovalent interactions. We divide them according to the bonding situation in which the quadrupolar nucleus is found, beginning with terminal (one-coordinate) atoms, for which Townes–Dailey equations (1) through (5) apply, followed by bridging (two-coordinate) atoms, for which equations (6) through (8) apply, followed by brief mention of some cases of central (three-coordinate or higher) atoms, for which a variety of Townes–Dailey equations can be derived but will not be described.

3.1 Applications Involving Terminally Single-bonded Halogen Complexes and Organometallic Compounds

3.1.1 *Relativistic Effects*

The s and p orbitals of heavy atoms undergo relativistic contraction: an electron in such an orbital is accelerated to a speed near that of light.[17] The electron increases in mass, and consequently is pulled closer to the nucleus: the electronegativity of the atom therefore increases. This effect reaches a maximum in elements close to gold, which therefore is predicted to show an unusually high electronegativity. The Pauling electronegativity of Au is the highest of any metal, 2.54, and is close to that of iodine, 2.66. Correspondingly, the terminal chlorines of Au_2Cl_6 have the highest ^{35}Cl NQR frequencies found in any metal chlorides, 36.094, and 33.401 MHz[18]; these values are similar to those found in I_2Cl_6, 35.680, and 33.916 MHz. (Much lower NQR frequencies would be predicted using the Allred-Rochow electronegativity of Au, 1.42, which is derived from the nonrelativistic approximations of Slater's rules.[17]) The chemistry of gold indeed shows remarkable similarities to that of iodine (e.g., Au forms Au^-). Relativistic effects on *EFG*s for elements through Np have been calculated.[19]

3.1.2 *Effects of Nearby Charges in Haloacetate Salts*

The properties of the familiar chloroacetate ion, $ClCH_2COO^-$, are surprisingly cation dependent: among group 1 chloroacetates in the solid state, thermal decomposition to metal chloride and the polymer poly(glycolide), $(CH_2CO_2)_n$,[20] does not occur in the lithium salt, but occurs at progressively lower temperatures with larger cations; the cesium salt decomposes at room temperature (Table 2). As noted earlier by Guibé,[21] the ^{35}Cl NQR frequencies in group 1 chloroacetates decrease for larger cations–for example, by 3.46% from the Li^+ salt to the K^+ salt. Ab initio calculations[6]

Table 2 NQR frequencies and decomposition temperatures of group 1 chloroacetates and hexachlorostannates

(d) Source: T. Janiak, I. Nikel, and J. Blazejowski, *J. Therm. Anal.*, 1990, **36**, 2205–2210.

on symmetrically chelated $ClCH_2COO$-M systems predict a 3.24% drop in electric field gradients (hence NQR frequencies) from the Li^+ salt to the K^+ salt. These calculations and the NQR data suggest that the Cl atom in the chloroacetate ion carries substantially more negative charge in salts of larger, less polarizing cations, and hence, is more readily lost as chloride ion. It should be noted that haloacetate salts typically have layer structures, in which the nearest neighbors of the halogen ends of the anions include no metal cations to attract neighboring layers of anions close together.

3.1.3 *Effects of Nearby Charges in Halometallate Salts*

In contrast, the thermal stability and NQR frequencies *increase* in hexahalometallate salts of larger group 1 cations (Table 2).[22] The trend in stability limits the usefulness of hexahalometallate ions as weakly coordinating anions, since they are easily broken down into MX_4, and so on, and group I MX by typical small or more highly charged cations. Hexahalometallate salts have typical ionic structures, in which anions and cations alternate, and halogen atoms have group 1 cations and chlorines of neighboring anions as neighbors. Due to the large numbers of electrons, the theoretical analyses of these trends have involved point-sphere and soft-sphere[23] along with MS-Xα[24] calculations. The latter two types of calculations successfully give the trend of increasing *EFG*s with increasing cation radius, and indicate that the gradient due to the lattice is responsible (the lattice gradient partially opposes the *EFG* due to the Sn–Cl bond). There is a good correlation of ^{35}Cl NQR frequencies with interionic chlorine–chlorine distances and with Born repulsive potentials $e^{-r/\rho}$ (r is the Cl–Cl interionic distance) in hexachlorostannates.[25] The calculations are consistent with the changes in the lattice *EFG*s due to changing polarization of the chlorine $p_{x,y}$ orbitals as they are drawn into closer contact with chlorine atoms in adjacent ions in salts of smaller group 1 cations. The calculations tend to refute another possible explanation: that smaller cations may polarize the Sn–Cl σ bond more toward chlorine.

3.1.4 *Effects of Nearby Charges in Organosilicon Compounds*

The electronegativity of silicon is well below that of carbon; consequently organosilyl chlorides R_3SiCl have lower ^{35}Cl NQR frequencies (16–20 MHz) than corresponding organic halides R_3CCl (33–42 MHz). We might expect the same trend if a –CH_2– group were to be inserted in the element–chlorine bond. But the opposite is, in fact, observed:[26] $(CH_3)_3$**Si**CH_2Cl (34.320 MHz) > $(CH_3)_3$**C**CH_2Cl (33.015 MHz); H_3**Si**CH_2Cl (34.3 MHz) > H_3**C**CH_2Cl (32.646 and 32.759 MHz); Cl_3**Si**CH_2Cl (36.786 MHz) > Cl_3**C**CH_2Cl (36.40 MHz). Computations suggest that the chlorine $3p_z$ orbital population in $(CH_3)_3$**C**CH_2Cl is anomalously higher (0.960 e^-) than the chlorine $3p_z$ population in $(CH_3)_3$**Si**CH_2Cl (0.948 e^-), while the corresponding chlorine $3p_{x,y}$ populations are virtually identical. It was concluded[27] that the direct cause of the anomalous frequency raising is due to the polarizing effect of the nearby partially positive $(CH_3)_3Si$ (and H_3Si) groups, which polarize the CH_2–Cl bond electrons toward CH_2. Measurements of η for some compounds of this type give values near zero. This and the calculations are inconsistent with earlier suggestions that this ''alpha effect''[28] is due to electron donation from the Cl $3p_x$ orbital to a vacant Si 3d orbital, creating some Si=Cl double bond character.

3.1.5 *Cis and Trans Influences in Substituted Halometallate Anions*

Ligands in octahedral complexes alter the bonding to ligands that are trans- to them in ways that are different

from the effects on ligands that are cis- to them.[29] This effect shows up through changes in bond lengths, but even more sensitively through changes in NQR frequencies. Alkyl groups are more strongly electron donating than halo groups due to electronegativity effects, while nitrido ions ($\equiv N^{3-}$) donate electrons not only via σ bonds, but also via two π bonds, so are also more strongly electron donating than halo groups. The nitrosyl ligand (N≡O) falls between nitrido and halo ligands in this respect.

The effects on halo groups depend, however, on whether the central metal ion of the complex is from the d block or the p block. In complexes of the type $[OsLX_5]^{2-}$, when L is changed from being another X^- to being NO and then to being N^{3-}, the effects on bond lengths and especially NQR frequencies are dramatically different for the four halogens cis to L as compared to the unique halogen that is trans to L. Data are shown in Table 3 for osmium chloro and bromo complexes of these ligands (it must be noted that the oxidation state of Os also changes during these substitutions). The chloro- or bromo-ligand trans to the new nitrido experiences an 8.5% increase in bond length, a 60% decrease in NQR frequency, and a 53% increase in partial charge δ (as computed from NQR frequencies). The effects on the four cis ligands are much more modest: a 1.6% decrease in bond length, a 21–26% increase in NQR frequency, and a 6–9% increase in δ. We note that these cis and trans effects manifest themselves both in NQR and in X-ray crystallographic data, but more dramatically in the NQR data.

Table 3 also shows data for $[SnLX_5]^{2-}$ complexes, in which L is changed from being another X^- to being a much more electron-donating alkyl group (ethyl or butyl). The effects in these p-block complexes are opposite to those seen above for the d-block element Os: when the alkyl ligand is introduced, the trans-halogen atom experiences a 0.5–1.5% *decrease* in bond length, an 8–14% *increase* in NQR frequency, and a 4–9% *decrease* in δ. Clearly the trans bond is strengthened in tin complexes but weakened in osmium complexes. In the tin complexes the cis ligands experience the largest, not the smallest effects: a 4% *increase* in bond length, a 27–30% *decrease* in NQR frequency, and a 10–14% *increase* in δ.

3.1.6 *Trihalide Ions*

Bromine and iodine atoms can be at the center of linear (two-coordinate) complexes when in the familiar trihalide ions, Br_3^- and I_3^-. NQR data are then available on all atoms in the complex,[30,31] and can be analyzed to show the charge distribution within the ion using equations corresponding to equation (2) and a related equation for the central halogen atom. When these simple Townes–Dailey equations presume

neither the involvement of halogen s nor halogen d orbitals, it is found that the totals of the three charges in all cases add up to sums (in practice, from -0.94 to $-1.06\,e^-$) close to the actual -1 charge on the trihalide ion. Although this could be due to fortuitous cancellation of the opposing effects of s and d hybridization, this seems unlikely since the conclusion holds for all 13 salts studied. In all cases the central halogen atom is computed to have a small *positive* partial charge of $+0.04 - +0.08$, while the terminal halogen charges average close to -0.50. This is consistent with three-centered, four-electron bonding, with the highest occupied molecular orbital being localized on the two outer (terminal) halogens.

However, the negative charge is not always equal on the two terminal halogen atoms. With very large cations (tetramethylammonium through tetrabutylammonium), each terminal bromine or iodine atom carries the same, or nearly the same charge of $-0.50\,e^-$ each. But with the smaller Tl^+, Cs^+, Rb^+, and $NH_4{}^+$ cations, one halogen atom carries most of the negative charge. For the extreme case, NH_4Br_3, one bromine atom has only a -0.18 charge while the opposite bromine atom bears a large -0.87 charge. The bond distances are all long, since the covalent bond orders are less than one: in $CsBr_3$ the shorter Br–Br bond distance is 244 pm and the longer 270 pm, as compared to the sum of Br covalent radii, 228 pm. Clearly, in such a case the two Br–Br bonds are unequal in covalent bond order: in this case it seems to be appropriate to call the bond to the second Br atom a *secondary bond*, and one might represent the bonding as $Br–Br\cdots Br^-$.

3.2 Applications Involving Secondary Bonding of Halogens to Metal Ions

Weak (‘‘noncovalent’’) interactions between molecules are currently of great interest in chemistry, not only in biochemistry (e.g., the study of enzyme-substrate bonding) but in the study of—host–guest interactions and crystal engineering, for example. (The very important phenomenon of hydrogen bonding falls in this category, but will not be considered here.) In the chemistry of halocarbons, metal halides, and even the halogens themselves, such bonding (to metal atoms or ions, or even other molecules of the same type) was originally overlooked, but is increasingly being found to be of interest. The earliest focus on it was perhaps in the review of Allcock, who termed such interactions *secondary bonding*.[32]

Secondary bonds are characterized crystallographically by bond lengths that are longer than the sums of covalent radii of the atoms involved, but are shorter than the sums of van der Waals radii. However, van der Waals radii are difficult to determine, since one must first be assured that there is, in fact, no bonding in the direction in which the nonbonded distances are measured.

For example, solid halocarbons commonly pack with halogen–halogen distances that are less than the sums of their van der Waals radii. This raises questions as to whether the van der Waals radii are incorrect, or differ in different directions around an organohalogen atom, or whether the radii are correct, and the halocarbon molecules are in fact bonding to each other via *halophilic* interactions.[33]

Furthermore, secondary bond distances vary widely, even among chemically equivalent bonds in the same complex (e.g., from 264.0 pm to 292.6 pm for $Ag\cdots Cl$ contacts in $Ag[CB_{11}H_6Cl_6]$[34]). One wonders whether these differences signify any difference in secondary bond strength or bond order, or whether secondary bonding involves such a shallow potential well that the differences merely represent variations in what is needed to achieve optimal solid-state packing.

Hence confirmation by another method is very helpful in determining whether a long metal-donor atom contact actually signifies secondary bonding and involves coordinate covalent bond formation. Most spectroscopic methods cannot reliably detect or interpret such subtle bonding interactions, but halogen NQR spectroscopy offers great promise here.

Even in the solid halogens themselves, halophilic secondary interactions (donation from a lone pair of electrons on one X_2 molecule to the empty σ^* orbital of another) occur between diatomic molecules in the same layers, giving interatomic distances much shorter within layers than between layers, and a lengthened σ bond in the case of I_2. This destroys the axial symmetry of the X_2 molecule, so that they have nonzero asymmetry parameters (Table 1, Column H): $\eta = 0.20$ for Cl_2 and for Br_2; $\eta = 0.175$ for I_2.

Secondary bonding of halogens in one molecule to metal or metalloid atoms in a neighboring molecule is a common feature in the chemistry of the halides of the heavier elements of the p- and late d blocks. With such weak interactions, the angle between the shorter primary bond in the molecule and the secondary bond to the metal center in the next molecule is normally in the range of $90° - 109°$. If there is one secondary interaction per halogen atom, and if the bond angle is taken as 90°, as discussed in Section 2.2 the situation from the halogen atom's point of view is similar to that in a double bond to the halogen, which involves a stronger (primary) σ bond using the p_z orbital and a weaker (secondary) π bond involving the p_y orbital. The consequence of such bonding is also similar: there is a nonzero asymmetry parameter, and a lowering of the quadrupole coupling constant and NQR frequency of the halogen atom (as suggested by equation (8)).

An analysis was made of 15 such cases of secondary bridging halogen atoms, primarily among adducts of HgI_2 and $SbCl_3$.[35] Values of η for these adducts ranged from 0.057 in $SbCl_3$ to 0.18 in $BiCl_3$ and AsI_3; the resulting secondary bond orders σ_{B2} computed using equation (6) ranged from 0.041 in $SbCl_3$ to 0.071 in AsI_3. For these adducts the Sb-halogen and Hg-halogen bonds do lengthen slightly upon coordination, so that the approximation of equation (8) is not justified. For seven of these adducts for which η, ν_T, and ν_B were all known, it was found that typically, about one-third of the electronic effect of secondary bonding is compensated by an alteration of the primary bonding. This gives a moderate alteration of

equation (8).

$$\sigma_{B2} = \frac{2.4(\nu_T - \nu_B)}{54.873} \qquad (9)$$

These calculations, of course, are subject to the usual limitations of Townes–Dailey theory, as well as the assumption that the bond angle is effectively 90°. So they are most likely useful to show, not absolute values of σ_{B2}, but periodic trends in those values.

3.2.1 *Halocarbons as Ligands*

For decades inorganic chemists assumed that chlorocarbons could safely be used as noncoordinating solvents for reactions of metal ions and complexes, but this view is no longer tenable,[36] particularly since the work of Strauss and others on Ag^I complexes of dichloromethane and related halocarbons.[37] As an example, they prepared the complex $[Ag(1,2\text{-}C_2H_4Cl_2)(OTeF_5)]_2$, with chelating chlorocarbons ligands having Ag···Cl secondary bond distances of 262.4–300.0 pm, longer than the sums of Ag and Cl covalent radii, 251 pm, but well within the sums of van der Waals radii, 340–350 pm. In this complex the ^{35}Cl NQR frequency of $1,2\text{-}C_2H_4Cl_2$, 34.361 MHz, is replaced by four frequencies between 31.700 and 32.036 MHz. The average $(\nu_T - \nu_B)$ is 2.513 MHz, so that σ_{B2} is 0.19 according to equation (8) or 0.22 according to equation (9). If these numbers are not too far off due to the approximations in the theory, the secondary bond order is about 20% that of a full covalent bond (as in Cl_2); qualitatively this seems plausible since the Ag···Cl distance is not so much longer than that expected for a covalent Ag–Cl bond. No value of η was obtained for these complexes.

The asymmetry parameter was measured for the intramolecularly coordinated organochlorine atom in the compound $ClCH_2CH_2CH_2SnCl_3$,[38] which has a five-coordinate tin atom with the organochlorine atom in an axial position, showing an Sn···Cl distance of 327.9 pm, intermediate between the 239-pm sum of covalent radii and the 400-pm sum of van der Waals radii. The ^{35}Cl NQR frequency for the organochlorine is 31.750 MHz, considerably below the value typical for longer-chain $Cl(CH_2)_nX$ compounds with $n \geq 3$, 33.1 MHz. The application of equations (8) and (9) gives values for σ_{B2} between 0.049 and 0.059. The value measured for η for this chlorine was 0.087 ± 0.020, which when used with equation (6) gives us $\sigma_{B2} = 0.034 \pm 0.008$, in rough agreement with the values obtained using equations (8) and (9).

Iodocarbons are expected to be softer bases than chlorocarbons, so should complex more strongly to the soft Ag^+ cation; Powell and others have found the synthesis of iodocarbon complexes of Ag^+ to be more facile and commonly achieved than the syntheses of chlorocarbon complexes; the iodocarbon ligands in these complexes tend to be bridging rather than chelating. For example, in $[Ag(I_2CH_2)_2](PF_6)$ the average Ag···I distance is 285.9 pm, only 0.9 pm longer than the sum of covalent radii, while the C–I bond lengths in such complexes is 211 pm, very slightly longer than the normal C–I bond length, 210 pm. The average C–I–Ag bond angle is 101.5°. For purposes of comparison, in diphenyliodonium salts (in which iodine is symmetrically bridging) the C–I bond lengths are 207–210 pm, and the C–I–C bond angles are 91.8°–93.2°.[39]

For $[Ag(I_2CH_2)_2](PF_6)$ the average e^2Qq_{zz} was 1744 MHz, below the 1897 MHz found in the free ligand, and η for iodine in the silver complex was quite substantial, 0.32. For diphenyliodonium salts e^2Qq_{zz} values range from 1944 to 1970 MHz, above the 1822 MHz average for C_6H_5I, and η for iodine in the iodonium salts is also quite substantial, 0.369–0.395.[40] (The values of η in these two free ligands are much smaller, 0.027 and 0.069, respectively.)

If one assumes that the Ag···I bond in $[Ag(I_2CH_2)_2](PF_6)$ is secondary, with no sp hybridization, substitution of the observed η in equation (6) gives a value for σ_{B2} of 0.162; this corresponds to the donation of the slight δ found in neutral CH_2I_2, 0.15 e^-, to Ag^+ to give a neutral iodine atom in the complex. However, use of the quadrupole coupling constants of the free and complexed ligand in equations analogous to equations (8) or (9) give significantly different σ_{B2} values of 0.067 and 0.080.

Because the Ag···I distance is so close to the sum of covalent radii, one may alternately assume that the Ag···I bond is a full covalent bond, not a secondary bond. If we then call the C–I–Ag bridging interaction ''symmetrical'', the covalent Ag–I bond order can be computed from the equation

$$\sigma_{B2} = \left(1 + \frac{\eta}{3}\right)\left(\frac{e^2Qq_{zz}}{e^2Qq_0}\right) \qquad (10)$$

and the value of σ_{B2} is computed to be 0.84, which is virtually identical to the C–I covalent bond order in the free CH_2I_2 ligand, 0.85. This then puts a large δ of +0.68 on the iodine atom, which is broadly comparable to the δ values found in iodonium ions (+0.78 – +0.81).[41] (However, contributions to *EFG* and η from the ionic lattice forces have not been taken into account; these could be significant.) With the assumption that the iodine atom in this complex undergoes sp hybridization that is set by the bond angle θ, the Townes–Dailey theory predicts:

$$\eta = -3\cos\theta \qquad (11)$$

From the observed asymmetry parameter $\eta = 0.32$, one calculates an interbond angle $\theta = 96°$, which is in the vicinity but not identical to the observed internuclear angle of 101.5°. It is unfortunate that the atoms involved are so heavy, as more detailed molecular-orbital calculations would help clarify whether the Ag–I interaction is secondary, fully covalent, or somewhere in between.

3.2.2 *Chloroacetates and Chlorophenolates as Cl-Donor Ligands*

Weak Cl···M secondary bonding is likely to be stabilized if the secondary bond completes the formation of a chelate ring, as in the case of $ClCH_2CH_2CH_2SnCl_3$ discussed previously. The crystal structure of calcium chloroacetate,[42] $Ca(ClCH_2CO_2)_2 \cdot H_2O$, involves one of the two chlorines in a chelate ring with a $Cl \cdots Ca^{2+}$ contact of 320.6 pm, which is long compared to the $Cl^- \cdots Ca^{2+}$ distance of 274.1 pm in $CaCl_2 \cdot 4H_2O$ (the van der Waals radius of Ca is unavailable for computing that sum). Because of the large difference in electronegativities and hard–soft properties, the $Cl^- \cdots Ca^{2+}$ secondary interaction is not expected to be coordinate covalent, but is more likely to be of an ion–dipole type. The crystal structure of dimeric silver chloroacetate,[43] $Ag_2(ClCH_2CO_2)_2$, shows interdimer coordination of all chlorines to silver at a distance of 290.3 pm, which exceeds the sum of Ag and Cl covalent radii, 251 pm, but is well under the 340–350 pm sum of van der Waals radii; covalent secondary bonding of soft Ag and Cl is considerably more likely here. The ^{35}Cl NQR spectrum[21] of $Ca(ClCH_2CO_2)_2 \cdot H_2O$ shows no significant difference between the free and coordinated chlorines: 34.49 and 34.77 MHz. The spectrum of $Ag_2(ClCH_2CO_2)_2$ shows four closely spaced NQR frequencies[6] averaging 33.671 MHz, which is much lower than found in covalent chloroacetates, but is in the range found for some ionic chloroacetates. Since no reference NQR frequency for a noncoordinated Cl in silver chloroacetate is available, a measurement of η would be useful.

The 2,6-dichlorophenoxide ion can readily form chelate complexes with a number of metal ions, in which coordination is through the oxygen and the 2-chlorine atoms, while the 6-chlorine remains noncoordinated (and thus provides the reference NQR frequency ν_T for a terminal atom). There is some π-bond character to the Cl-aromatic C bond (η values of several percent are found). In principle these alter the usefulness of equations (8) and (9)—in practice, insignificantly so—but the usefulness of equation (6) is significantly compromised by this π bonding.

We first consider complexes of some d^{10} metal ions. Substituted phenyl mercury chlorophenolates gave frequency differences ($\nu_T - \nu_B$) between the 2- and 6-chlorines in the range 0.88—1.25 MHz,[44,45] which is barely outside of the 0.8-MHz spectral width expected for molecular compounds. The crystal structure of phenylmercury 2-chloro-4-bromophenolate shows a Cl···Hg intramolecular bond distance of 303 pm, which is well over the sum of covalent radii, 247 pm, but which is still under the sum of van der Waals radii, 330 pm. The d^{10} ions Ag^+ and Cu^+ gave larger frequency differences of 1.675 MHz and 1.88–2.05 MHz in the compounds $(Ph_3P)_2Ag(OC_6H_3Cl_2{-}2,6)$ and $(Ph_3P)_2Cu(OC_6H_3Cl_2{-}2,6)$, respectively, and 1.50 MHz in $(Ph_3P)_2Ag(OC_6H_2Cl_3{-}2,4,6)$.[46] The crystal structure of the latter compound showed a Cl···Ag intramolecular bond distance of 316 pm, which is 65 pm over the sum of covalent radii, 251 pm. A very acute O–Ag–Cl bond angle of 64.5° is found, which was attributed to strain in the nonplanar chelate ring. Finally, NQR data were obtained for two Zn^{II} 2,6-dichlorophenolates,[47] one containing two pyridine (py) ligands and the other containing one tetramethylethylenediamine (TMED) ligand. The frequency differences averaged 1.191 MHz and 1.116 MHz, respectively, and thus were similar to those found in Hg^{II} derivatives.

The study was then extended leftward in the periodic table to incorporate the 2,6-dichloro-, 2,4,6-trichloro-, and 4-bromo-2,6-dichlorophenolates of the d^7 through d^9 ions Co^{2+}, Ni^{2+}, and Cu^{2+}, with (mainly) the coligands py, TMED, and N-methylimidazole.[47–49] Crystal structures of several complexes of these metals and ligands (generally involving 2,4,6-trichlorophenolato groups) are also available. Figure 2 shows that there is a good (though nonlinear) correlation of the NQR frequency differences between the 2-chlorine and the 6-chlorine, and the excess M···Cl bond distance (the observed M···Cl distance minus the normal single M···Cl bond distance). (It should be noted that this correlation is for chlorophenolates, and does *not* apply to silver-chlorocarbon complexes.)

Finally, it was determined that the NQR frequency difference depended strongly on the identity (d^n electron configuration) of the metal ion, as would be expected from the (inorganic) crystal field theory. With complexes of M^{II} 2,6-dichlorophenolates and common coligands (TMED or two py), if the 2-chlorine is coordinated to the metal and is acting as a classical ligand, one has octahedral complexes; if the chlorines are not coordinated, one has tetrahedral complexes. The octahedral site stabilization energy (OSSE) (energy preference for octahedral over tetrahedral coordination) depends on the

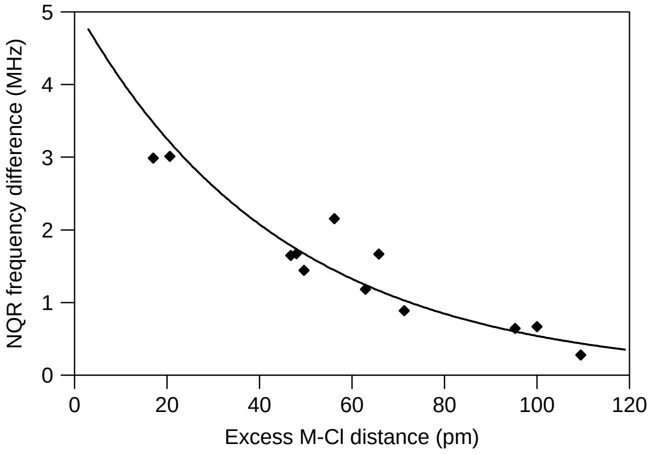

Figure 2 Average ^{35}Cl NQR frequency difference of coordinated ortho-chlorine and noncoordinated (free) ortho-chlorine atoms in 2,6-dichlorophenolato(*O,Cl*) complexes of metals, as a function of the excess M–Cl distance, defined as the average observed M–Cl distance minus the normal M–Cl single bond distance in octahedral complexes, from A. G. Orpen, L. Branner, F. H. Allen, O. Kennard, D. G. Watson, and R. Taylor, *J. Chem. Soc., Dalton Trans.* 1989, S1–S83

Table 4 Effects of OSSE on average ^{35}Cl NQR frequency differences of coordinated and free *ortho* chlorines 2,6-dichlorophenolato(*O,Cl*) complexes of late transition metals (as compared to zinc complexes)

d^n electron configuration, and is zero for the d^{10} ion Zn^{2+}. As indicated in the first row of Table 4, the d^7 and d^9 ions Co^{2+} and Cu^{2+} ions have intermediate OSSE (for weak-field ligands such as in these complexes), and the largest stabilization energy is expected for the d^8 Ni^{2+} ion. As shown in the remainder of Table 4, nickel chlorophenolates indeed give significantly the largest frequency differences between free and coordinated ortho chlorines of any of these metals (in Table 4, these are compared to the frequency differences of the zinc chlorophenolates). It may be noted that there is a great deal of variability for the Cu^{II} complexes: the chlorines in these octahedral complexes occupy sites showing quite variable Jahn-Teller elongation.

Another example not involving 4th-period d-block ions or chlorophenolates has been studied. The Schiff base formed from 2-chloroaniline and 2,6-dichlorobenzaldehyde undergoes oxidative addition to $Mo(CO)_6$ to give a d^4 molybdenum tricarbonyl complex with a Mo···Cl–(aniline) distance of 262.4 pm, only a little longer than the single inorganic Cl–Mo bond distance of 247.3 pm in the same compound.[50] The ^{35}Cl NQR frequency of the complexed Schiff base is 3.685 MHz lower than the free Schiff base. Applying equations (8) and (9) allows us to estimate $\sigma_{B2} = 0.134–0.161$. This large value can be justified by noting that Period 5 metal ions give larger crystal field stabilization energies than do Period 4 metal ions, especially when strong-field ligands such as CO are present.

3.2.3 *Weakly Coordinating Anions*

Chemists working in catalysis need weakly coordinating anions[51] as counterions to serve as good leaving groups from complexes of very reactive cations such as silylium ions, R_3Si^+, porphyrinatometal cations, (porphyrinato)Fe^+, and various catalytically active transition-metal organometallic cations, most importantly the zirconocene catalysts that are used in the industrial polymerization of alkenes.[52] Almost all anions will bond to such cations in preference to the neutral substrates (e.g., alkenes) required for the catalytic process involved. Therefore, one seeks very weakly coordinating anions that would be bound to the reactive cation only by very weak secondary bonding or even only by weak (since long-range) electrostatic (ion–ion or ion-induced dipole) interactions.

In order to be weakly attracted electrostatically to the cation, a weakly coordinating anion should have a low charge and a large size over which the charge can be dispersed: it should be as nonbasic[17] as possible. The weakly basic and poorly coordinating properties of anions such as methanesulfonate ($CH_3SO_3^-$), tetraphenylborate, $[B(C_6H_5)_4]^-$, and 1-carba-*closo*-dodecaborate, $(CB_{11}H_{12})^-$ can be further reduced by extensively substituting them with very electronegative atoms such as halogens, to give anions such as $CF_3SO_3^-$ and $[B(C_6F_5)_4]^-$.

However, such fluorine atoms are hard bases, and have been shown to coordinate to the (presumably) hard zirconium cation.[53] It is worth investigating whether the secondary bonding would be weaker if the fluorine atoms on typical nonbasic anions were replaced with softer chlorine, bromine, or iodine atoms. Perhaps, in this light, it may be significant that zirconocene catalysis is especially efficient when the anion is $(CB_{11}H_6X_6)^-$ (X = Cl, Br, or I).

Since the oxygen atoms of carboxylate anions or even sulfonate ions are hard bases, they coordinate readily to zirconium, as indicated by the infrared spectra of zirconocene and hafnocene bis(chloroacetates) and by X-ray crystallography for titanocene bis(trifluoromethanesulfonate).[54] Thus we envision the design of a large, low-charged, nonbasic anion that might be very weakly coordinating to hard acids such as the zirconocene cation having *no* hard-base atoms on its surface, yet having electronegative atoms (hence Cl, Br, or I). Oxygen atoms would either have to be absent from this anion, or would have to be confined to its interior. An example of the former

might be a C_{60}^{-} anion which had been thoroughly chlorinated, so that no double bonds were available to coordinate to Zr; an example of the latter might be the perchloro analogue of the well-known weakly coordinating anion $[Al(O\text{-}tert\text{-}C_4F_9)]^-$, in which the oxygen atoms are inaccessible.

We might be able to use chlorine NQR to identify whether such an anion showed secondary bonding interactions with catalyst cations, or whether it interacted with them only by long-range (and therefore weak) interionic attractions. Such an anion probably *would* show secondary interactions with soft cations such as Ag^+, which would result in low halogen NQR frequencies for the coordinated chlorines (and, if measurable, high asymmetry parameters). However, we would hope for no such results for hard-acid cations that are similar in charge and size to Ag^+ (e.g., Na^+ or K^+).

However, there *would* be significant ''crystal field effects'' from nearby ions. As we discussed earlier, these are significant, and differ in how they depend on cation size. If our salts adopted typical ionic lattices as found in the hexahalometallate salts discussed earlier, we might again see *increases* in NQR frequencies with increasing group 1 cation radius. Since we hope that our anion would be less polarizable (and less easy to dismember) than $SnCl_6^{2-}$, we would then look for *smaller* increases with increasing cation size. On the other hand, the zirconocene cation itself is only open to coordinate anions on one side, so that its salts might adopt layer type lattices (or even be present as discrete ion pairs). In this case we might see *decreases* in NQR frequencies with increasing cation size, but they would hopefully be less than is the case in chloroacetates. And in such a case, the chlorines on one side of the large perchlorinated anion would not be close to a cation at all, so their NQR frequencies might be independent of cation size. Regardless of whether the salts adopted typical ionic lattices or layer lattices, we would look for an anion in which the effect of the hard-acid cation on the NQR frequency was notably small.

3.3 Applications Involving Multivalent Central Atoms

The Townes–Dailey approach to interpreting NQR spectra of atoms at the center of polyatomic ions or complexes depends in its details on the geometry and bond angles of the central atom, so no attempt will be given here to summarize the equations; we will only mention a few examples to illustrate the availability and use of the data.

High-temperature superconductors are based on copper, which has NQR-active nuclei, and NQR spectra can be obtained on these superconductors while they are in the superconducting state, which excludes magnetic fields. For the classic superconductor $YBa_2Cu_3O_{6.9}$, two ^{63}Cu NQR signals can be obtained. The square-planar-coordinated Cu(1) gives an NQR signal at 22.05 MHz, for which $e^2Qq_{zz} = 38.9$ MHz and $\eta = 0.95$; the square-pyramidal-coordinated Cu(2) gives an NQR signal at 31.5 MHz, for which $e^2Qq_{zz} = 63.08$ MHz and $\eta = 0.04$.[14,55] Data have also been obtained using the medium-abundance isotope ^{133}Ba, as well as ^{139}La in the La_2CuO_4–related superconductors. We also mention a review of Cu NQR spectroscopy in Cu^I complexes.[56]

There have been reviews of NQR spectroscopic studies of central-atom nuclei in complexes[57,58] and in organometallic compounds.[59] The interpretation of the e^2Qq_{zz} and η values of these nuclei depends on the coordination number of the atom, the bond angles, the covalency of the bonds to the central atom, and lattice effects, so it is not practical to summarize the field. We illustrate with a ^{59}Co NQR and NMR spectroscopy study[60] of a series of cobaloxime (bis-dimethylglyoximato)cobalt(III), $[XCo(dmg)_2L]$ complexes, in which dmg is the dimethylglyoximato monoanion, L is a Lewis base such as methanol, pyridine, trimethylamine, halide ion, and triphenylphosphine, and X is an anion such as CH_3^-, $CHCl_2^-$, Cl^-, and Br^-. (These complexes are of interest as bioinorganic models for Vitamin B_{12} (cobalamin).) A ''partial field gradient'' model was developed for the bonding, composed of contributions from the equatorial (dimethylglyoximato) and the axial (X and L) ligands. It proved to be less appropriate to derive fixed partial field gradients for each ligand, than to assume that the sums of all partial field gradients were constant in this set of complexes (changing the axial ligand also changed the partial field gradient due to the equatorial bis(dimethylglyoximato) ligand). Then it was possible to order the axial ligands in terms of the ratios of the axial and equatorial partial field gradients: for example, methanol > trimethylamine > pyridine > triphenylphosphine.

Studies have also been made of complexes from the point of view of the nitrogen atom in the ligand. Because of the low NQR frequencies of ^{14}N, these have often been done using NMR–NQR double resonance techniques. Again we cite only one example, a series of studies of pyridine (C_5H_5N) ligands coordinated to different diamagnetic metal[61] (and even nonmetal)[62] atoms. Through another adaptation of the Townes–Dailey method, the electron populations of the σ-donating orbital of the pyridine nitrogen atom were deduced, and showed reasonable trends: free pyridine (2.00 e^-) > $Cdpy_2Cl_2$ (1.87 e^-) > $Znpy_2Cl_2$ (1.79 e^-) > $py \cdot I_2$ (1.74 e^-) > $Fepy(CO)_4$ (1.72 e^-) > $[Ipy_2]ClO_4$ (1.64 e^-) > $[pyH]NO_3$ (1.38 e^-). In this series, the coordinate covalent bond order would then proceed in the other direction, from 0.00 in free pyridine to 0.62 in the $[pyH]^+$ cation.

The usefulness of NQR spectroscopy is thus not confined to the study of weak secondary bonds, but can be applied to ordinary covalent or coordinate covalent bonding as well. Hopefully with the advent of modern pulse-FT NQR methods, easier structural determination by X-ray crystallography, and more powerful computational methods to handle the many bonds in complex ions, NQR can resume its contribution in this area of inorganic chemistry as well.

4 ABBREVIATIONS AND ACRONYMS

CW = continuous-wave; CW-NQR = continuous wave NQR; DFT = density functional theory; EFG = electric field gradient; IR = infrared; NMR = nuclear magnetic resonance; NQR = nuclear quadrupole resonance; OSSE = octahedral site stabilization energy; PAC = perturbed angular correlation; pulse-FT = pulse-fourier transform; TMED = tetramethylethylenediamine.

METHOD SUMMARY

Acronyms, Synonyms

- Nuclear Resonance Vibrational Spectroscopy (NRVS)
- Nuclear Resonant Inelastic X-ray Scattering (NRIXS)
- Nuclear Inelastic Scattering (NIS)
- Phonon-assisted Mössbauer effect

Measured physical quantities

- Simultaneous excitation of Mössbauer nucleus and vibrational quanta; vibrational features appear as sidebands on recoilless resonance.

Information available

- Complete vibrational spectrum of probe nucleus.
- isotope-specific; access to individually labelled metal sites.

Information not available, limitations

- no direct sensitivity to vibrations of other atoms;
- resolution slightly lower than Raman or infrared (IR).

Examples of questions that can be addressed

- Strength of metal coordination
- Energetic cost of probe displacement
- Distinguish metal-ligand vibrations from cofactor or peptide vibrations
- Local versus global character of active site vibrations

Major advantages

- selective to vibrations of Mössbauer isotope;
- quantitative information on vibrational amplitudes, as well as frequencies;
- single crystal measurements selective for motion along X-ray beam;
- applicable to photolabile samples;

- equally applicable to all ligation and oxidation states;
- direct comparison to predicted vibrational frequencies, amplitudes, and directions.

Major disadvantages

- Low count rate experiments; limited to highly specialized synchrotron beam lines.
- Limited range of accessible nuclei with current technology; primarily ^{57}Fe for bioinorganic applications.

Sample constraints

- requires isotopic enrichment with Mössbauer isotope;
- high concentrations (5–10 mM) of probe nucleus required;
- volume approximately 100 µL (depending on beam size);
- detailed interpretation requires cryogenic temperature.

1 INTRODUCTION

Mössbauer experiments (*see* ***Mössbauer Spectroscopy***) rely on constraining the probe nucleus in a solid in order to enable the recoilless absorption of incident γ rays.[1] However, this does not stop the probe nucleus from undergoing vibrational motions. Soon after the Mössbauer effect was discovered, it was suggested that it could be extended to measure the vibrational spectrum of the Mössbauer nucleus in the solids by tuning the photon energy to excite vibrational energy levels coincident with the nuclear excitation.[2,3] This suggestion is the genesis of nuclear resonance vibrational spectroscopy (NRVS).

Typical vibrational quanta lie in the order of tens of meV ($1\,\mathrm{MeV} \approx 8\,\mathrm{cm}^{-1}$); however they correspond to inconveniently large Doppler velocities on the order of hundreds of meters per second. As a result, practical experimental realization of this idea required the development of appropriate technology at brilliant third-generation synchrotron radiation facilities, where X-rays can be generated and tuned over the range needed to excite vibrational quanta. This was first accomplished only about a decade ago.[4–6] NRVS has become the most common terminology for applications of this method to inorganic and bioinorganic systems.[7,8] However, the same technique is described in the literature using alternate names, including nuclear resonant inelastic X-ray scattering (NRIXS),[9] nuclear inelastic scattering (NIS),[10] and the phonon-assisted Mössbauer effect.[11]

In traditional vibrational methods such as Raman or IR spectroscopy (*see* ***Vibrational Spectroscopy***), only vibrational modes allowed by selection rules will appear in the spectra. To help assign the modes, isotope difference spectra are used. But owing to selection rules, some modes do not appear in the spectrum. Spectral congestion also raises difficulty in resolving modes with close frequencies, particularly for macromolecules containing thousands of atoms.

NRVS is both more selective and more comprehensive than Raman or IR. NRVS reveals all vibrations of the probe nucleus, ignoring motions of all other atoms. ^{57}Fe, with a nuclear resonance energy $E_0 = 14.4125\,\mathrm{kev}$, is a Mössbauer isotope with favorable properties for currently available sources. Moreover, iron plays important roles in many proteins, including heme proteins and iron–sulfur proteins.[12]

Synchrotron-based nuclear resonance methods have revealed the vibrational dynamics of the iron atom in numerous systems, including alloys, amorphous materials, nanomaterials, and materials under high pressure.[9,13–15] The above-mentioned selectivity for the probe nucleus is particularly valuable for biological macromolecules, which may contain many thousands of atoms, but a localized active site is often the true center of interest. Since its availability,[4–6] NRVS has been applied to study the vibrational dynamics of Fe in proteins,[7,11,16–19] porphyrin model compounds,[8,20–26] and iron–sulfur clusters.[27–29] It is shown that NRVS can provide frequencies, amplitudes, and directions for Fe vibrations in the samples. It helps to clarify mode assignments in vibrational spectra and reveals many important vibrational modes of Fe that cannot be seen by other methods. In particular, NRVS reveals low-frequency motions of the Fe down to below $100\,\mathrm{cm}^{-1}$ that control biological reactions. The applications presented here use ^{57}Fe as the probe nucleus, but the principle applies to other Mössbauer isotopes such as ^{119}Sn, ^{83}Kr, ^{61}Ni, and ^{67}Zn if appropriate sources are available.

2 TECHNICAL BACKGROUND

2.1 Overview of Experiment

NRVS is related to Mössbauer spectroscopy (*see* ***Mössbauer Spectroscopy***), but it cannot be easily realized using conventional Mössbauer equipment. Practical NRVS experiments target the sample containing the probe nucleus (^{57}Fe, for example) with X-rays generated by a synchrotron radiation facility. The incident photon energy varies around

the nuclear resonance energy $E_0 = 14.4125$ kev with a typical resolution of about $1\,\text{meV} \approx 8\,\text{cm}^{-1}$ sufficient to provide vibrational resolution. It can be tuned to more than 100 meV from E_0 to explore sidebands that result from excitation of vibrations consistent with population of the nuclear excited state. The energy range must be large enough to include all vibrations with significant Fe amplitude, with a resolution sufficient to resolve individual vibrational modes. The energy bandwidth is much larger than the hyperfine splittings detected in conventional Mössbauer measurements (*see* ***Mössbauer Spectroscopy***), and all of the nuclear sublevels are excited in these synchrotron-based experiments.

Figure 1 depicts a typical sequence of events started by absorption of an incident photon with an energy near the nuclear excited state energy E_0. The ^{57}Fe nucleus has an excited state lifetime of 141 ns, and excited nuclei have two decay channels. About 10% of them reemit a 14.4 kev photon. For recoilless absorption, where no vibrational levels are excited, time-resolved measurements of 14.4 kev photons scattered in the forward direction reveal information on hyperfine interactions comparable to conventional Mössbauer spectroscopy (*see* ***Mössbauer Spectroscopy***). The remaining nuclei expel electrons from the atomic K shell, followed by 6.4 kev atomic fluorescence when an electron drops from a higher level to fill this hole. These delayed signals at 6.4 and 14.4 kev indicate nuclear resonance absorption of the X-ray and constitute the NRVS signal. The relative contribution of 6.4 and 14.4 kev photons will depend on sample thickness and detection efficiency.

2.2 Source Characteristics and Detection

Because of the extremely narrow energy window selected, practical NRVS measurements require the highest X-ray brilliance currently available at third-generation light sources. At present, there are three major synchrotron radiation sources for nuclear resonance experiments: beam line 3ID at the Advanced Photon Source (APS) at Argonne National Lab, in the USA,[30] beam lines ID18 and ID22N at the European Synchrotron Radiation Facility (ESRF) in France,[31] and beam line BL09XU at SPring8 in Japan.[32] These are public beam lines and users can submit research proposals to apply for beam time for experiments.

Figure 2 illustrates the experimental setup at the APS. Separated electron bunches circulate at a speed very close to the speed of light in the storage ring, which is 1100 m in circumference. X-rays are generated over a broad bandwidth when the electrons pass through the undulator. Diffraction from perfect single crystals selects a narrow range of energies that meet the Bragg diffraction condition.

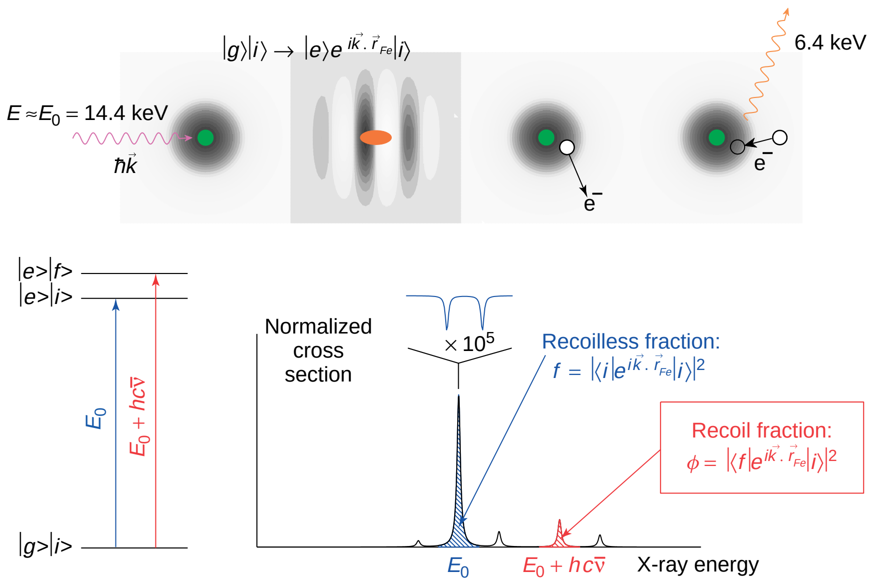

Figure 1 Excitation of the ^{57}Fe resonance at $E_0 = 14.4125$ kev. Absorption of a 14.4 kev photon by a hypothetical free nucleus (top) in an initial state $|i\rangle$ would leave it in a final state $|f\rangle = \exp(i\vec{k}\cdot\vec{r}_{\text{Fe}})\,|i\rangle$, in order to conserve momentum. The primary decay channel for the nuclear excited state is to expel one electron from the atomic K shell, which is followed by 6.4 kev fluorescence when an electron drops from a higher energy level to fill the resulting vacancy. Emitted 6.4 kev photons, together with 14.4 kev photons emitted from the nuclear excited state, are delayed with respect to the excitation by a time on the order of the 141 ns nuclear excited state lifetime, and constitute the detected nuclear resonance signal. In a realistic experimental situation (bottom), the nucleus is bound to neighboring atoms, final states are quantized, and a series of vibrational sidebands appear, corresponding to transitions to a final vibrational state $|f\rangle$ with energy $hc\bar{\nu}$ coincident with the nuclear excitation. Each transition appears at an energy $E_0 + hc\bar{\nu}$ with a relative area $|\langle f|\exp(i\vec{k}\cdot\vec{r}_{\text{Fe}})|i\rangle|^2$. Unlike conventional Mössbauer measurements, synchrotron-based measurements do not directly resolve hyperfine splittings of the recoilless resonance $(|f\rangle = |i\rangle)$ at $E = E_0$

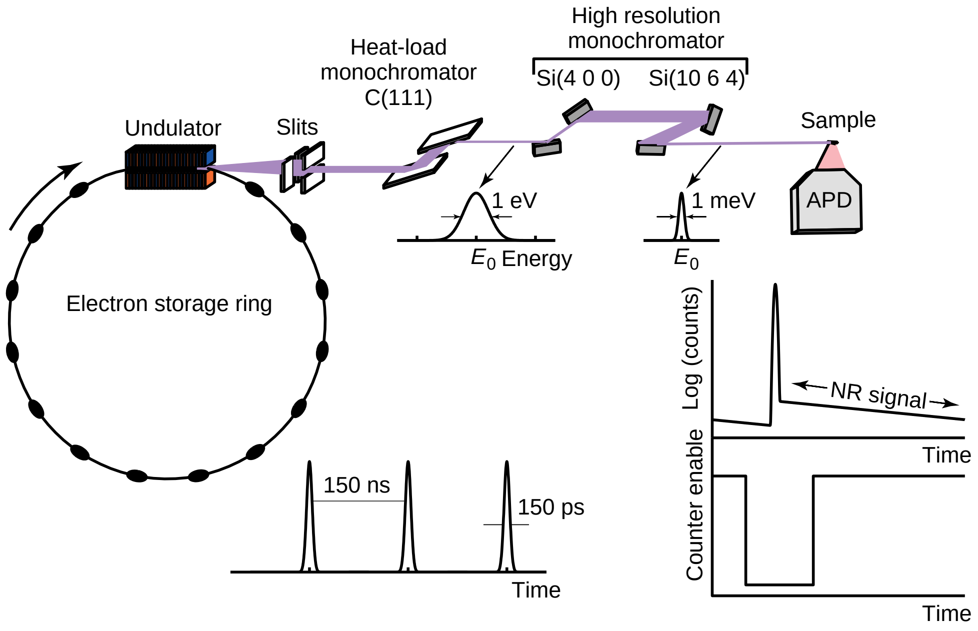

Figure 2 Experimental arrangement for measurements of the ^{57}Fe nuclear resonance at the Advanced Photon Source (APS). In the standard fill pattern, electron bunches with a duration of 100 ps are separated by 153 ns. X-ray pulses are generated when alternating magnetic fields in the undulator accelerate these electron bunches. The spectral bandwidth of the X-rays is reduced to ~1 eV by the heat-load monochromator and to ~1 meV by the high-resolution monochromator. At the sample, the flux of the beam is about 10^9 photons/s. APD indicates the avalanche photodiode used to detect emitted X-rays. The lower right inset illustrates that counting is enabled only for times well-separated from the X-ray pulse, so that only delayed photon emission resulting from decay of the nuclear excited state contributes to the experimental signal

Following the heat-load monochromator, the X-ray bandwidth is narrowed to approximately 1 eV and centered on the nuclear resonance energy (14.4 kev for ^{57}Fe). The high-resolution monochromator[33] further reduces the X-ray bandwidth to about 1 meV and motorized scanning of this monochromator tunes the energy over a range (typically within 100 meV of the resonance) adequate to explore excitation or annihilation of vibrational quanta. The X-ray flux at the sample is about 10^9 photons/s (~10 µW), which is very low compared to typical milliwatt beam powers in laser-based Raman experiments (*see* ***Vibrational Spectroscopy***). Additional X-ray optics may reduce the beam size. The cross section of the beam at the sample point is currently about 0.5 × 0.5 mm^2 at station D of beam line 3ID at APS.

Detection of nuclear resonance signals exploits the time structure of the electron bunches circulating in the storage ring. The standard fill pattern at the APS, with bunches separated by 153 ns, is favorable for ^{57}Fe measurements. Ideally, each bunch is about 100 ps in length. When the resulting X-ray pulse hits the sample, it interacts with the ^{57}Fe nuclei, as well as with electrons. Strong prompt signals as high as 6 MHz result from electronic scattering coincident with the X-ray pulse. This signal is not related to the nuclear resonance at all, and the counting electronics are gated off during a time interval surrounding the arrival time of the X-ray pulse (see inset in Figure 2). The X-ray photon can be absorbed by the ^{57}Fe nucleus only when its energy matches the nuclear resonance transition energy (with or without excitation or annihilation of vibrational quanta). Photons emitted as a result of nuclear excitation arrive with a delay on the order of the lifetime of the nuclear excited state (141 ns for ^{57}Fe). The maximum delayed count rate near E_0 is typically on the order of 100 Hz for protein samples and 1000 Hz for model compounds with appropriate concentrations described in the next section. The vibrational signal is substantially weaker.

The avalanche photodiode detector (APD) has nanosecond time resolution and is controlled by timing circuits so that only delayed signals are counted to give a NRVS spectrum. Under favorable operating conditions, electronic noise is the main source of background. The APD is designed to work at room temperature, and care must be taken to avoid unwanted noise generated by cold air from a nearby cryostat. Electronic timing errors or beam fill errors may also contribute to background noise by causing electronically scattered photons to register as delayed counts. An acceptable noise level of 0.03 Hz or less can usually be achieved with an X-ray flux of 10^9 photons/s.

2.3 Sample Characteristics

Several factors have to be considered when preparing samples for NRVS measurements.

First, the sample must be isotopically enriched with ^{57}Fe or other Mössbauer nucleus of interest. Small molecule

samples such as porphyrins enriched with up to 95% ^{57}Fe are prepared according to the small scale metalation procedure of Landergen and Baltzer.[34] Proteins are usually enriched with ^{57}Fe through reconstitution. For many heme proteins, the Fe protoporphyrin [Fe(PPIX)] can be extracted using Teale's method[35] and then replaced with commercially available [^{57}Fe(PPIX)].[7,18] Harsher procedures are required to extract and replace the Fe from the covalently bonded heme in cytochrome *c*.[36] Proteins can also be expressed, for example in *Escherichia coli*, with ^{57}Fe supplied in the culture medium. In favorable cases, reconstitution may provide an opportunity to selectively label one of multiple distinct Fe sites, a feature often exploited in Mössbauer spectroscopy (*see* ***Mössbauer Spectroscopy***).

Another important factor is the sample concentration or, more specifically, the ^{57}Fe concentration, which must be high enough to yield reasonable signal strength. Solutions of protein enriched with ^{57}Fe at a single site and which are of concentration 5–10 mM yield interpretable NRVS data at 8 cm^{-1} resolution within 20–30 hours of beam time at the APS.[18] The small size of molecules designed to mimic protein-active sites allows significantly higher concentrations, often reducing measurement times to a few hours. For porphyrin samples, using a $1 \times 2 \times 10\,mm^3$ sample holder, a sample of up to ∼26 mg can be used, corresponding to $1–2 \times 10^{19}$ ^{57}Fe nuclei.

Sample purity is a key concern. The NRVS experiment is a bulk technique sampling all ^{57}Fe nuclei, and impurities that also contain the probe nucleus may confound quantitative data interpretation. Impurities may be introduced during sample preparation or may result from sample instability during measurement. Because of this, care must be taken to ensure purity and reproducibility as judged by Mössbauer (*see* ***Mössbauer Spectroscopy***), single-crystal X-ray diffraction, electronic absorption spectroscopy (*see* ***Electronic Spectroscopy***), Raman spectroscopy or other qualitative techniques.

To make full use of the incident beam, the sample volume should be large enough to fill the beam. Single crystals should ideally exceed the area of the beam ($0.5 \times 0.5\,mm^2$) to maximize signal. Single crystals are aligned using a four-circle diffractometer, which adds the additional degree of freedom (χ) needed for single-crystal alignments. Careful observation of crystal morphology along with molecular packing acquired on natural abundance iron samples may allow an approximate alignment. In the ideal crystalline case, the porphyrins are all coplanar. It is beneficial to place the porphyrin plane, or plane normal to the porphyrin plane, along the goniometer arcs. Use of an eucentric goniometer head for all alignments allows for fine orientation adjustment without significant recentering.

Sample holders for powders and solutions consist of a high-density polyethylene (HDPE) block with a $1 \times 2 \times 10\,mm^3$ milled well. The sample is placed into the well, a small Teflon seal is placed on the block, and a sapphire window is placed over the seal. Brass screws attach the HDPE block to a round copper block to facilitate heat transfer to the cold finger of a helium-flow cryostat. Some practice may be needed to avoid bubbles created when the Teflon seal or sapphire wicks viscous protein solutions out of the well. If possible, it may be helpful to freeze the solution in the cell before placing the sapphire window. Isolated polycrystalline samples are mulled with a minimal amount of Apiezon M vacuum grease on a microscope slide using a *non*-metallic instrument and placed in the sample holder.

In the experiment, the high-resolution monochromator tunes the incident X-ray energy through the recoilless nuclear transition energy E_0. The energy range must include all vibrational signals for accurate normalization. A typical range around E_0 is $[-30, 80]$ meV for heme proteins or porphyrins at $T < 30\,K$, but larger ranges may be required at higher temperature or for certain samples to enable data normalization, at the cost of increased measurement time. The energy sampling interval should be less than the resolution of the monochromator. A step size of 0.25 meV is typical for 1 meV energy resolution, with an accumulation interval of 5 s/point, allowing completion of one full energy scan within 1 h. Typically, multiple scans are averaged to improve signal-to-noise ratios, and to identify possible scan-to-scan variations resulting from instrumental artifacts or from sample instability. For porphyrin model compound samples, either in the form of crystal or powder, three to four scans may be enough to obtain acceptable data quality. Satisfactory results on concentrated protein samples may require more than 20 scans (about 1 d).

Unless there is specific interest in temperature dependence, data interpretation is simplest at the lowest temperatures that are conveniently achievable. Crystal samples can be placed in a cold nitrogen gas stream and powder or solution samples can be mounted on a helium-cooled cryostat. Figure 3 shows NRVS data recorded for an Fe(TPP)(1-MeIm)(NO) crystal at two different temperatures with the heme plane lying nearly parallel to the X-ray beam. Differences between the two spectra are apparent both for the central line (Figure 3 inset) and for the higher frequency signals. Thermal excitation of low-frequency vibrations with increasing temperature leads to the appearance of unresolved shoulders on all bands, including the recoilless line (inset), reducing the effective experimental resolution. Substantial ''anti-Stokes'' signals resulting from vibrational deexcitation also appear at energies below E_o as the temperature increases, necessitating measurement over a larger frequency range to ensure spectral normalization. However, the relative intensities of these ''anti-Stokes'' signals provide a useful measure of sample temperature (see next section).

Figure 4 shows a typical design of a helium-cooled cryostat, which balances the competing requirements for X-ray detection and temperature control. Samples are loaded in the

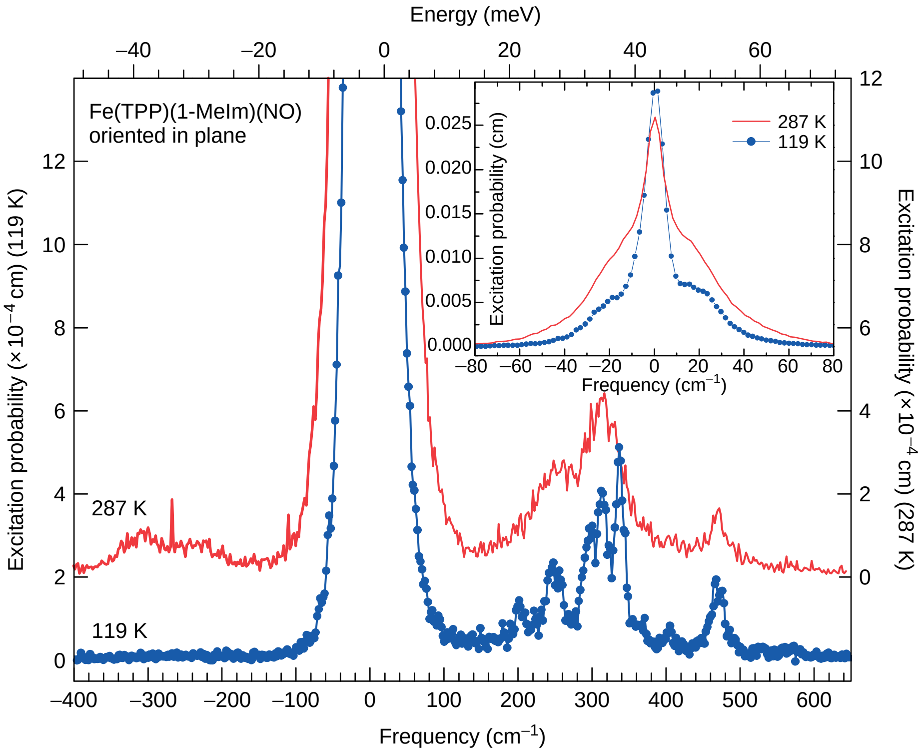

Figure 3 NRVS data recorded on a single crystal of Fe(TPP)(1-MeIm)(NO), oriented with the X-ray beam 13.8° from the planes of all porphyrin molecules, at two different temperatures, 119 K (blue) and 287 K (red). The two curves in the main panel are normalized according to Lipkin's first moment sum rule (equation 2) and scaled up by 200 times. It is apparent that increasing temperature leads to effective line broadening and to signals at negative energy resulting from vibrational deexcitations. The inset shows an expanded view of the recoilless line, with shoulders due to low-frequency lattice vibrations

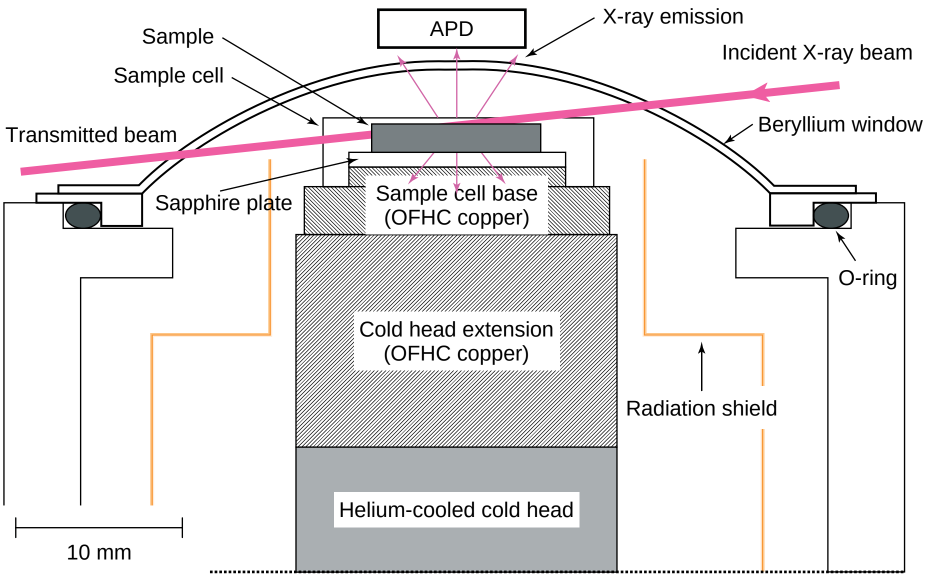

Figure 4 Typical cryostat design for solution and powder samples. This design features an expanded beryllium dome, which allows detection of the transmitted beam as well as the emitted X-rays that contribute to the NRVS signal. The Be dome and a thin polyethylene window on the front face of the sample cell minimize the absorption at 6.4 and 14.4 kev. A sapphire plate provides excellent thermal contact between the sample cell and the cryostat cold head, as well as allowing optical access for off-line Raman measurements to monitor sample integrity. Sample temperatures in the 20–30 K range are typically achieved for both solutions and powders

cup, which has good thermal contact with the cold head. The cryostat chamber is kept in a vacuum state of 10^{-5} mbar during experiments. The beryllium dome is transparent to X-rays. The APD detector is placed as close as possible to the sample to maximize the solid angle over which X-rays are collected. If desired, a second APD can be used to detect the forward scattering beam.

2.4 Data Collection

As with all beam line experiments, advance planning is essential. The availability of beam time is not entirely predictable, may be awarded with relatively short notice, and cannot be rescheduled because of the large number of users affected. Facilities for preparing or modifying samples will be very limited or nonexistent. Moreover, the round-the-clock attention required for successful NRVS data collection, particularly on samples with low count rates, provides little opportunity for sample modification.

If a previous user has performed measurements using the same nuclear resonance, data collection may commence near the start of the assigned beam time. Otherwise, time must be invested in adjusting the undulator, aligning the monochromator, finding the resonance, optimizing energy resolution and throughput, and establishing appropriate voltage thresholds and timing for detection of delayed counts. These are specialized operations that are usually performed by trained beam line personnel, who may also handle certain local arrangements such as the availability of cryogens.

Users take primary responsibility for all other aspects of data collection and analysis, although further guidance from beam line personnel may be required if problems arise. Because experimental problems occur, data are nearly always recorded as multiple energy scans, which are subsequently summed. The energy sampling interval is usually chosen to be smaller than the energy resolution (typical values are 0.25 and 1 meV), so that scans containing unphysical features narrower than the experimental resolution can be excluded. Other reasons for excluding individual scans include high background count rate and interruptions in the X-ray beam. Excluded scans may indicate a problem that will compromise further data collection, and such problems should be identified and addressed before continuing.

The actual beam energy typically deviates slightly from the value selected by the nominal monochromator position, because the lattice constants of the crystals respond to temperature variations. Small energy corrections are automatically determined at each monochromator setting from temperature sensors in thermal contact with the crystals. Data summation software must account for the resulting small scan-to-scan variations in energy values. Crystal temperatures should be continually monitored for changes larger than this level, and the start of new scans is usually delayed to allow reestablishment of equilibrium following any event that substantially alters crystal temperature, such as an interruption in the X-ray beam. Ideally, the monochromator is housed in a separate enclosure upstream from the experimental station containing sample and detector, in order to keep temperature variations below 10 mK over the course of an energy scan.

Energies should be reproducible from scan to scan, with the exception of the small variations just described. However, it is customary to obtain data on a standard sample to verify the accuracy of the overall energy scale. This may be a sample whose vibrational frequencies have been well established in the scientific literature, or a sample measured at a previous data collection run. An alternative procedure involves measuring a concentrated sample, such as an ^{57}Fe foil whose temperature can be accurately measured, and adjusting the energy scale to ensure that $S(E)/S(-E) = \exp(E/k_BT)$. Such overall energy scale corrections may be on the order of 1%.

Data analysis usually involves subtraction of the recoilless absorption line at $E = E_0$, which has the shape of the monochromator energy resolution function, because the fundamental linewidth is orders of magnitude smaller than the experimental resolution. Delayed 14.4 kev photons scattered in the forward direction from a ^{57}Fe foil carry no vibrational signal and provide a straightforward experimental determination of the resolution function. Appropriate experimental design may allow this measurement in parallel with the NRVS measurement, using the X-ray beam transmitted through the sample (Figure 4). However, if the monochromator is stable, it may be sufficient to average two to three scans of the delayed forward scattering measured over a limited energy range (typically ± 10 meV) at occasional intervals during the data collection period.

Continuous monitoring of experimental performance is essential in order to minimize the number of scans that ultimately need to be excluded because of experimental problems, and thus to ensure optimal use of limited beam time. Individual scans should be compared periodically to monitor sample stability, although experience to date has revealed no evidence of radiation damage resulting from exposure of cryogenic samples to the low X-ray flux in NRVS measurements. Sample temperature must also be monitored because averaging of scans at different temperatures may interfere with accurate data analysis.

Monochromator throughput should be recorded at the beginning of each scan, along with user-determined experimental parameters such as energy sampling interval and dwell time. Efficient use of measurement time requires maintaining the incident X-ray flux, and may necessitate occasional adjustments to monochromator alignment to maximize throughput, with guidance from beam line personnel if needed. Depending on monochromator design and on which crystal is adjusted, this may require redetermination of the experimental resolution function.

It is especially important to systematically monitor the level of background noise from the detector, because apparently unobtrusive increases in background noise may

degrade the experimental signal-to-noise ratio as badly as decreases in X-ray flux. A straightforward noise check is to monitor the detector signal after setting the energy 200 meV below the recoilless resonance energy E_0, where delayed counts cannot be attributed to genuine nuclear resonance signal. Under favorable operating conditions at the APS, the count rate may be 0.02–0.03 counts/s. Action must be taken if the background count rate rises significantly above this level, particularly for low count rate samples such as protein solutions.

The most common reasons for elevated background levels are electronic detector noise and timing problems. Sources of electronic noise, particularly machinery such as vacuum pumps, must be placed outside the experimental station and the detector must be protected from possible temperature variations resulting from proximity to cryogenically cooled samples. Users can exercise limited control over noise levels by setting the voltage threshold of a discriminator to exclude low amplitude voltage pulses while registering larger pulses due to genuine photon detection events.

Beam fill errors can create stray electrons that are temporally separated from the main bunch, leading to detection of electronically scattered photons within the time interval where delayed emission from the nuclear excitation is expected. This signal will vary weakly across the narrow energy window of a NRVS scan, and thus contribute to a uniform background. In many cases, adjustments to the width and delay time of the gate signal can eliminate this contribution to background.

Software available at the beam line allows individual energy scans to be selected and added, and the summed scans should be periodically examined during data collection in order to identify any unanticipated experimental problems. The software calculates each experimental energy from the monochromator position, with correction for temperature variations of the monochromator crystals if needed. A fit in the region of the intense recoilless absorption line determines zero energy precisely. Measured counts are then binned according to the calculated energies and added. Variations of the incident X-ray flux during each energy scan are usually small, but are ordinarily measured and used to normalize the measured counts energy by energy in individual scans before summing. An optional input scale factor allows rescaling of the energy axis, if needed, to agree with energy calibration measurements. The data in Figure 3 are a sum of three to four scans, followed by an overall normalization as described in the following section.

2.5 Data Analysis

The measured NRVS signal is proportional to the number of resonant ^{57}Fe nuclei in the effective sample volume and to an excitation probability[2]

$$S(\bar{\nu}) = \sum_{if} p_i \left|\left\langle f|e^{i\vec{k}\cdot\vec{r}_{\rm Fe}}|i\right\rangle\right|^2 \mathcal{L}(\bar{\nu}-\bar{\nu}_{if}) \tag{1}$$

measured as a function of the energy separation $hc\bar{\nu} = E - E_0$ from the resonance energy E_0. Here, $|i\rangle$ and $|f\rangle$ represent the initial and final states of the nuclear center of mass. In thermal equilibrium, the occupation probabilities $p_i = \exp(-E_i/k_BT)/\sum_i \exp(-E_i/k_BT)$ weight the relative contribution of each initial state to the sum in equation (1), while the matrix element $\langle f|e^{i\vec{k}\cdot\vec{r}_{\rm Fe}}|i\rangle$ determines the contribution of the final states.

In the hypothetical scenario of absorption by a free nucleus (Figure 1, top), initial and final states both correspond to free translation of the nucleus and the only allowed final state $|f\rangle = e^{i\vec{k}\cdot\vec{r}_{\rm Fe}}|i\rangle$ corresponds to the absorbing nucleus recoiling with the momentum $\hbar\vec{k}$ of the incident photon. In this hypothetical situation, the excitation probability would consist of a single feature at an energy $E_0 + hc\bar{\nu}_R$ exceeding the nominal resonance energy E_0 by the amount of the nuclear recoil energy $hc\bar{\nu}_R = \hbar^2k^2/2m_{\rm Fe}$. This feature would have unit area, since the line shapes and the initial state probabilities are both normalized, $\int\mathcal{L}(\bar{\nu})\,{\rm d}\bar{\nu} = 1$ and $\sum_i p_i = 1$.

However, this freely recoiling state is not a stationary state of the Hamiltonian in relevant experimental situations, where the ^{57}Fe nucleus is bound to other atoms in a condensed phase. In general, a series of discrete lines appear in the spectrum (Figure 1, bottom), corresponding to a range of possible final states. Conventional Mössbauer spectroscopy relies on the presence of a narrow line ($f = i$) at E_0, with an area proportional to the recoilless fraction

$$f = \sum_i p_i \left|\left\langle i|e^{i\vec{k}\cdot\vec{r}_{\rm Fe}}|i\right\rangle\right|^2$$

to perform extremely high-resolution measurements of hyperfine interactions (*see* ***Mössbauer Spectroscopy***). In contrast, NRVS measurements exploit the appearance of a number of sidebands at energies separated from the resonance energy E_0 by the energy difference $hc\bar{\nu}_{if} = E_f - E_i$ between initial and final energy levels. Each sideband has an area

$$\phi = \sum_{if} p_i \left|\left\langle f|e^{i\vec{k}\cdot\vec{r}_{\rm Fe}}|i\right\rangle\right|^2$$

that can be considered a ''recoil fraction''. (Here, the sum over f is restricted to final states with a constant energy separation with respect to the initial state.)

The total spectral area is normalized, $\int S(\bar{\nu})\,{\rm d}\bar{\nu} = 1$, independent of the nuclear environment, since $\int\mathcal{L}(\bar{\nu})\,{\rm d}\bar{\nu} = 1$, and a simple closure argument ensures that $\sum_f \left|\left\langle f|e^{i\vec{k}\cdot\vec{r}_{\rm Fe}}|i\right\rangle\right|^2 = 1$. As a result, $f + \sum\phi = 1$, and situations that reduce the Mössbauer signal correspondingly strengthen the integrated NRVS signal. Lipkin[37] has shown that the first moment

$$\int_{-\infty}^{\infty} \bar{\nu}S(\bar{\nu}){\rm d}\bar{\nu} = \bar{\nu}_R \tag{2}$$

of the excitation probability yields the recoil energy. Since the recoil energy has a precisely determined value ($\bar{\nu}_R = 15.8\,\text{cm}^{-1}$ for ^{57}Fe), equation (2) provides a practical recipe for normalizing the experimental data to obtain a signal proportional to the excitation probability.

NRVS data are commonly interpreted within a harmonic approximation,[8,38] which describes molecular vibrations in terms of independent oscillations along a set of normal coordinates $Q_a = \sum_j \vec{e}_{j\alpha} \cdot \vec{r}_j m_j^{1/2}$ related through a linear transformation to the Cartesian coordinates $\vec{r}_j$ of atoms j weighted by their masses m_j. Molecular rotation and translation lead to six modes having zero frequency. Projection of the transformation coefficients $\vec{e}_{j\alpha}$ onto the direction $\hat{k}$ of the X-ray wave vector $\vec{k} = (E_0/\hbar c)\,\hat{k}$ determines the recoil fraction

$$\phi_\alpha = \frac{\bar{\nu}_R}{\bar{\nu}_\alpha} f\,(\bar{n}_\alpha + 1)\,(\hat{k} \cdot \vec{e}_{j\alpha})^2, \tag{3}$$

which is the fractional contribution of a feature appearing at frequency $\bar{\nu}_\alpha$ to the area of the excitation probability $S_j\,(\bar{\nu})$ of atom j, resulting from a single excitation of vibrational mode α. These fundamental transitions ($n_\alpha \longrightarrow n_\alpha + 1$) dominate the observed data at high frequencies and low temperatures, but weak vibrational overtones and combinations can be resolved under favorable conditions.[39] Spectral features corresponding to deexcitation of mode α appear at frequency $-\bar{\nu}_\alpha$, with an area given by an expression identical to equation (3) but with the factor $\bar{n}_\alpha + 1$ replaced by $\bar{n}_\alpha$.[a] The latter features become significant at temperatures high enough (or frequencies low enough) that the mean occupation number $\bar{n}_\alpha = [\exp\,(hc\bar{\nu}_\alpha/k_B T) - 1]^{-1}$ of mode α becomes significant (e.g., Figure 3).

The spectral area provides quantitative information on the amplitude and direction of motion of the probe nucleus through the final factor $(\hat{k} \cdot \vec{e}_{j\alpha})^2$ in equation (3). This information can be determined for each mode using equation (3). Alternatively, further analysis of the data can yield an estimated vibrational density of states (VDOS)

$$D_{\hat{k}}\,(\bar{\nu}) = \sum_\alpha (\hat{k} \cdot \vec{e}_{j\alpha})^2 \mathcal{L}(\bar{\nu} - \bar{\nu}_\alpha) \tag{4}$$

for the probe atom. $D_{\hat{k}}\,(\bar{\nu})$ is normalized such that $\int D_{\hat{k}}\,(\bar{\nu})\,\text{d}\bar{\nu} = 1$ and represents the contribution of motion of the probe atom along $\hat{k}$ to the total vibrational density of states $D\,(\bar{\nu}) = \sum_\alpha \mathcal{L}(\bar{\nu} - \bar{\nu}_\alpha)$, with $\int D\,(\bar{\nu})\ \text{d}\bar{\nu} = 3N$.

Practical measurements involve averaging over a large ensemble of molecules. For randomly oriented molecules, as in a solution or a polycrystalline powder, $\langle(\hat{k} \cdot \vec{e}_{j\alpha})^2\rangle = \frac{1}{3}e_{j\alpha}^2$, the recoil fraction becomes

$$\phi_\alpha = \frac{1}{3}\frac{\bar{\nu}_R}{\bar{\nu}_\alpha} f\,(\bar{n}_\alpha + 1)\,e_{j\alpha}^2 \tag{5}$$

and the partial VDOS

$$D\,(\bar{\nu}) = \sum_\alpha e_{j\alpha}^2 \mathcal{L}(\bar{\nu} - \bar{\nu}_\alpha) \tag{6}$$

represents the contributions from probe motion in all three directions. (Note that $\int D\,(\bar{\nu})\,\text{d}\bar{\nu} = 3$.) However, the directional information implicit in equations (3) and (4) is partially or completely retained in measurements on oriented single crystals (e.g., Figure 3), where the crystal structure restricts molecular averaging to a discrete set of orientations.

Figure 5 presents an example of the excitation probability $S\,(\bar{\nu})$ and the VDOS $D\,(\bar{\nu})$ for the iron atom in the molecule Fe(TPP)(1-MeIm)(CO), as determined from measurements on a polycrystalline sample. Sharp features in both representations of the experimental data clearly identify vibrational frequencies above $100\,\text{cm}^{-1}$, although low-frequency vibrational features are more apparent in the VDOS representation. The VDOS also provides the most convenient estimate of the mode composition factor $e_{j\alpha}^2$, since the area of each feature directly yields the sum of $e_{j\alpha}^2$ values for all contributing vibrations. This avoids the need to remove the additional factors in equation (5) that contribute to the area of a feature in $S\,(\bar{\nu})$, with the subtleties associated with determining an appropriate value for the recoilless fraction f.[8,39] However, calculation of $D\,(\bar{\nu})$ from $S\,(\bar{\nu})$ involves implicit assumptions that may not be valid in some situations, for example, when more than one molecular species contributes to the experimental signal or when vibrational anisotropy is significant.

The program PHOENIX[40] implements the calculation of $D\,(\bar{\nu})$ from $S\,(\bar{\nu})$, using the Fourier-log deconvolution method.[41] This program reads two input data files containing the summed sample data and the experimental resolution function, and two input parameters, background and temperature, are specified. The background is typically estimated from the counts in the high or low energy limit of the sample data, where no genuine vibrational signal is expected. The initial temperature can be estimated from a temperature reading or from the relative size of features at negative frequency, but is usually iterated to obtain a consistent analysis. Most protein solutions and polycrystalline porphyrin samples are measured in a helium-flow cryostat at 20–30 K, while the single crystals are typically measured in a cold gas stream near 100 K. After subtraction of the background, the data are normalized to satisfy equation (2), thus providing the excitation probability $S\,(\bar{\nu})$.

Subtraction of the resolution function reveals the vibrational contribution $S'\,(\bar{\nu})$ to the excitation probability. PHOENIX adjusts the subtraction weight to achieve the best match to the one-phonon contribution to the vibrational signal near E_0 expected for a Debye frequency distribution $\left(D\,(\bar{\nu}) \propto \bar{\nu}^2\right)$. The Fourier-log algorithm[5,41] then yields the dominant first-order vibrational contribution

$$S_1\,(\bar{\nu}) = \frac{1}{3}\frac{\bar{\nu}_R}{\bar{\nu}_\alpha}\,(\bar{n}_\alpha + 1)\,D\,(\bar{\nu})$$

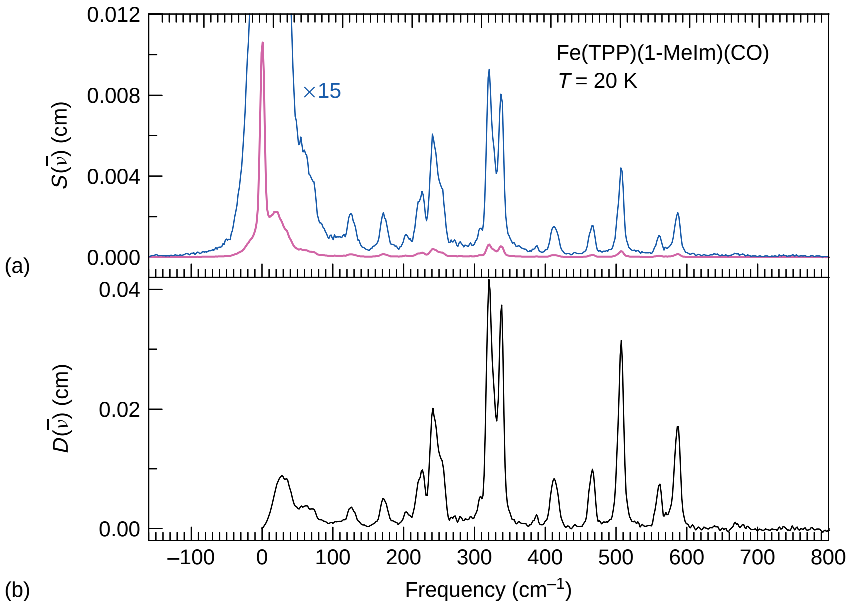

Figure 5 The excitation probability $S(\bar{\nu})$ (a) and corresponding Fe vibrational density of states $D(\bar{\nu})$ (b) of polycrystalline Fe(TPP)(1-MeIm)(CO). $S(\bar{\nu})$ results from normalization of summed experimental scans according to equation (2), and $D(\bar{\nu})$ results from Fourier-log deconvolution as implemented by the program PHOENIX[40]

to the excitation probability, from which the VDOS $D(\bar{\nu})$ is readily calculated.

Output results include a quantitative indication of how consistent the input temperature value is with the detailed balance condition $S'(\bar{\nu})/S'(-\bar{\nu}) = \exp(hc\bar{\nu}/kT)$. The recoilless fraction f and other vibrational properties that can be calculated from moments of $S'(\bar{\nu})$ according to sum rules given by Lipkin[37] are compared with values calculated directly from $D(\bar{\nu})$ as further consistency checks. Small adjustments in the values input for temperature and background are typically needed to achieve self-consistent results. In our experience, the resulting estimate of the sample temperature may be 10 K or more higher than the reading of a nearby sensor because of temperature gradients. Output spectral files include first-, second-, and higher-order contributions $S_1(\bar{\nu})$, $S_2(\bar{\nu})$, and $\sum_{n>2} S_n(\bar{\nu})$, to the excitation probability as well as the total vibrational contribution $S'(\bar{\nu}) = \sum_{n\geq 1} S_n(\bar{\nu})$ and the VDOS $D(\bar{\nu})$.

As noted above, the area of a peak in the VDOS provides a straightforward measure of the mode composition factor $e_{j\alpha}^2$ according to equation (6) (possibly summed over a number of unresolved modes). However, there are nontrivial approximations implicit in the calculation. In addition to the Debye approximation used to subtract the recoilless contribution, the Fourier-log algorithm assumes a unique environment for the probe atom and neglects vibrational anisotropy. The resulting errors are often smaller than the experimental uncertainty, particularly for protein samples. However, there may be situations where these assumptions are questionable, for example, if the probe nucleus occupies more than one distinct site. If there is reason to believe that this is not adequate, careful analysis of the recoil fraction according to equation (5) provides an independent estimate of $e_{j\alpha}^2$.

3 APPLICATIONS: HEME PROTEINS/ PORPHYRINS

3.1 Heme Proteins

NRVS represents the ultimate limit in vibrational selectivity, because it reveals the vibrational spectrum of an individual probe atom even when embedded in a complex environment such as a biomolecule containing thousands of other atoms. ^{57}Fe NRVS is thus an exquisite probe for the structure and dynamics of the immediate coordination sphere of the iron, which is the heart of the reactivity of numerous important proteins.

The earliest protein applications have involved myoglobin (Mb)[16,7,11], which can be reconstituted with ^{57}Fe and prepared at concentrations exceeding 10 mM. Early measurements required days of data collection, but continual experimental improvements now allow collection of interpretable data from 5–10 mM solutions in 20–30 h of beam time, as illustrated by the data shown for nitrosylmyoglobin (MbNO) in Figure 6.[18]

Fe–ligand vibrations dominate the NRVS signal. In this section, we survey the character of the observed modes for heme proteins, and briefly consider their importance for future

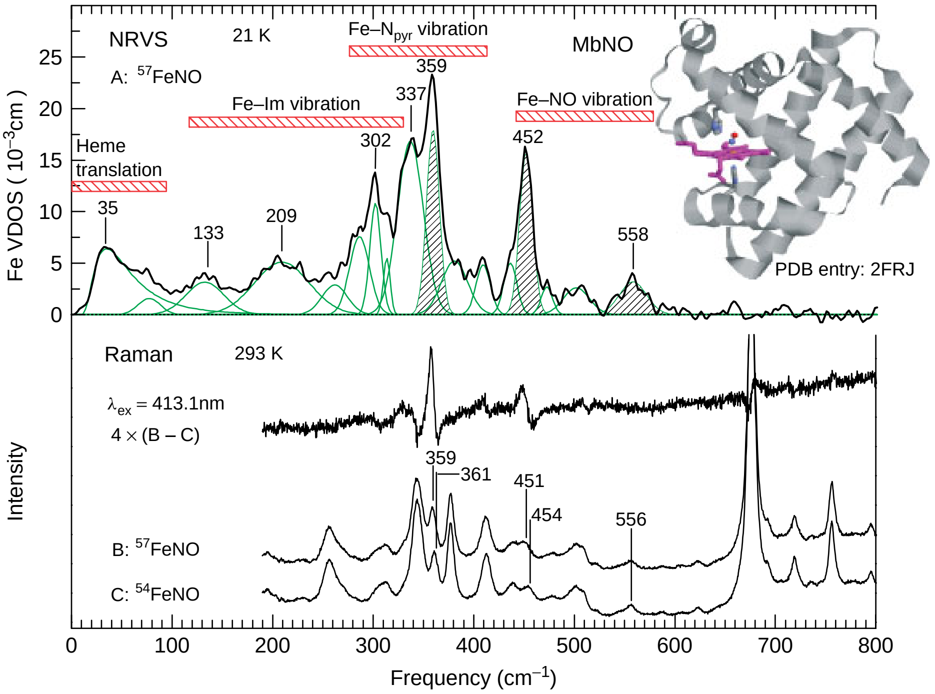

Figure 6 Comparison of NRVS and resonance Raman data on nitrosyl myoglobin (MbNO). (A) Fe VDOS determined from experimental NRVS data at 21 K. The peaks fit to the curve are also shown. Cross-hatched horizontal red bars indicate frequency ranges for Fe–ligand vibrations and for low-frequency vibrations attributed to translation of the entire heme. (B, C) Resonance Raman spectra of MbNO labeled with ^{57}Fe and ^{54}Fe, respectively, recorded at ambient temperature. The difference between these two spectra is expanded by a factor of 4. Raman-active vibrations that are sensitive to Fe mass also contribute strongly to the NRVS signal

applications. Subsequent sections will describe in greater detail the identification of these modes through comparison with data on single crystals of iron porphyrins and with the results of calculations.

The vibrational characteristics of MbNO are likely to be characteristic of other six-coordinate heme proteins having NO and histidine as axial ligands to the heme iron (Figure 6). Vibrations involving the FeNO fragment appear above 400 cm^{-1}. Simplified vibrational models have suggested that the nonlinear FeNO geometry leads to significant mixing of Fe–NO stretching and FeNO bending contributions to these modes.[42] Isotope substitution allows identification of the same vibrations in the Raman spectrum of MbNO in resonance with the heme Soret band.[18]

Quantitative comparison of isotopic frequency shifts with NRVS data suggests that motion of the nitrosyl N atom accounts for 80% of the mode energy for the higher frequency mode near 560 cm^{-1}.[18] The Fe amplitude, and consequently the NRVS signal, is thus relatively low. Although several modes contribute to this region of the Raman spectrum, the FeNO vibration is clearly identified by subtracting spectra of samples labeled with ^{14}NO and ^{15}NO.[43,44]

The FeNO vibration near 450 cm^{-1} is easily identified in both NRVS and Raman data for MbNO. Although FeNO bending and porphyrin vibrations also contribute to this mode, measurements on oriented single crystals of [Fe(TPP)(1-MeIm)(NO)] reveal that the Fe motion is primarily perpendicular to the plane of the porphyrin, as expected for stretching of the Fe–NO bond. We attributed the large frequency decrease relative to the approximately 530 cm^{-1} Fe–NO stretching frequency measured for five-coordinate NO derivatives of heme proteins and iron porphyrins to a significant weakening of the Fe–NO bond in the presence of the histidine ligand.[18]

NRVS measurements on MbCO[7] revealed the Fe–CO stretching and FeCO bending modes that have been extensively characterized using Raman measurements. The linear FeCO geometry allows observation of a pure Fe–CO stretching mode well described as a two-body Fe–CO oscillator.[25] Extensive studies have established a linear correlation between the Fe–CO and C–O stretching frequencies that is attributed to varying backbonding between Fe d_π and CO π^* orbitals controlled by the local electrostatic field.[45–47] As a result, this vibration is a well-calibrated probe of the local electrostatic environment.[48] In contrast, the mode mixing described above has complicated the establishment of such a correlation involving N–O stretching and Fe–NO vibrations.[44,49–51]

Each of these features contributes an area e^2_{Fe} to the VDOS[b] that can be compared quantitatively with the frequency shift between ^{57}Fe and ^{54}Fe-labeled molecules observed using resonance Raman spectroscopy. For MbNO,

the fitted area of the 452 cm^{-1} feature in the NRVS VDOS is 0.25, in reasonable agreement with the value $e^2_{Fe} = 0.29$, obtained from the Raman isotope shift.[18] (see equation (7) below)

Although useful, practical Raman measurements on proteins are restricted to modes that couple to an electronic excitation such as the heme Soret transitions. A great advantage of NRVS is that it reveals the complete spectrum of ^{57}Fe vibrational dynamics even for nonheme centers that do not display Raman activity, such as the ferrous state of the iron–sulfur center in rubredoxin[52,17] or the FeMoCo cluster in nitrogenase.[53] Vibrations of the remaining heme Fe–ligand vibrations must also contribute to the VDOS derived from NRVS measurements, although none have been conclusively identified in extensive Raman investigations of six-coordinate diatomic ligand adducts of heme proteins.

The Fe–His bond holds particular interest as a probe of the covalent connection with the protein.[54,55] Calculations and single-crystal NRVS data on NO and CO derivatives of imidazole-ligated iron porphyrins identify multiple modes with Fe–Im stretching character.[25,26] Many of the frequencies are considerably lower than the 200–230 cm^{-1} range observed in NRVS data for five-coordinate deoxyMb[7] and for the Fe(TPP)(2-MeHIm) mimic for the deoxyMb active site.[21] This again suggests that NO binding weakens the *trans* Fe–Im bond, consistent with indirect indications from measurements of the Fe–NO stretch (above)[18] as well as with the increased bond length observed in structural studies[56] and mechanisms proposed for NO activation of heme proteins such as soluble guanylate cyclase (sGC).[57,58]

Numerous investigations have used the Raman-active Fe–His vibration to probe heme–protein interactions and protein structural dynamics for five-coordinate heme proteins. Identification of a similar vibrational probe for six-coordinate heme proteins would be valuable. Comparison with results on iron porphyrins suggests that the feature near 130 cm^{-1} in the MbNO data (Figure 6) is a potential candidate for probing the Fe–His bond. We note the absence of this feature in the five-coordinate [Fe(PPIXDME)(NO)].[23] Further studies, including density functional theory (DFT) calculations, will clarify the character of this mode. However, the relatively small Fe amplitude with respect to the Fe–His mode in deoxyMb[7] indicates an altered mode character.

Fe motion along the two in-plane directions constitutes two thirds of the VDOS, and vibrations of the in-plane bonds to the pyrrole nitrogens appear to dominate the VDOS reported for heme proteins and iron porphyrins.[7,18,59] NRVS data on deoxyMb allowed the first identification of the Fe–N$_{pyr}$ vibrations for a heme protein.[7] The appearance of two resolved features at 251 and 267 cm^{-1} for deoxyMb (Figure 7) indicates that deviations from fourfold symmetry are sufficient to remove the nominal equivalence between the two in-plane directions. Comparison of experimental and computational results on iron porphyrins indicates additional structure that is not resolved experimentally. The in-plane vibrations

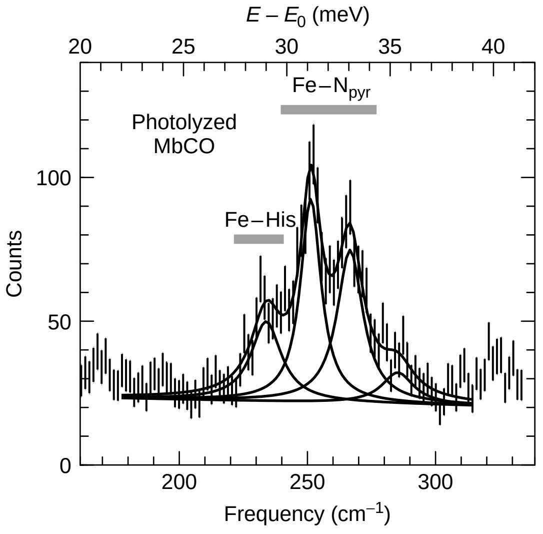

Figure 7 Experimental signal recorded for photolyzed MbCO. Fe–ligand vibrations dominate the cluster of modes observed in the 230–270 cm^{-1} region. The clearly resolved frequency separation between the in-plane Fe–N$_{pyr}$ frequencies at 251 and 267 cm^{-1} reflects the asymmetric interactions with the histidine ligand. The Fe–histidine stretching frequency appears at 234 cm^{-1}. Data were recorded under continuous illumination by a 15 mW helium neon laser with $\lambda = 633$ nm. The temperature of a sensor mounted in the sapphire sample block was 15 K

apparently have little Raman activity, although they have been identified in IR data on ferric halide octaethylporphyrin (OEP) compounds.[60]

NRVS measurements unambiguously identified in-plane motion as the primary contribution to the NRVS signal between 30.2–36.5 meV (244–294 cm^{-1}) for an oriented single crystal of metMb,[59] which contains a high-spin ferric heme with a solvent water molecule bound as a sixth Fe ligand.

We suggest identification of the complex feature in the 340–360 cm^{-1} region of the MbNO VDOS (Figure 6) with Fe–N$_{pyr}$ vibrations, based on comparison with iron porphyrins with NO and 1-MeIm as axial ligands to the iron, although calculations on a computational model for MbNO or measurements on oriented MbNO crystals will be needed to confirm this. Similar comparisons with NRVS measurements on CO derivatives of imidazole-ligated iron porphyrins[25] suggest that in-plane vibrations dominate the 320–360 cm^{-1} region of the VDOS reported for MbCO.[7,25,11]

The increase of approximately 90 cm^{-1} with respect to the in-plane frequencies reported for deoxyMb (Figure 7)[7] indicates a strong sensitivity to the decrease in average Fe–N$_{pyr}$ bond length from 206 pm in the high-spin deoxyMb[61] to 200 pm in the low-spin MbNO.[62] Once assignments are firmly established, these frequencies should provide a reliable vibrational marker for Fe spin state in heme proteins.

Data on all proteins examined to date includes significant signal below 100 cm^{-1} (Figure 8) that is not attributable to the vibrational dynamics of the immediate

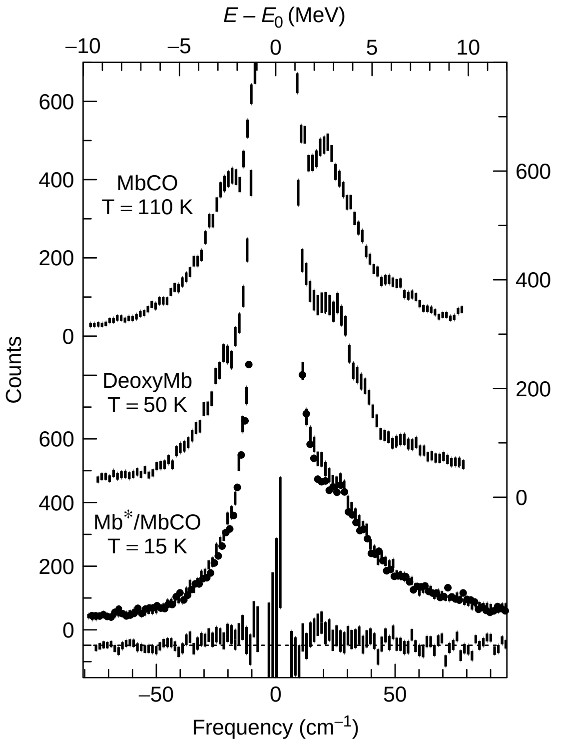

Figure 8 Low-frequency spectra of MbCO, deoxyMb, and photolyzed MbCO (Mb*). Shoulders on the recoilless absorption line are attributed to translational motion of the heme in response to global oscillations of the surrounding protein matrix, and become more prominent with increasing temperature. Filled circles overlaid on the photolyzed MbCO spectrum represent the spectrum of unphotolyzed MbCO. Subtraction of the latter two spectra reveals no measurable influence of ligand binding on these vibrations

Fe coordination sphere. For myoglobin, the Fe-weighted density of states peaks near $30\,\mathrm{cm}^{-1}$,[7] and qualitatively resembles the hydrogen-weighted density of states determined using inelastic neutron scattering (INS)[63–65] (*see* ***Neutron Scattering***). We proposed that translation of the entire heme in response to the same global protein vibrations responsible for the neutron signal dominates the NRVS signal in this frequency region.[7] No changes in this frequency region were detected following CO photolysis from MbCO (Figure 8), consistent with the attribution to global modes and in contrast with the large changes observed in all Fe–ligand vibrations.[7] This contribution dominates the raw experimental signal (Figure 8) because of the inverse dependence on frequency.

Careful investigations revealed that the VDOS varies as the square of the frequency below $10\,\mathrm{cm}^{-1}$ for deoxyMb solutions, as predicted from a Debye model, but reveal significant deviations from Debye behavior at higher frequencies,[11] reminiscent of the ''boson peak'' observed in amorphous solids.[13] Interestingly, these deviations were not observed for deoxyMb crystals.[11]

The area expected for heme motion can be estimated from the area $3m_{\mathrm{Fe}}/M$ of the total density of states that can be attributed to pure translation of a molecule of mass M. However, there is some ambiguity regarding the number of atoms included in the effective translational mass M. Taking the mass $M = 357$ of the Fe and the 24 atom porphyrin core leads to the prediction that translational degrees of freedom contribute 15% of the total VDOS.

This estimate may be questioned, especially in situations where the heme has several covalent attachments to the proteins, as for cytochrome c[36] and cytochrome f.[19] It will be of some interest to observe how NRVS data reflect such factors.

3.2 Studies of Small Molecule Systems

As established in earlier sections, the measured NRVS spectral intensities determine the VDOS for the Mössbauer active nucleus. The VDOS includes all modes that involve motion of the Mössbauer active nucleus, which in our current discussion is limited to iron. The richness of the observation of all vibrational modes is a case of a ''good news–bad news'' situation. A major concern is how to manage the assignment of vibrational modes to the observed NRVS frequencies. Two complementary approaches, one experimental and the other computational, show substantial utility for the challenge of making assignments and understanding the vibrational complexity of the systems. It is important to recognize that NRVS provides information on modes that are not observable, or at least not easily observable, by any of the commonly used vibrational methods (*see* ***Vibrational Spectroscopy***).

The geometry of planar heme derivatives naturally provides for an important partitioning of the vibrations: those that are in-plane with iron motion parallel to the porphyrin plane and those that are out-of-plane with iron motion perpendicular to the porphyrin plane. The NRVS experiment can easily distinguish between the two cases whenever an appropriately aligned sample can be measured. Whether these heme plane orientations are accessible in an appropriately aligned single crystal depends on the crystallographic characteristics of the sample. Both in-plane and out-of-plane orientations are accessible in single crystalline materials belonging to the triclinic system; an in-plane orientation can always be measured for monoclinic system crystals.

The NRVS spectra obtained for the (triclinic) crystalline species [Fe(TPP)(2-MeHIm)] in the two orientations are compared in Figure 9. These spectra are also compared to the powder spectrum obtained. The differences in the two orientations are clearly apparent and the utility of such measurements for spectral assignments is clear. In this figure, the signal intensities have been scaled to the approximate relation $D_{tot}(\bar{\nu}) = D_z(\bar{\nu}) + 2D_x(\bar{\nu})$ that results from assuming $D_x(\bar{\nu}) = D_y(\bar{\nu})$. Although most of the observed frequencies in the in-plane and out-of-plane oriented crystal measurement are resolved, some spectral overlap (at $200–220\,\mathrm{cm}^{-1}$) is

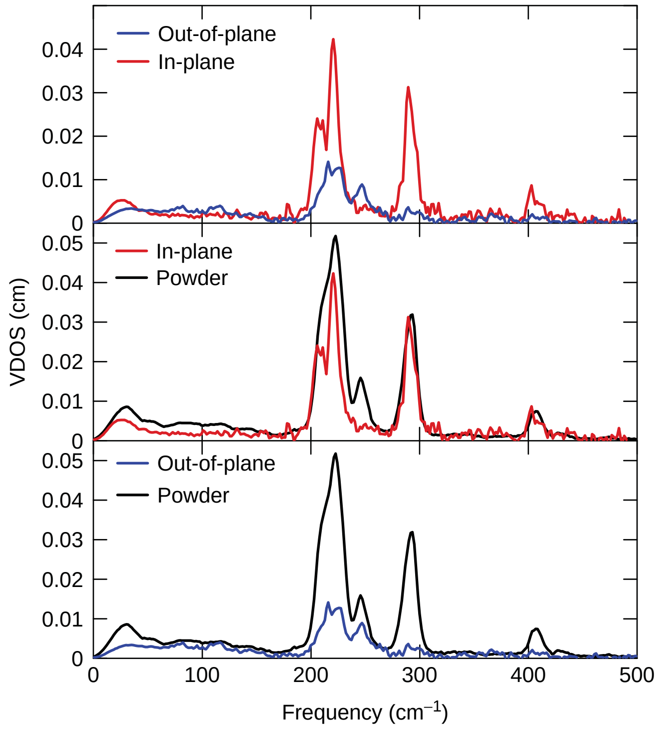

Figure 9 Experimental NRVS spectra of polycrystalline (powder, $D(\bar{\nu})$) and single-crystal (in-plane, $D_x(\bar{\nu})$ and out-of-plane, $D_z(\bar{\nu})$) [Fe(TPP)(2-MeHIm)]. Crystals are oriented with porphyrin planes parallel (in-plane) and perpendicular (out-of-plane)

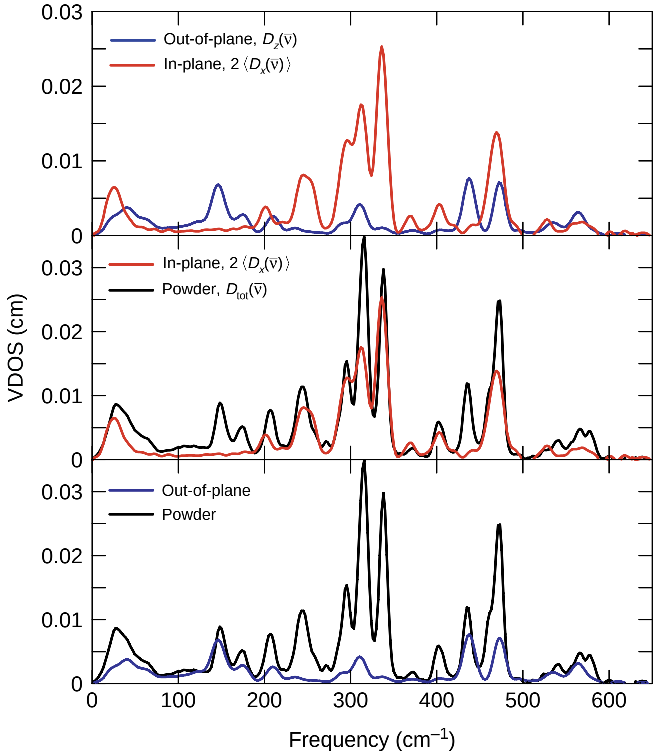

Figure 10 Experimental NRVS spectra of polycrystalline (powder, $D(\bar{\nu})$) and single crystal (in-plane, $D_x(\bar{\nu})$ and out-of-plane, $D_z(\bar{\nu})$) [Fe(TPP)(1-MeIm)(NO)]. Due to porphyrin packing in the $P2_12_12_1$ space group, the ''in-plane'' orientation orients all porphyrin planes 13.8° from the incident beam. The ''out-of-plane'' orientation obtained by rotation of the crystal by 90° orients all porphyrin normals to within 13.8°

observed. This appears to be a general feature of the oriented crystal heme spectra in that, in every case studied to date, at least one modest out-of-plane feature is in the same frequency range as a set of more dominant in-plane features.

Despite the fact that the triclinic system is the only crystallographic system that unequivocally allows single-crystal orientations to provide both enhanced in-plane and out-of-plane NRVS spectra, many other crystalline heme derivatives fortunately have all porphyrin planes close to being parallel to a common crystallographic plane. For example, [Fe(TPP)(1-MeIm)(NO)] has four independent porphyrin plane orientations, but all planes are within 13.8° of a common plane in the crystal. Data were collected using this common plane as the crystal-orienting plane to obtain an ''in-plane'' and an ''out-of-plane'' spectrum. As shown in Figure 10, a comparison of the ''in-plane'', ''out-of-plane'', and powder spectra show that useful intensity enhancements are still evident. Moreover, and fortunately, this situation of nearly coincident planes appears to be moderately frequently observed.

While the qualitative partitioning of in-plane and out-of-plane character is a powerful tool in spectral assignments, the quantitative features of NRVS spectra are also of significant assistance in making assignments (see following section). The most complete use of the frequency and amplitude (e^2_{Fe} values) comes from the use of DFT calculations to obtain predicted frequencies and e^2_{Fe} values. In the two published studies where comparisons between the DFT-predicted and the NRVS-obtained values have been made in the greatest detail, there has been good overall agreement between the predicted and observed general character, frequencies and e^2_{Fe} values.[23,25] The e^2_{Fe} values in particular are a quantitative measure of the agreement between the calculated and observed spectra. Our experiences to date lead us to believe that DFT calculations provide useful descriptions of detailed mode compositions, especially in conjunction with oriented crystal measurements. As described in the next paragraph, an important proviso must be attached to the use of DFT for mode calculations.

The use of DFT calculations for mode assignments requires the determination of an energy-minimized structure of the molecule in question. Theoretical calculations on porphyrin systems have been traditionally simplified by truncating the porphyrin skeleton; DFT calculations have typically used the porphine core, deleting all peripheral group atoms other than hydrogen atoms. However, it has become clear that many features of the vibrational spectrum depend strongly on peripheral groups of the porphyrin moiety.

The importance of the peripheral groups on the vibrational spectrum leads to the necessity of including the complete molecule in the DFT calculation and thereby substantially increasing the computational time required. Accordingly, the required DFT calculations for mode assignments are near the current practical limit. The importance of the peripheral groups on the vibrational spectroscopy of the iron atom can be readily seen from Figure 11, which displays the experimental NRVS spectra observed for five different five-coordinate nitrosyl complexes. What remains to be ascertained is whether there are systematic differences in the effects of meso-substituents versus β-pyrrole substituents. This issue is important in assaying how results from the small molecule studies may be related to those of the proteins.

The most prominent features in NRVS spectra are the strong set of peaks in the middle portion of the spectrum, which are principally from the in-plane motion of iron. At this time, a complete general analysis of the in-plane modes is not possible. However this is probably not a final state. A relationship between the frequencies of the in-plane modes, iron spin state, and coordination state can be reasonably expected and is qualitatively observed. The increasing database of NRVS measurements on oriented single crystals of iron porphyrins should enable a more quantitative approach to understanding the relation between the set of iron in-plane modes and the Fe–N_p bond lengths.

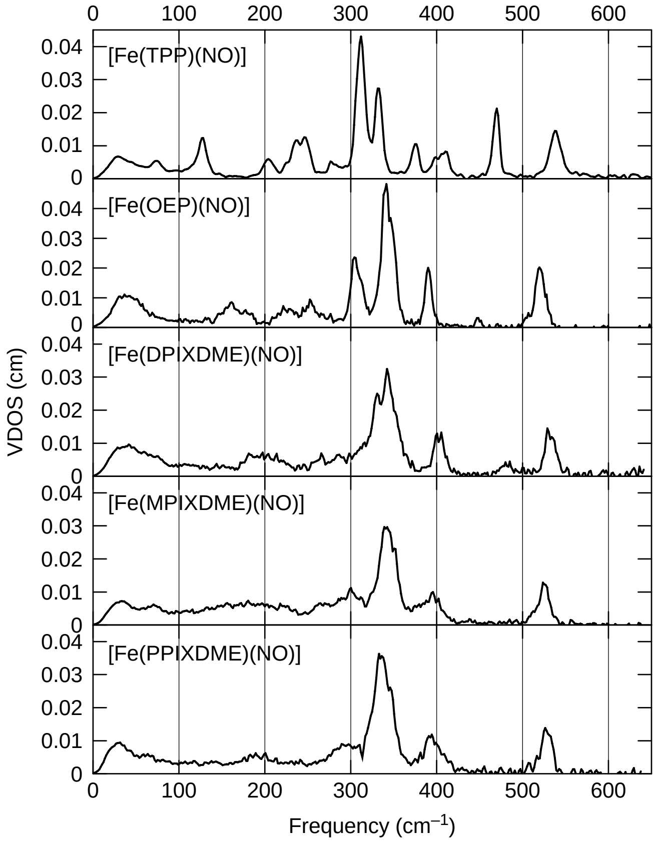

Figure 11 Diagram illustrating the experimental NRVS spectra of five different [Fe(Porph)(NO)] derivatives, each with varying substitution patterns on its periphery

The in-plane modes for [Fe(TPP)(NO)] were the first to be studied and have been predicted in detail from DFT studies.[23] Near-degenerate pairs of Fe–N_p in-plane modes are expected for this five-coordinate species. Pairs of bands with in-plane iron motion along with larger contributions to the total kinetic energy from porphyrin motion are observed (predicted) at 236, 248 (241, 253) cm^{-1}, 410 (410, 413) cm^{-1}, and 470 (474, 476) cm^{-1}. Not surprisingly, in all of these in-plane modes the iron motion is in the direction of the Fe–N_p bond. The description of the most intense set of in-plane modes (observed at 313 and 333 cm^{-1}) is more complex. The intensities of this pair are not equal, but both are clearly in-plane modes with a substantial iron contribution. The DFT calculations suggest that there are two near-degenerate pairs of in-plane modes with three of the four predicted at 308, 317, and 318 cm^{-1}, all within the resolution of the experiment and are thus seen as a single NRVS peak. The fourth band, with a predicted frequency of 334 cm^{-1} is distinct. This leads to the difference in intensities of the observed ''pair''. These in-plane modes are vibrationally mixed with FeNO bending and Fe–NO bending modes. In two of these strong in-plane modes, predicted at 308 and 334 cm^{-1}, the iron motion is approximately parallel to the FeNO plane and has some out-of-plane motion of the iron as well. The other two modes, predicted at 317 and 318 cm^{-1}, have the iron motion approximately perpendicular to the FeNO plane.

Investigations of six-coordinate derivatives [Fe (Porph)(XO)(1-MeIm)] with the diatomic ligands NO or CO have been carried out on both powder and oriented single-crystal samples.[25,26] The oriented crystal data have allowed clear assignments of the in-plane and out-of-plane modes. The most intense in-plane modes in the two distinct [Fe(TpFPP)(NO)(1-MeIm)] derivatives (predicted frequencies at 339 and 321 cm^{-1}) have the iron motion directed perpendicular and parallel to the FeNO plane and not along the Fe–N_p directions. The motion of the 321 cm^{-1} band is complex with iron having both in-plane and out-of-plane components. This is distinctly different from the analogous carbonyl derivatives where the principal predicted modes with in-plane motion are more complex (at 318, 321, 323, and 329 cm^{-1}), but are along the Fe–N_p bond directions. The CO and NO systems suggest that orientation of the imidazole ligand has little effect on the in-plane iron motion. In addition, a mode at 320 cm^{-1} in the CO complex is an out-of-plane mode in which the iron and the axial diatomic CO move together perpendicular to the porphyrin core. It is important to note that the complexity of the predicted spectra are verified by the mode-specific single-crystal measurements of both the nitrosyl and carbonyl complexes.

The information available thus far on the iron in-plane motion direction shows that there are substantial possible effects from the axial ligand. More generally the measurements

raise the possibility that the environment could have significant effects on the directions of the in-plane iron motions.

As outlined below, NRVS studies have provided information on iron out-of-plane modes that was previously unavailable. For five-coordinate nitrosyl complexes, classical theory predicts that the three-atom FeNO grouping should have three modes: the N–O stretch, the Fe–N stretch, and the FeNO bend, with the latter two expected to be found in the region below 600 cm^{-1}. In a detailed analysis of [Fe(TPP)(NO)] provided by a series of DFT calculations, the predicted frequency of the stretch was overestimated when the calculation used the BP86[66,67] functional and underestimated when the B3LYP[68,69] functional was employed.[23] The reasons for the difficulties in this prediction appear to arise from the unusual nature of the unpaired electron in the compound that is significantly delocalized over the NO ligand as well as the metal.[50] In this case, the Fe–N stretch was actually observed at 540 cm^{-1} for [Fe(TPP)(NO)] powder at 80 K.[8,20,23] This vibration is also seen at similar frequencies in several other five-coordinate nitrosyls (see Figure 11). What is not identified in the VDOS for [Fe(TPP)(NO)] is a frequency in which the principal contributor is the FeNO bend. Rather this mode is distributed over a number of frequencies. This illustrates what has become an important general feature of the NRVS-revealed VDOS, namely that the total spectral features that involve iron motion involve many mixed modes.

NRVS studies have illuminated the nature of the axial modes involving the diatomic ligand in [Fe(Porph)(XO)(1-MeIm)] (NO or CO) derivatives. In MbNO, NRVS has clarified the assignment of the frequency with predominant Fe–NO stretch character.[18] Although a band at 558 cm^{-1} shows a substantial shift on ^{15}NO substitution, the NRVS studies show that it has only a small iron contribution to its kinetic energy distribution (KED). Rather, the band at 452 cm^{-1} has motions that are more characteristic of the Fe–NO stretch. However, both bands do have some contributions from the FeNO bend, smaller in the 452 cm^{-1} band and larger in the 558 cm^{-1} band. Finally, a band similar to the ~470 cm^{-1} band originally found in [Fe(TPP)(NO)] and assigned as an FeNO bend by empirical methods[20] is also seen in the six-coordinate systems. NRVS spectra/DFT calculations show that the iron contribution is small and it is principally a porphyrin-phenyl mode.

However, FeCO bending modes are clearly seen in the six-coordinate carbonyl complexes. In [Fe(TPP)(1-MeIm)(CO)], two bands are observed at 561 and 586 (predicted at 560, 566, 580 and 583) cm^{-1} corresponding to two distinct FeCO bending modes as shown in Figure 12. The two observed modes are predicted by DFT to be degenerate x, y pairs with separations less than the resolution of the experiment. The sets of modes correspond to differing coupling of the porphyrin motions, especially the phenyl ring motions, with the FeCO bend. The bending modes in [Fe(OEP)(1-MeIm)(CO)] appear to be somewhat less complicated owing to a reduction in mode mixing with porphyrin core

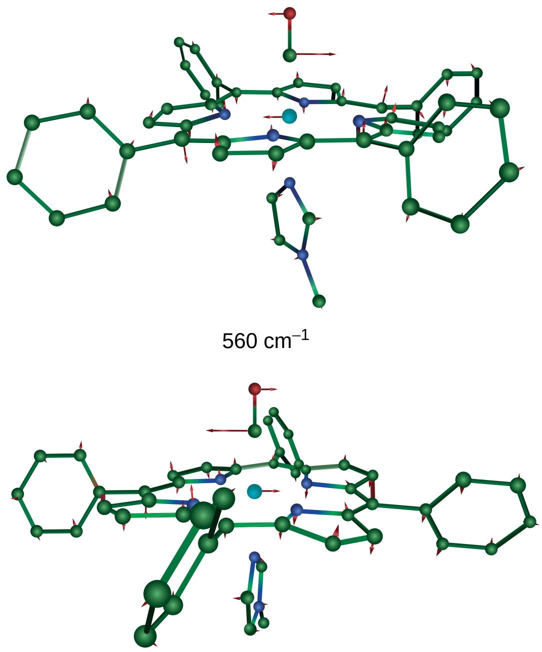

Figure 12 FeCO bending modes predicted by DFT. The relative phase of the FeCO bending and porphyrin motions reverses between 560 and 580 cm^{-1}

distortions, attributed to the different peripheral substituent pattern observed in the β-substituted porphyrinates.[25]

An important point found from the measurements is that the NRVS-observed kinetic energy contribution of iron to the bending modes is much larger than the predicted value from a classical treatment of an FeCO group. This is not the case for the Fe–CO stretch that is observed at 507 cm^{-1} in [Fe(TPP)(1-MeIm)(CO)]. The classical model prediction for the iron kinetic energy contribution to this mode and the NRVS-observed value are in much closer agreement. The difference between the classical theory prediction and experiment are likely related to the suggestion that a combined Fe–CO tilt and FeCO bend is a low-energy mode in carbonyl complexes. The softness of this mode is consistent with an FeCO group that is readily deformable from linearity.[70] The in-phase component will occur at low frequency (70–80 cm^{-1}), but the out-of-phase component of this mode is suggested as an explanation of the unusually high frequency the FeCO bending mode, consistent with the NRVS observations. This issue has been dealt with in an earlier publication that should be consulted for additional detail.[25]

An especially interesting mode in six-coordinate hemes with a diatomic axial ligand and a trans-imidazole is the identification is the Fe–Im stretch.[25] This band has never been identified in the resonance Raman spectra of such species. NRVS data on six-coordinate NO and CO derivatives allow the identification of several frequencies that involve significant simultaneous motion of the iron and the imidazole. For the

carbonyl complex, [Fe(TPP)(1-MeIm)(CO)], a total of four bands have been predicted at 157, 182, 214, and 320 (observed at 172, 225 and 321) cm^{-1}. One of these, the vibration at a frequency of 214 cm^{-1}, has motion that qualitatively resembles a classical Fe–Im stretch, although none of the four modes can be described quantitatively as a simple two-body oscillator. The modes with predicted frequencies of 157 and 182 cm^{-1} have motions that change the Fe–Im distance but the relative motions of the Fe and Im are complex. Although the iron motion in these two is perpendicular to the porphyrin plane, the motion of the imidazole is much more a torsional motion with respect to the porphyrin plane. Finally the band at 320 cm^{-1}, which is in the middle of the in-plane motions, but has been experimentally found in oriented single crystal measurements to be an out-of-plane contributor, has translational motion of the FeCO group. All of these bands display some sensitivity to the Fe–Im distance.[25] The character of the modes, as predicted by the DFT results, are shown in Figure 13. In the analogous nitrosyl complexes with a longer Fe–Im bond distance, these bands are predicted to appear at 146, 164.5/169, 195, and 323 cm^{-1}. Moreover, the observed counterparts in two crystalline modifications of [Fe(TpFPP)(1-MeIm)(NO)] with a small (0.038 Å) difference in Fe–N_{Im} show a systematic shift to lower frequency for the form with the longer Fe–Im distance.[26]

The possible mechanistic importance of the Fe–imidazole(histidine) bond, especially in various models for hemoglobin cooperativity, has been recognized for some time.[71–73] NRVS clearly provides the first experimental method for systematic studies of how the Fe–Im bond strength can be modulated in six-coordinate hemes, both by protein environmental effects as well as by the consequences of systematic ligand change.

The very low frequency bands also provide information on the doming mode, which has proved to be very difficult to observe. The doming mode describes the motion of the iron perpendicular to the porphyrin plane with the iron motion opposed by motion of the core atoms. This mode is expected to be of substantial utility in understanding the reactivity of heme derivatives that are involved in the association/dissociation of small ligands. In the complex [Fe(TPP)(NO)] there are two low-frequency modes at 74 and 128 cm^{-1} that are the prime candidates for assignment as the doming mode. Perhaps surprisingly, the predicted mode corresponding to the higher frequency more closely resembles a doming mode , while the lower frequency mode primarily involves motion of the NO oxygen. However, we suggested significant mixing of the character of the observed modes.[23] Similar complexities are seen in the motions of six-coordinate carbonyls. Modulation of these motions by the protein environment may have important implications that affect mechanism and biological function in heme proteins.

The combination of experimental and theoretical data based on the technique of NRVS has shown that the vibrational spectral features of the iron-containing hemes are quite complex. NRVS experiments and calculations have clearly demonstrated that the expectations from simple models, for example, the three-atom model for FeCO, are inadequate. Other iron-containing systems are undoubtedly equally complex and present challenges in the spectral assignments. We are still in the early stage of understanding the complexities of the vibrational motions of hemes. Nonetheless, the power of the method in understanding the dynamics of iron-containing systems, biomolecules and others, should be evident. It is to be hoped that a coherent view of the Fe–ligand modes, which are clearly very mixed, will allow, inter alia, an understanding of how the iron dynamics can be modulated by the protein environment.

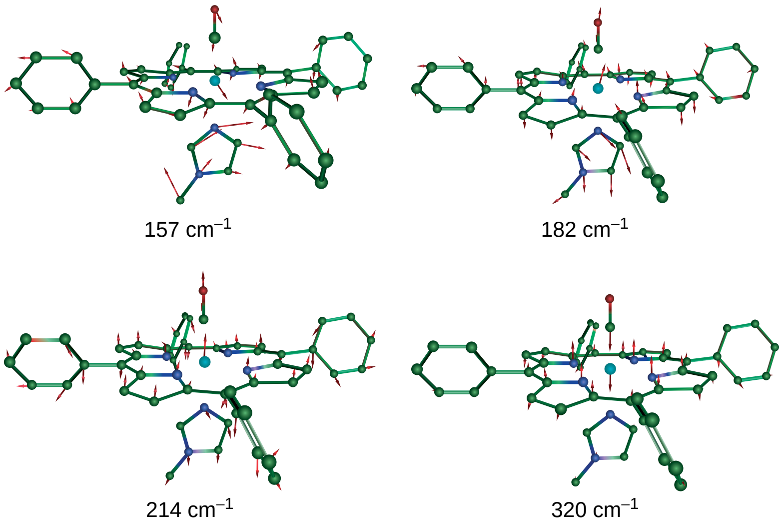

Figure 13 Predicted vibrational modes of [Fe(TPP)(1-MeIm)(CO)] with frequencies 157, 182, 214, and 320 cm^{-1} involve Fe–Im motion

3.3 Description of Mode Character: Quantitative Vibrational Dynamics

The coefficients $\vec{e}_{j\alpha}$ governing the mathematical transformation from normal coordinates Q_α to atomic Cartesian coordinates $\vec{r}_j$ provide a transparent description of mode character. The vector $\vec{e}_{j\alpha}$ parallels the motion of atom j in normal mode α, while the squared magnitude $e^2_{j\alpha}$ describes its relative mean squared amplitude. Normalization, according to $\sum_j e^2_{j\alpha} = 1$, then ensures that the mode composition factor $e^2_{j\alpha}$ is equal to the fraction of mode energy associated with motion of atom j. The resulting KED, together with the directional information, facilitates model-independent comparison of experiments with each other and with computational predictions.

NRVS directly samples the KED because the spectral area contributed by mode α directly yields the mode composition factor e^2_{Fe} for the ^{57}Fe probe atom, according to equations (3–6). Using more traditional vibrational methods, frequency shifts resulting from isotope substitution of atom j can yield an estimate[8]

$$e^2_{j\alpha} = -2\frac{d(\ln \bar{\nu}_\alpha)}{d(\ln m_j)} \approx -2\frac{\Delta\bar{\nu}_a/\bar{\nu}_a}{\Delta m_j/m_j} \tag{7}$$

of its mode composition factor. Although the implicit assumption that the mode character is unaltered by the isotope substitution may not always be valid, this expression establishes an approximate quantitative correspondence between NRVS and other vibrational methods such as Raman, and also extends the description of the KED to include atoms other than the NRVS isotope.

Investigation of MbNO has illustrated the value of quantitative comparisons between NRVS and Raman isotope shift measurements.[18] For a mode at 556 $\mathrm{cm^{-1}}$, the KED indicated 80–90% of mode energy localized on FeNO with primary involvement of the nitrosyl N atom $\left(e^2_N = 0.8\right)$, while Fe motion dominated the KED of a second FeNO vibration at 451 $\mathrm{cm^{-1}}$. These results supported the attribution of Fe–NO stretching character to the 451 $\mathrm{cm^{-1}}$ mode, with consequent sensitivity to the Fe–NO bond strength. For a Raman peak near 360 $\mathrm{cm^{-1}}$, NRVS signal in excess of that expected on the basis of the e^2_{Fe} value estimated from isotope shift measurements was rationalized in terms of unresolved contributions from two in-plane modes. This conclusion would not be possible on the basis of either NRVS nor Raman measurements individually.

The wealth of quantitative vibrational information available from NRVS also facilitates unusually detailed and quantitative comparison with theoretical predictions. NRVS data on model compounds[20–22,28,29,74,75] and on proteins[17,76,77] have been successfully reproduced by adjusting force constants in empirical potentials. Moreover, NRVS provides a particularly rigorous test of vibrational predictions from quantum chemical models, which may otherwise be difficult to test for transition metal systems. DFT methods have now reproduced vibrational frequencies, amplitudes, and directions for several iron porphyrins with sufficient fidelity that quantum chemical methods are emerging as the most effective methods to understand the character of modes that contribute to the NRVS signal.[23,25,26,29,39]

In contrast with empirical models, quantum chemical methods do not provide adjustable force constants. It is therefore not unexpected that quantitative discrepancies appear when quantum chemical predictions are compared in detail with the results of NRVS measurements.[23,25] NRVS results thus provide a benchmark for development of quantum chemical methods for transition metal systems. Using quantum chemical results as starting input in empirical calculations may be a valuable approach for future work. Meanwhile, however, reproduction is sufficiently accurate to guide the understanding of observed vibrational features. Mode descriptions given in the previous section largely rely on comparison with quantum chemical predictions.

The quantitative information derived from measurements of spectral areas is a characteristic strength of NRVS measurements, but imposes certain requirements that must be borne in mind during sample preparation and data collection. Accurate interpretation of peak areas relies on having a pure sample or at least knowing the fraction of molecules that contribute to an individual spectral feature. In addition, measurements must be conducted over an energy range sufficient to encompass all significant vibrational signals in order to ensure accurate normalization according to equation (2).

3.4 Summary and Prospects

Although NRVS measurements are restricted to molecules that can be labeled with an appropriate isotope such as ^{57}Fe, they provide important advantages over established vibrational spectroscopies. NRVS is a uniquely quantitative and informative probe of vibrational dynamics, yielding not only the frequency but also the amplitude and direction of motion for all vibrational modes involving the probe nucleus. IR and Raman spectroscopies (*see* ***Vibrational Spectroscopy***) have been the favored techniques for biomolecular applications, partly because appropriate techniques provide selectivity for active sites. However, information on individual atomic motions must be obtained indirectly through isotope editing. For INS measurements (*see* ***Neutron Scattering***), the experimental signal is proportional to the atomic amplitude but represents an average over all atoms (weighted by scattering length). As a result, INS applications to biological macromolecules have been most effective as probes of global dynamics, and indeed provide an important quantitative test for molecular mechanics potentials, but lack selectivity to local sites. In many ways, NRVS combines the advantages of existing techniques, extending selectivity to the ultimate limit of a single atom among thousands while revealing detailed *quantitative* information on vibrational dynamics.

The future appears bright for NRVS applications to protein active sites, and a number of promising ideas remain to be fully exploited. As experimental count rates improve, results on more complex molecules with multiple metal sites are beginning to appear,[27,53] and selective isotope labeling of distinct Fe sites should be particularly illuminating for proteins. Light-driven reactions have been successfully monitored using NRVS,[7] setting the stage for using NRVS to monitor reaction-induced changes in structure and dynamics. Single crystals have been crucial for establishing vibrational mode descriptions in iron porphyrins,[20,21,23,25,26] and analogous experiments on proteins only require ^{57}Fe-enriched crystals of sufficient size, since the ^{57}Fe concentration will exceed that in solution samples. Among the more intriguing observations to date is the experimental and theoretical identification of low-frequency modes involving Fe displacement out of the porphyrin plane, resembling the heme doming motion long hypothesized to control heme reactivity.[20,21,23,25,26] NRVS measurements may allow quantitative estimates of the contribution of reactive modes to the energy of transition states.

The growing NRVS database also exposes unanticipated interpretational challenges. Simulation of a restricted set of atoms has been a cornerstone of the traditional approach to understanding the properties of protein-active sites. However, NRVS measurements on proteins lend credence to expectations that vibrations may involve protein regions distant from the active site.[7,77] The frequency range over which vibrations remain localized is not only a challenge to accurate modeling of observations but may also conceivably influence active site functionality, if reactive vibrations involve large regions of the protein.[7] Even for small molecule models, NRVS measurements and quantum chemical modeling are revealing unanticipated vibrational complexities, which are not fully resolved experimentally. In some cases, the extraction of effective force constants directly from experimental data may provide valuable model-free information on proteins.[37,78,19]

METHOD SUMMARY

Acronyms, Synonyms

- Time Differential Perturbed Angular Correlation (TDPAC)
- Perturbed Angular Correlation (PAC).

Measured physical quantity

- Hyperfine interactions, that is the interaction of a nuclear magnetic moment with extranuclear magnetic fields and the interaction of a nuclear quadrupole moment with electric field gradients from extranuclear charge distributions, are measured via time differential perturbed angular correlation (TDPAC) of γ-rays emitted from radioisotopes.

Information available

- Probe site coordination geometry (types, number, and geometric arrangement of coordinating atoms) is available.
- If several probe sites are present, the signals can often be resolved and the relative population determined.
- Probe site dynamics on a time scale dictated by properties of the nucleus in question–typically nanoseconds (exchange dynamics, molecular reorientational correlation times) is available.

Information not available, limitations

- Full structural information on coordination geometry is not available.
- The structural information is limited to a radius of 3–5 Å from the probe site.

Examples of questions that can be answered

- What is the coordination geometry at a probe site?
- How does the probe site coordination geometry change, for example, during a metalloenzyme-catalyzed reaction or a pH titration?

- Does a molecule labeled with a PAC isotope bind to proteins, DNA, membranes, or other macromolecular partners (via determination of rotational correlation times) in solution?
- Is local dynamics, for example, ligand exchange, occurring at the PAC probe site (provided it occurs in the time window ‘‘visible’’ to PAC spectroscopy)?

Major advantages

- Very small amounts of sample are required ($\sim 10^{10}$ probe atoms)
- The signal is very sensitive to structural changes–often a change of a few degrees in a ligand-probe-ligand angle significantly changes the signal.
- Measurements can be carried out over a broad temperature and pressure range because the anisotropy is essentially determined by nuclear properties.
- In most cases the γ rays emitted in the nuclear decay have sufficiently high energy such that there are basically no constraints for sample containers.
- All inequivalent probe sites yield a signal, that is, there is no ‘‘missing fraction’’.
- Samples can be solid, liquid, immobilized on a surface, or in many other physical states—even in vivo experiments are possible.

Major disadvantages

- Only PAC isotopes with appropriate nuclear properties can be used (*see* the list in the text); most of them are metals.
- A radiochemistry laboratory is required; some of the probe isotopes have short half-lives (∼minutes–hours) and thus they require relatively fast sample preparation.
- For biological samples, for example, metal ion binding proteins, the native metal ion must be exchanged with a suitable PAC isotope.
- So-called after effects from the decay of the mother isotope can give rise to difficult and even incorrect interpretation of the data. This is often the case for electron capture but not for isomeric transitions.

Sample constraints

- Typical sample volumes are 0.05–1.0 mL, but in principle, they are not limited to this range.

1 INTRODUCTION

Perturbed Angular Correlations (PAC) spectroscopy belongs to the family of techniques monitoring hyperfine interactions, such as nuclear magnetic resonance (NMR) (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Inorganic/Organometallic Molecules***, ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Metallobiomolecules***), nuclear quadrupole resonance (NQR) (*see* ***Nuclear Quadrupole Resonance (NQR) Spectroscopy***), electron paramagnetic resonance (EPR) (*see* ***Electron Paramagnetic Resonance (EPR) Spectroscopy***), and Mössbauer spectroscopy (*see* ***Mössbauer Spectroscopy***). In inorganic and bioinorganic chemistry, the most common applications of PAC spectroscopy provide information on the local electronic and molecular structure and dynamics at the site of the PAC probe via the electric interaction between the nuclear charge distribution and the surrounding charge distribution (the nuclear quadrupole interaction (NQI)). Thus, the technique provides a spectroscopic fingerprint of the local molecular and electronic structure at the site of the PAC probe. The focus of this work is on the NQI, although magnetic interactions have also been studied in magnetically ordered inorganic materials. Dynamics may also be monitored if it occurs within the time window ‘‘visible’’ by PAC spectroscopy (vide infra).

The PAC technique relies on the fact that particles emitted in cascades in nuclear decays are not detected in random directions with respect to each other, due to the conservation of angular momentum. For example, in a nuclear decay where two γ rays are emitted in succession, the first γ ray may be detected in a certain direction. The second γ ray is then in general emitted anisotropically with respect to the first. For ^{111m}Cd, a commonly used PAC isotope, the second γ ray is most likely emitted in the same direction as or opposite direction of the first, and least likely at right angles to the first. This so-called angular correlation, representing the last two letters in the PAC acronym, was first described theoretically by Hamilton in 1940[1] and confirmed experimentally in 1947 by Brady and Deutsch.[2–4] In itself this is entirely uninteresting from the point of view of chemistry, although of great interest in nuclear physics. However, if the nucleus interacts with extranuclear fields, for example, from the surrounding charge distribution in an inorganic or bioinorganic complex, the angular correlation is perturbed, as described theoretically in 1946 by Goertzel[5] and demonstrated experimentally five years later by Frauenfelder *et al.*[6,7] The first application of

such perturbations was the determination of nuclear magnetic moments (or g-factors) by applying external magnetic fields to a sample containing a suitable probe nucleus. A breakthrough was the introduction of time differential measurements of the angular correlation, that is, the angular correlation was recorded as a function of the time between the first γ-quantum populating the intermediate nuclear state and the second γ-quantum which depopulates it. In this way, perturbation functions could be determined as a function of time, and it is for this reason that the term ''time differential perturbed angular correlation'' or ''TDPAC'' was coined. Frequently, the abbreviation ''PAC'' is used synonymously because time integral measurements are no longer performed whenever possible.

A pioneering effort dealing mainly with inorganic chemistry was conducted by Haas and Shirley in 1973[8] and the first bioinorganic application was an investigation of serum albumin carried out in 1968 using ^{111}In as PAC probe.[9] Since these groundbreaking achievements, PAC spectroscopy has been applied in a variety of inorganic and bioinorganic investigations. In 1987, a comprehensive table of NQI-data in compounds obtained by PAC spectroscopy was compiled.[10] In bioinorganic chemistry many fundamental problems have been addressed, most notably structure, function, and nanosecond dynamics of metal ion binding sites in proteins and protein–protein interactions.[11] The latter is possible as the PAC signal is affected by the rotational diffusion (Brownian tumbling) of the macromolecule to which the PAC isotope is bound, and this tumbling depends on—apart from viscosity and temperature—the size of the molecule or molecular complex. Most bioinorganic applications have focused on the function of zinc, copper, or iron binding proteins using ^{99}Mo, ^{111m}Cd, ^{111}Ag, ^{111}In, ^{181}Hf, and ^{199m}Hg as PAC probes. Peptides, DNA, and proteins with a function in heavy metal detoxification have also been studied, and even whole cell and in vivo experiments have been carried out on bacteria and mice.

Several technical improvements have appeared over the past 10–20 years. Efficient spectrometers such as the six-detector TDPAC-camera,[12] and progress in γ-ray scintillation detector performance with respect to timing and energy resolution (BaF_2, and recently, $LaBr_3$(Ce)) have allowed for considerable improvement in signal-to-noise ratio, and thus reduced the time required to record a PAC spectrum to minutes in favorable cases. New spectrometers with ultrafast digitizers may further advance this trend. Rapid freeze quench technology (*see* ***Freeze-Quench Kinetics***) combined with PAC spectroscopy appears to be a promising approach for studies of chemical and biochemical reactions or molecular dynamics on the millisecond time scale (or slower), allowing for trapping of intermediates in enzyme catalysis and protein folding. Facilities such as CERN(www.cern.ch), providing beams of radioactive PAC isotopes, have promoted the field, especially for the production of high purity trace amounts of short-lived isotopes. This allows for PAC studies at very low concentrations of biomolecules in solution, including normal physiological conditions. PAC spectroscopy has traditionally been limited to elements of the periodic table for which radioactive nuclei with appropriate properties exist. Synchrotron-based PAC spectroscopy, in which the angular correlation between an incoming high energy photon that excites the nucleus and the photon emitted as the nucleus decays, may extend the range of accessible elements considerably.[13] Synchrotron-based PAC spectroscopy has been successfully applied to iron in ferrocene, and this technique holds promise to foster further applications in inorganic and bioinorganic chemistry. Finally, the recent advancement of first principle quantum mechanical calculations of electron densities and electric field gradients (EFGs) in molecules, periodic lattices, and of surface species, including lattice relaxations around the probe atom, has become a central element in the identification of probe geometries.

Reviews on PAC theory,[14–16] applications of TDPAC in materials science and chemistry,[17] in the border region between physics, chemistry, and biology,[18] and in biology[11,19] as well as a comprehensive compilation of NQI-data obtained by TDPAC[10] can be found under References.

2 TECHNICAL BACKGROUND

2.1 What is Measured in PAC Spectroscopy?

Using PAC spectroscopy, the NQI can be measured. The NQI is the electric interaction between the nuclear charge distribution and the surrounding charge distribution. At the risk of offending the knowledgeable reader we proceed via a very figurative and qualitative description of NQIs and PAC, in order to highlight the basic principles of the spectroscopy. We strongly recommend that the reader consults relevant references where a more thorough treatment of the theory and instrumentation is presented.[11,12,14–19] In Figure 1, a simplified classical (i.e., nonquantum mechanical) picture of a nucleus in the external electric field gradient from two negative point charges is presented, followed by a discussion on the corresponding NQI between the nuclear charge distribution and the surrounding charge distribution.

In state (c) the energy is lowest because the electrostatic interaction between the positively charged nucleus and the external negative point charges is largest; state (a) is intermediate, and in state (b) the energy is highest. We include this simple picture because it illustrates that in order to measure an NQI, (i) the nucleus must be nonspherical, and the measure of this is the nuclear electric quadrupole moment Q; and (ii) the surrounding charge distribution must deviate from spherical or cubic symmetry. For example, highly symmetric structures such as a perfect tetrahedral or octahedral coordination geometry with four or six identical ligands will not give rise to a measurable NQI. The relevant property of the charge distribution surrounding the nucleus is the EFG tensor at the position of the nucleus, which reflects the deviation

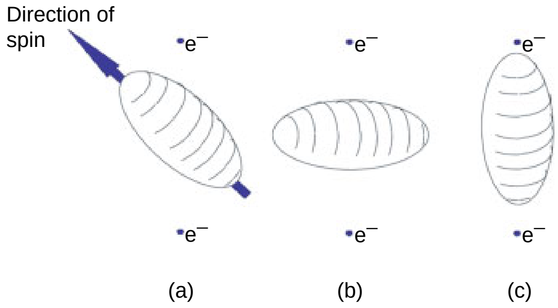

Figure 1 Nucleus in external electric field gradient—a classical picture. The nuclear quadrupole interaction (NQI) between the positive nuclear charge distribution and the surrounding charge distribution (in this case two negative point charges) leads to the energy being lowest in (c), intermediate in (a), and highest in (b). Similarly in a quantum mechanical picture the NQI leads to a splitting of a nuclear energy level into a number of sublevels, depending on the spin, I, of the nucleus ($I + 1/2$ sublevels for half-integer spin and $2I + 1$ for integer spin). In PAC spectroscopy this hyperfine splitting is measured, providing a ''fingerprint'' of the local charge distribution. (Reprinted with permission from E. Danielsen's lecture notes on PAC spectroscopy (http://www.matfys.kvl.dk/biophys/notes.pdf))

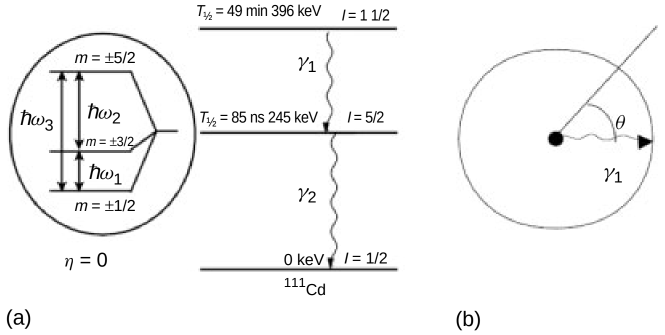

Figure 2 The decay of ^{111m}Cd–a commonly used PAC isotope (a) ^{111m}Cd decays by the successive emission of two γ rays, and in PAC spectroscopy the hyperfine splitting of the intermediate nuclear level ($I = 5/2$) is measured. The hyperfine splitting is shown magnified by about a factor of 10^{12} in the circle to the left for the case of an axially symmetric EFG from the surrounding charge distribution ($\eta = 0$, see the text). (b) The angular correlation between γ_1 and γ_2 is shown; the distance from the center to the curve is proportional to the probability of detecting γ_2 at a given angle, θ, with respect to γ_1

from spherical symmetry. Finally, the figure illustrates that if the nuclear spin direction is inverted is not affected the NQI (in an axially symmetric EFG). These qualitative arguments imply that, contrary to NMR, for example, the $m = +3/2$ and the $m = -3/2$ states of spin $I = 3/2$ nucleus are degenerate, as the geometric arrangement between nucleus and external charges is the same in these two cases. Thus, the NQI leads to a splitting of the nuclear energy levels for nuclei with $I \geq 1$. In the general case where the EFG is not axially symmetric, the m-states are no longer eigenstates of the Hamiltonian, but the same number of substates appear for half-integer spins because the ±degeneracy is not lifted. For integer spins, this is not the case and thus $2I + 1$ sublevels appear. *The energy differences between these sublevels are dictated by the NQI, and thus by the local electronic and molecular structure around the PAC probe, and this ''fingerprint'' of the local structure is measured in PAC spectroscopy.*

2.2 How are These Energy Differences Measured?

As briefly touched upon in the introduction, there is an angular correlation between particles emitted in succession in a nuclear decay. They are not emitted in random directions with respect to each other, due to the conservation of angular momentum in the nuclear decay. In Figure 2, the properties of the nuclear decay of ^{111m}Cd, a commonly used PAC isotope, are presented.

Two γ-rays are emitted (γ_1 and γ_2) in succession, and the angular correlation between them inherent in the nuclear decay is depicted in Figure 2(b). This angular correlation is perturbed by the NQI that the nucleus experiences in the time between emission of γ_1 and γ_2, that is, while it is in its intermediate state (the $I = 5/2$ state for ^{111m}Cd, Figure 2(a)). It turns out that the effect of the NQI is that the probability of detecting γ_2 at a given angle with respect to γ_1 changes in a periodic manner with time. For example, for ^{111m}Cd the probability of detecting γ_2 at 180° with respect to the first γ ray is maximal at time = 0 ns (Figure 2b) but after a certain time it will fall to a minimum, then increases to the maximum again, and so on, in an oscillatory manner, similar to watching a lighthouse, where the probability of seeing a photon also varies periodically. This so-called perturbation function is, however, in most cases more complicated than just a single cosine; it is a linear combination of cosines. The frequencies (ω_i) in this periodic function are those corresponding to transitions between the nuclear energy sublevels ($\hbar\omega_i$) described above; this is the essence of PAC spectroscopy, because it allows for measurement of these energy differences. For a spin 5/2 intermediate nuclear state, which splits into three sublevels (Figure 2(a)), transitions may occur between sublevel 1 and 2, 1 and 3, or 2 and 3, leading to three frequencies (ω_1, ω_2, and ω_3). Notice that $\omega_1 + \omega_2 = \omega_3$, so only two independent parameters are determined (for PAC measurements on randomly oriented samples). In a single crystal experiment, it is, in addition, possible to determine the orientation of the principal coordinate system of the EFG tensor, that is, to record five independent parameters. *In PAC spectroscopy the NQI is measured through the time dependent change of the angular correlation between γ-rays emitted in succession in nuclear decays.*

If the EFG changes in the time between the emission of the first and second γ ray, that is, while the nucleus is in the intermediate state, the PAC signal is affected. Such dynamic features may originate from Brownian tumbling of the molecules in solution or from dynamics at the site of

the PAC probe. Consequently PAC spectroscopy can provide information on dynamics if it occurs on the timescale of the lifetime of the intermediate level (or faster[20–24]) of the PAC probe.

As α- and β-particles will not escape the sample (e.g., a solution or crystals) and a test tube to any significant degree, only $\gamma-\gamma$ PAC spectroscopy has been applied in chemistry.

In Table 1, relevant data for selected PAC isotopes are presented. Several other PAC isotopes exist, for example (mother/daughter nucleus): ^{115}Cd/^{115}In, ^{117}Cd/^{117}In, ^{118m}Sb/^{118}Sn, ^{129m}Te/^{129}I, ^{140}La/^{140}Ce, ^{172}Lu/^{172}Yb, and we refer the reader to the bibliography for details on these.[25–27] The three nuclei decaying via isomeric transitions (^{111m}Cd, ^{199m}Hg, and ^{204m}Pb) are attractive because no change of element accompanies the nuclear decay. So-called after effects of the nuclear decay can cause serious complications in the interpretation of the experimental data, a problem that is particularly pronounced for electron capture (EC) processes.

2.3 How are the Data Extracted in an Experiment?

The six-detector PAC instrument[12] has γ-ray detectors positioned at either 90° or 180° with respect to each other (Figure 3).

When a γ_1 is detected in one detector a clock is started. If a γ_2 is detected in one of the remaining five detectors within 5–10 times the lifetime of the intermediate level (85 ns for ^{111m}Cd) the time and angle (90° or 180°) between γ_1 and γ_2 is recorded. In a PAC measurement a large number of such $\gamma_1-\gamma_2$ coincidences are recorded, and the data are transformed into the so-called perturbation function, that is, the periodic function containing the transition frequencies described above. That is, the perturbation function holds the information about the NQI and therefore, about the local electronic and molecular structure that can be determined in a PAC experiment. The perturbation function is subsequently Fourier (or cosine-) transformed, and this gives a spectrum with a number of peaks depending on the nuclear spin; in the case of $I = 5/2$ three peaks at ω_1, ω_2, and ω_3 are found (Figure 4).

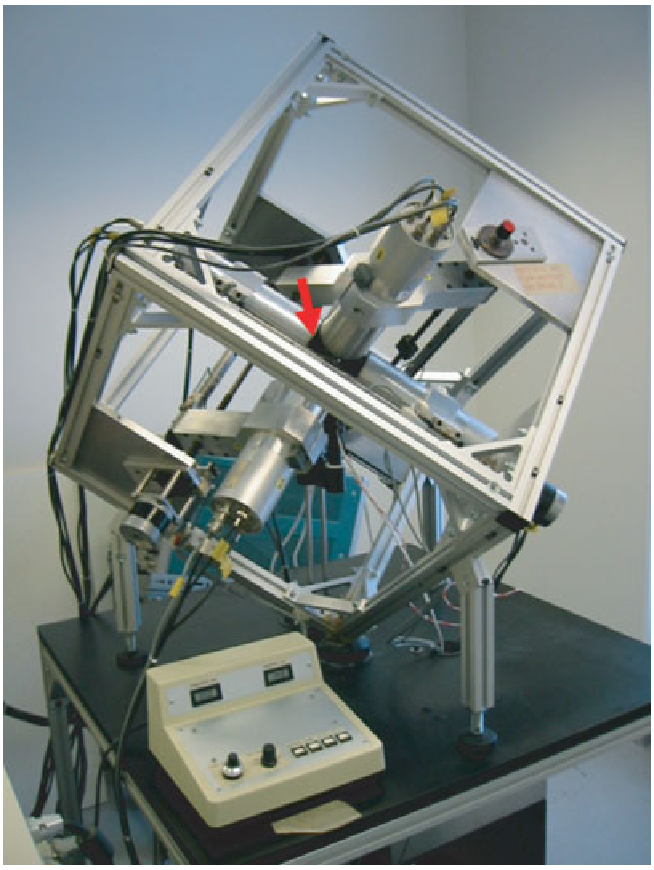

Figure 3 Six-detector PAC instrument. The arrow indicates the position of the sample, which in this setup is a regular test tube. The six detectors face the sample (two of the detectors are not visible; they are hidden behind the other detectors)

Table 1 Properties of selected PAC isotopes[25]

Parent	Half-life	Decay	Daughter	Intermediate state half-life (ns), spin	E(γ_1) keV	E(γ_2) keV
^{44}Ti	47 years	EC	^{44}Sc	153, 1	78	68

2.4 Parameters Determined in a PAC Experiment

The analytical expression for the perturbation function is known, and this is fitted to the experimentally determined perturbation function. This leads to the determination of not only the transition frequencies described above, but also of other parameters related to amplitude and lineshape of the signal, as described in the following text. For a spin 5/2 intermediate nuclear state, the data analysis leads to the determination of ω_1, ω_2, and ω_3. Usually ω_1, ω_2, and ω_3 are not reported in themselves, but transformed into two other independent parameters (recall that only two of these frequencies are independent). There are various traditions in terms of which parameters to report, but qualitatively one refers to the NQI strength $\nu_Q = eq_{zz}Q/h$ (or $\omega_Q = \omega_E = 2\pi/(4I(2I-1))\nu_Q$),

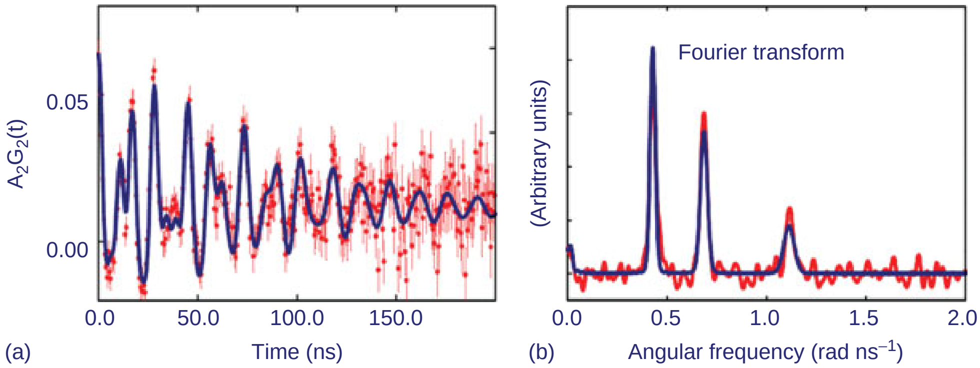

Figure 4 ^{111m}Cd PAC data—example. (a) Experimentally determined perturbation function that contains the information on the local structure and dynamics at the PAC probe site (data points with error bars and fit (full line)).(b) Fourier transform of the experimental data (red) and of the fit (blue). This dataset was recorded for the cadmium-substituted blue copper protein azurin.[28] (After Figure 6 in[11])

where q_{zz} is the numerically largest eigenvalue of the EFG tensor, and Q is the electric quadrupole moment of the nucleus in the intermediate state with nuclear spin I ($\omega_0 = (3\pi/10)\nu_Q$ is used for ^{111m}Cd and ^{111}Ag). The other refers to the asymmetry parameter ($\eta = (q_{xx} - q_{yy})/q_{zz}$, where eq$_{ii}$ are the eigenvalues of the EFG tensor ordered such that $|q_{zz}| \geq |q_{yy}| \geq |q_{xx}|$) and thus to the asymmetry of the structure at the site of the PAC probe. In an axially symmetric structure η is 0, and the largest value of this parameter, namely 1, is found, for example, in a tetrahedral complex with 2A and 2B ligands. η and ν_Q can be calculated for a given molecular structure using first principles quantum mechanical methods.[29–36] For cadmium a semiempirical method has been developed[37] based on complexes of relevance in bioinorganic chemistry.

The amplitude of the signal, A, is also determined. It depends on spins, multipolarities, and eventually on mixing ratios of the transitions involved, that is, entirely on nuclear parameters, and thus is a well-known quantity; in practice, it is further reduced by solid angle correction factors. If more than one structure at the site of the PAC probe is present in the sample, the relative amplitudes will, in general, directly reflect the relative population of the different sites.

The lineshape of the Fourier transformed data can be affected by structural variations at the site of the PAC probe from one molecule to the next, reflected in the relative peak width δ. Thus, δ qualitatively reflects the structural flexibility at the site of the PAC probe. Dynamics similarly affects the PAC signal, and is reflected in the parameter τ_c. An important difference between static inhomogeneous linebroadening and dynamic linebroadening is given by the fact that in the former case a time-independent fraction (1/5 for half-integer spins) of the anisotropy remains whereas in the latter case the angular correlation is completely lost for sufficiently long times.

To summarize, five parameters (A, η, ν_Q (or ω_0), δ and τ_c) are determined for each structure present at the site of the PAC probe in the sample.

3 APPLICATIONS

3.1 Bioinorganic Chemistry

In this section we illustrate the problems that may be addressed using PAC spectroscopy by a variety of examples from the literature. We aim to cover the central aspects of application of PAC spectroscopy in bioinorganic chemistry using these selected examples, rather than to provide a description of all papers published in this field.

It is well-known that the key processes of life, including enzyme catalysis, biochemical signalling via protein–protein interactions and protein structure, dynamics, and folding require the presence of metal ions in many cases. In PAC spectroscopy the native metal ion has to be replaced with a radioactive element with appropriate nuclear properties, and the most commonly used isotopes in bioinorganic applications are ^{99}Mo,^{111m}Cd, ^{111}Ag, ^{111}In, ^{181}Hf, ^{199m}Hg, and very recently, also ^{204m}Pb. Cd(II) is a useful substitute for Zn(II) in biochemistry because it holds the same formal charge and is a closed shell ion, and usually Cd(II)-substituted zinc ion containing enzymes are still active. Ag(I) is similarly a useful substitute for Cu(I), and several copper ion binding proteins have been investigated using PAC spectroscopy. Both Zn(II) and Cu(I) are silent in most other spectroscopic (except X-ray and nuclear) techniques, and PAC spectroscopy offers a unique approach to study zinc[38–62] and copper ion[28,47,48,53,58,59,63–74] containing proteins. ^{181}Hf, ^{111}In, and ^{99}Mo have been applied to study iron ion and molybdenum ion containing proteins, respectively.[75–92] Finally, ^{111m}Cd and ^{199m}Hg have been used in studies of de novo designed heavy metal ion binding proteins and proteins involved in bacterial heavy metal resistance.[71,93–97] Other applications include cadmium and indium binding to bovine serum albumin and DNA, as well as in vivo experiments on bacteria.[84–87,94,98–115]

3.1.1 Structure at the Site of the PAC Probe

The most common application of PAC spectroscopy in bioinorganic chemistry is the elucidation of the local structure at the PAC probe site. Selected examples of this type of application are covered in the following paragraphs.

Certain bacteria have developed resistance toward heavy metals such as mercury, and a well characterized system is that of the MerR and MerA proteins. MerA is an enzyme that reduces Hg(II) to the less toxic Hg, and MerR is a DNA-binding protein that regulates the expression of MerA. If Hg(II) is present at concentrations above about 10 nM in the cell, the MerR mercury biosensor binds the Hg(II) and consequently MerA is expressed. The high affinity and high selectivity for Hg(II) at the binding site in MerR has led to considerable effort to uncover how this binding site is designed, that is, what is the coordination geometry of the bound Hg(II). Initially, this was studied using ^{199}Hg NMR leading to the conclusion that Hg(II) is bound in a planar trigonal structure with three cysteines coordinating in both the free and the DNA-bound protein.[116] The free protein was studied a few years later by ^{199m}Hg PAC spectroscopy. In order to interpret the PAC spectrum recorded for MerR a variety of small Hg(II) complexes with known structure were investigated with ^{199m}Hg PAC spectroscopy. Using this reference data set the ^{199m}Hg PAC data for MerR was assigned to an almost perfect trigonal planar coordination geometry in agreement with the NMR data.[117] Similarly, the Hg(II) coordination geometry was studied for the MerA enzyme.[65,117] The interpretation of the PAC data was also carried out using a theoretical approach, and it was demonstrated that using first principles density functional calculations on selected thiol containing Hg(II) complexes, agreement with experimental data within about 20% was obtained.[36] In the investigation of the MerR and MerA proteins PAC spectroscopy is particularly useful, as a PAC probe (^{199m}Hg) exists for the biochemically relevant element (Hg(II)), and no potential artifacts occur due to the replacement of the native metal ion with a different probe.

In an effort to uncover the basic chemistry of heavy metal–protein interactions, the group led by Pecoraro carried out de novo design of a variety of thiol-rich heavy metal ion binding peptides, and characterized the metal site structure using (extended X-ray absorption fine structure, *see* ***X-Ray Absorption Spectroscopy***) EXAFS, UV-Vis absorption spectroscopy (of the sulfur-to-metal charge transfer bands), electronic circular dichroism (CD), and NMR spectroscopy. In the first ^{111m}Cd PAC study of these peptides, it immediately became clear that PAC spectroscopic data contributed unique information on the Cd(II) coordination geometry:[95] Only one ^{113}Cd NMR signal was observed, but surprisingly two ^{111m}Cd PAC signals were observed for several of the peptides. The explanation for this apparent discrepancy is found in the time scales on which the two techniques monitor the sample. In the PAC experiment the two NQIs recorded correspond to two coordination geometries in slow exchange, which are stable on a timescale of nanoseconds (this timescale is dictated by the lifetime of the intermediate level in the nuclear decay; 85 ns for ^{111m}Cd). One NQI was unambiguously assigned to a trigonal planar structure with three coordinating cysteines, while the other was tentatively assigned to a tetrahedral structure with an additional coordinating water molecule. The NMR signal is in fast exchange, that is, the water molecule jumps on and off on a timescale faster than milliseconds. The group led by Pecoraro then redesigned the peptides, and managed to construct peptides which displayed exclusively one or the other of the two coordination geometries, as supported by both NMR and PAC data recorded for these species.[96] In Figure 5,

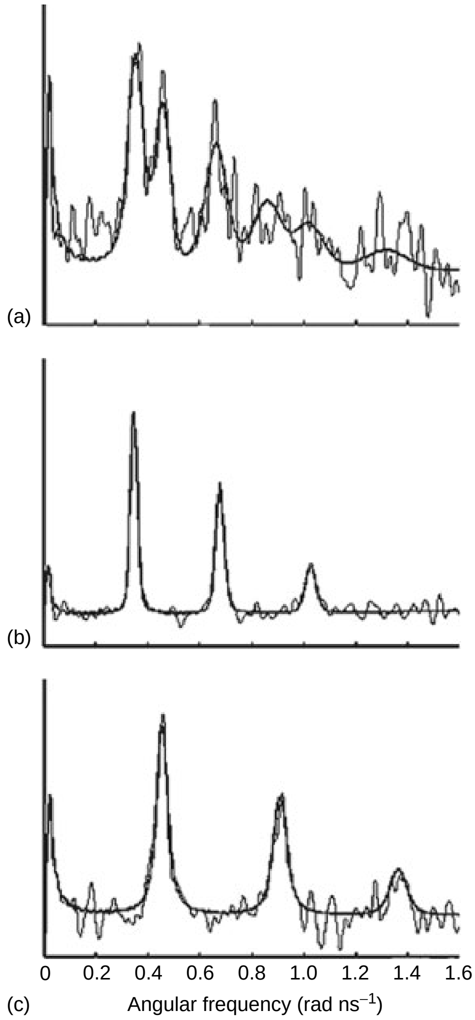

Figure 5 ^{111m}Cd PAC spectra for de novo designed peptides. Fourier transform of the experimental data (thin line) and Fourier transform of the fit (bold line). (a) Two coexisting coordination geometries in slow exchange in $[Cd(II)(TRI\ L16C)_3]^-$, (b) the signal interpreted as a tetrahedral structure with three cysteines and one water molecule coordinating in $[Cd(II)(TRI\ L12A/L16C)_3]^-$, and (c) the signal from a trigonal planar structure with three cysteines coordinating in $[Cd(II)(TRI\ L16Pen)_3]^-$. Note that adding spectrum (b) and (c) gives spectrum (a). (Reprinted with permission from Lee, Cabello, Hemmingsen, Neil, Marsh and Pecoraro.[96] © 2006 Wiley-VCH)

the PAC spectra are shown for the peptide with a pure trigonal Cd(II) coordination geometry (c), a pure tetrahedral coordination geometry (b) and the more complex spectrum of the peptide with the two coordination geometries coexisting in slow exchange (a). Recently, ^{199m}Hg PAC spectroscopic studies of Hg(II) binding to de novo designed peptides has been undertaken. The results indicate that the fundamental chemistry, for example, affinity and selectivity, of Hg(II) binding to proteins can be explored successfully.[118]

A particular advantage of PAC spectroscopy is the extreme sensitivity to changes in the first coordination sphere of the PAC probe. Examples of such changes include titration of a metal ion-bound water molecule in the enzyme alcohol dehydrogenase, binding of inhibitors to the blood pressure regulating enzyme angiotensin converting enzyme (ACE), and metallo β-lactamases, structural changes at the metal site of carboxypeptidase during catalysis, and several others. As an example, Figure 6 shows the ^{111m}Cd PAC spectra recorded for horse liver alcohol dehydrogenase at different pH values.[38] The spectra clearly change with pH. At pH 7.9, only one NQI is found, giving rise to a broad peak at about 450 Mrad s^{-1}. In principle, three peaks should be observed, but in this case the line broadening of the two first peaks, which are close to each other, is so large that they coalesce into one, and the third peak (at about 900 Mrad s^{-1}) is so broad that it vanishes in the noise. (There is an additional small signal at low frequency that originates from cadmium that has migrated to the so-called structural site of the enzyme.) On increasing the pH, a new signal at about 250 Mrad s^{-1} appears, whereas the signal at 450 Mrad/s^{-1} decreases, and a pK_a of 11.0 can be fitted to

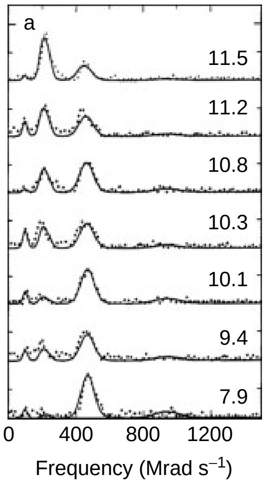

Figure 6 ^{111m}Cd PAC spectra for horse liver alcohol dehydrogenase at different pH values. Fourier transform of the experimental data (dotted line) and Fourier transform of the fit (bold line). The spectrum changes with pH (indicated for each spectrum), and this is interpreted as the titration of a metal ion-bound water molecule with a pK_a of 11.0. (Reprinted with permission from Hemmingsen, Bauer, Bjerrum, Zeppezauer, Adolph, Formicka and Cedergren-Zeppezauer.[38] © 1995 American Chemical Society)

the data. In the resting state, the enzyme supplies three ligands to the metal ion binding site, two cysteines and a histidine, and the fourth ligand position is occupied by a water molecule. The pK_a of this water molecule is of considerable interest as it may affect the function of the enzyme. In the native enzyme a Zn(II) ion essential for the function of the enzyme is bound at the active site. The Cd(II)-substituted species is still catalytically active, although with a lower specific activity than the native enzyme at the pH of the standard assay. Kvassman and Pettersson[119] carried out a careful analysis of the pH dependence of the association of the oxidized and reduced coenzyme (nicotinamide adenine dinucleotide (NAD^+) and reduced nicotinamide adenine dinucleotide (NADH)), and found a pK_a of 9.2, regulating the association but the coenzyme binding probes a large part of the active site, and the pK_a might originate from other titrating groups than the metal ion-bound water molecule. The PAC data are specific for the very local surroundings of the metal ion, and spectral changes as large as those reported in Figure 6 indicate that the titrating group is in the first coordination sphere. It can be observed that the NQI falls off rapidly with the distance from the cadmium nucleus (roughly as r^{-3}),[29] and typically changes within the first 3–5 Å can be abserved. The fact that the pK_a observed for the Cd(II) substituted enzyme is higher than that observed for the native Zn(II) containing enzyme is expected, as the ionic radius of Cd(II) is larger than that of Zn(II), and thus Cd(II) is less potent at polarizing the metal ion-bound water molecule. Thus the two sets of experiments indicate that the pK_a of the metal ion-bound water molecule is 9.2 for the native free enzyme. Similarly, a pK_a of 9.6 was determined in ^{111m}Cd PAC studies of the binary complex between enzyme and NAD^+, whereas no pK_a was observed for the binary complex between enzyme and NADH, probably because it lies above the pH range covered. The quantitative structural analysis in Ref. 38 was based on the Bauer's axially symmetric independent ligands model (BASIL) (previously denoted the angular overlap model (AOM) for PAC spectroscopy),[37] and a few years later a comprehensive analysis using a combined quantum mechanical and molecular mechanical (QM/MM) method was preserved.[32]

The linebroadening of the PAC signal offers information on the structural flexibility and dynamics at the site of the PAC probe. Qualitatively, a structurally flexible site will result in slightly different structures from one molecule to the next, giving rise to a distribution of NQIs, typically observed as a relatively broad signal. In this paragraph we will focus on structural flexibility, returning to dynamics later (*see* Section 3.1.2). One example of this is the signal recorded for carboxypeptidase A under different physical conditions (Figure 7). In the crystalline state, the lines in the Fourier transform of the perturbation function are narrow, indicating that the structure at the metal ion binding site is relatively rigid, as expected. In solution the signal is very similar, but the lines are broadened, indicating that the metal site structure is more flexible than in the crystalline state, at least for the

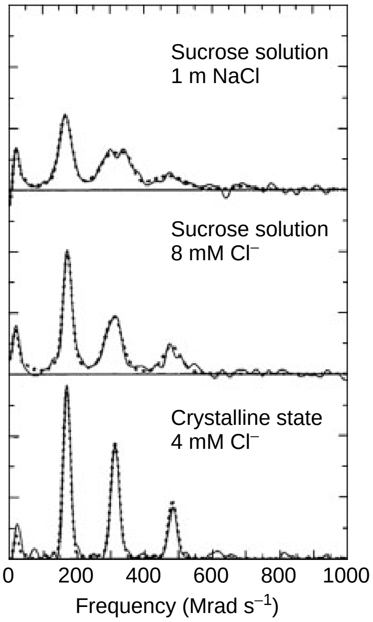

Figure 7 ^{111m}Cd PAC spectra for carboxypeptidase A under different physical conditions. Fourier transform of the experimental data (dotted line) and Fourier transform of the fit (bold line). The line broadening found in solution as compared to the crystalline state indicates that the metal ion binding site is structurally more flexible in solution. (Reprinted with permission from Bauer, Danielsen, Hemmingsen, Sørensen, Ulstrup, Friis, Auld and Bjerrum.[42] © 1997 American Chemical Society)

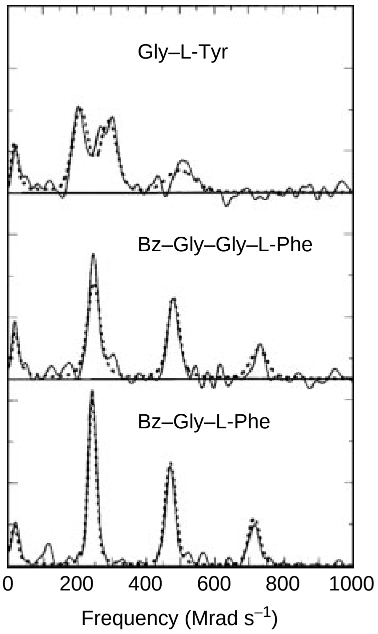

Figure 8 ^{111m}Cd PAC spectra for Carboxypeptidase A under steady state hydrolysis of small peptides. Fourier transform of the experimental data (dotted line) and Fourier transform of the fit (bold line). The lines are relatively narrow for the two ''good'' substrates Bz−Gly−L-Phe and Bz−Gly−Gly−L-Phe, but relatively broad for the ''poor'' substrate Gly−L-Tyr, indicating that the active site structure is more rigid for the ''good'' substrates, possibly because it is optimized for catalysis. (Reprinted with permission from Bauer, Danielsen, Hemmingsen, Sørensen, Ulstrup, Friis, Auld and Bjerrum.[42] © 1997 American Chemical Society)

enzyme in the resting state. In a 1M NaCl solution the signal is also broadened, and different from the signal with low chloride concentration, indicating that chloride affects the coordination geometry. This example also illustrates that PAC spectroscopy can be applied to different physical states, for example, in addressing the question whether the structure in the crystalline state (used in X-ray diffraction based protein structure determination) represents that found in solution. In several PAC studies on enzymes it has been observed that the metal site structure is flexible in the free enzyme, but rigid in complexes with substrate or inhibitors.

PAC spectroscopic studies may be carried out during catalysis, as has been demonstrated under steady state conditions for the hydrolysis of peptides by cadmium-substituted carboxypeptidase A[42] (Figure 8). The ^{111m}Cd PAC spectra reflect the structure(s) present at the rate determining step of the reaction. The two substrates Bz−Gly−L-Phe and Bz−Gly−Gly−L-Phe are hydrolyzed relatively fast by the enzyme, that is, they are ''good'' substrates, whereas Gly−L-Tyr is hydrolyzed relatively slowly. The line width for the two ''good'' substrates is relatively small, indicating that the metal site coordination geometry is very well defined, probably optimized for catalysis. In contrast, there is considerable line broadening for Gly−L-Tyr, possibly reflecting the suboptimal structure for catalysis in this case. An interesting new approach to the study of enzyme catalysis is the combination of PAC spectroscopy with rapid freeze quench equipment (*see* ***Freeze-Quench Kinetics***).[120] The enzyme and substrate are simply mixed and frozen rapidly (on the time scale of milliseconds or slower), and the freeze quenched samples then placed in the PAC spectrometer. Rapid freeze quenching has been successfully combined with several other spectroscopic techniques such as electron nuclear double resonance (ENDOR) (*see* ***Electron-Nuclear Double Resonance (ENDOR) Spectroscopy***), EPR (*see* ***Electron Paramagnetic Resonance (EPR) Spectroscopy***), EXAFS (*see* ***X-Ray Absorption Spectroscopy***) and Mössbauer spectroscopy (*see* ***Mössbauer Spectroscopy***). This, in principle, allows for real time recording of spectroscopic snapshots of structures evolving and decaying during the reaction, in analogy to stopped flow UV-Vis absorption (*see* ***Rapid Scan, Stopped-Flow Kinetics***) spectroscopy.

As indicated in the introduction, it is possible to carry out PAC experiments under physiological conditions, and even in vivo experiments are possible. One example of the latter is the study of the fast inhibition of photosynthesis in cyanobacteria.[98] Photosynthesis in cyanobacteria is inhibited within about 15 min after exposure to Cd(II). Exposing the cyanobacteria to ^{111m}Cd it was possible to follow the fate of Cd(II) in terms of binding to biomolecules, as the biological

material is almost transparent to the γ-rays. Combining the PAC spectroscopic data with other spectroscopic data, SDS PAGE, and bioinformatics analysis of potential metal ion binding proteins in the genome of the bacteria, it was concluded that there may be a variety of biomolecules binding the Cd(II) ions, but that carbonic anhydrase is a probable candidate in the context of inhibition of photosynthesis. Similar investigations have been carried out with ^{99}Mo PAC on Fe/Mo-nitrogenases in *Azotobacter vinelandii*.[84–87]

A final but exclusive advantage of PAC spectroscopy is the possibility to work at extremely low probe concentrations. In principle, only of the order of 10^{10} probe nuclei are necessary for an experiment, corresponding to a concentration of about 10 pM in a 1 mL sample. However, the presence of other metal ions, even in well prepared samples where the concentration of such pollution is minimized, may interfere with the binding of the PAC probe to the biomolecule of interest. To avoid this problem, the PAC probe concentration is often kept above 1–10 μM. In addition, working with very low concentrations there is a risk that the PAC probe will be lost, for example, due to adsorption to the surface of the glassware or test tube. Nonetheless, several examples of successful PAC experiments carried out under such (so-called carrier-free) conditions exist in the literature. One particularly interesting application which can only be carried out with PAC spectroscopy, is the titration of PAC probe into a solution of a protein with two or more metal ion binding sites, starting from carrier-free conditions and ending with fully loaded protein. The final data point may be studied with most techniques, but the initial data point in this titration requires extremely low probe concentration. This has been done in a ^{111m}Cd PAC spectroscopic study of metallo β-lactamases.[40] Metallo β-lactamases are bacterial enzymes that hydrolyze penicillin and similar β-lactam based antibiotics, as a defense mechanism against these drugs. This leads to resistance against these drugs, and is currently a serious threat to public health. These enzymes have two metal ion binding sites, and the PAC spectra display two NQIs at carrier-free conditions. On increasing the Cd(II) concentration to fully load the two metal ion binding sites in the enzyme, the two NQIs change into two new NQIs. Thus, the metal ion binding site structure changes for both sites when the enzyme is fully loaded. The most straightforward explanation of this is that (i) at carrier-free conditions either site may be occupied, one in some enzymes, and the other site in others, and (ii) the two binding sites are positioned relatively close to each other, so the PAC signal in one site depends on whether the other site is occupied or not. Interestingly, the titration of Cd(II) into the protein solution allows for investigation of whether the binding of the two metal ions is cooperative (the signal from the binuclear site appears already at low Cd(II) to protein stoichiometry) or not. Such studies have been carried out both with and without the presence of inhibitors of the metallo β-lactamases.

3.1.2 Dynamics at the Site of the PAC Probe

Dynamics at a metal ion binding site in a protein may originate from qualitatively different sources, for example rotational diffusion (Brownian tumbling) of the molecules, conformational dynamics, or ligand exchange. In this section we illustrate how dynamics affects the PAC signal and how this may be used to derive information on protein–protein interactions, dynamics of protein folding, and metal site exchange dynamics.

In a dynamic situation where the EFG changes during the time the nucleus spends in the intermediate state, the NQI also changes, and this can lead to linebroadening or even total loss of anisotropy in the perturbation function and thus, to the loss of the PAC signal, or it can lead to motional narrowing in analogy to NMR in the case of fast exchange between two structures, a description of which follows. The dynamics is reflected in the rotational correlation time, τ_c, fitted to the PAC data, as indicated in the section on technical background. It is, in principle, possible to discriminate between structural flexibility (vide supra) and dynamics in PAC spectroscopy.

For the small blue copper protein plastocyanin the pH dependence of the metal site structure of the Cd(II)-substituted species has been investigated by ^{111m}Cd PAC. Plastocyanin is an electron transfer protein involved in photosynthesis.[74] For all these experiments 55% w/w sucrose was added to the solution to slow the Brownian tumbling of the molecules, an approach used routinely in biological applications of PAC spectroscopy. At pH 7.5 one dominating metal site coordination geometry is detected (see Figure 9, top panel), and as the pH is lowered to 4.4, the metal ion dissociates from the protein, giving a characteristic signal from Cd(II) in 55% w/w sucrose solution at 1 °C. Upon subsequent increase of the pH to 7.5 the original signal is recovered, but surprisingly, a new signal is also present (indicated by an arrow in Figure 9(b), lower panel). The relative population of the two signals changed on a timescale of hours, increasing the fraction of the signal originally recorded at pH 7.5, indicating that a slow structural relaxation occurred to the coordination geometry originally found at pH 7.5. As the second signal is not observed in the initial experiment at pH 7.5, where the apoprotein was incubated with cadmium for about 15 min before carrying out the experiment, the structural relaxation is not related directly to the association of the metal ion at this pH. The fact that the two signals are quite similar, indicates that the same ligands are coordinating to the metal ion. Thus, the relaxation may reflect structural changes further away from the metal ion binding site, possibly slow refolding of the protein from a local energy minimum to the native state, with a barrier large enough that this refolding intermediate exists for hours.

For rotational diffusion of the protein molecules two extreme situations can be described analytically: in the case of slow reorientation of the EFG, the amplitude of the perturbation function is damped exponentially, but oscillations are still present, and in the other extreme of fast reorientation of the EFG, the oscillations in the perturbation

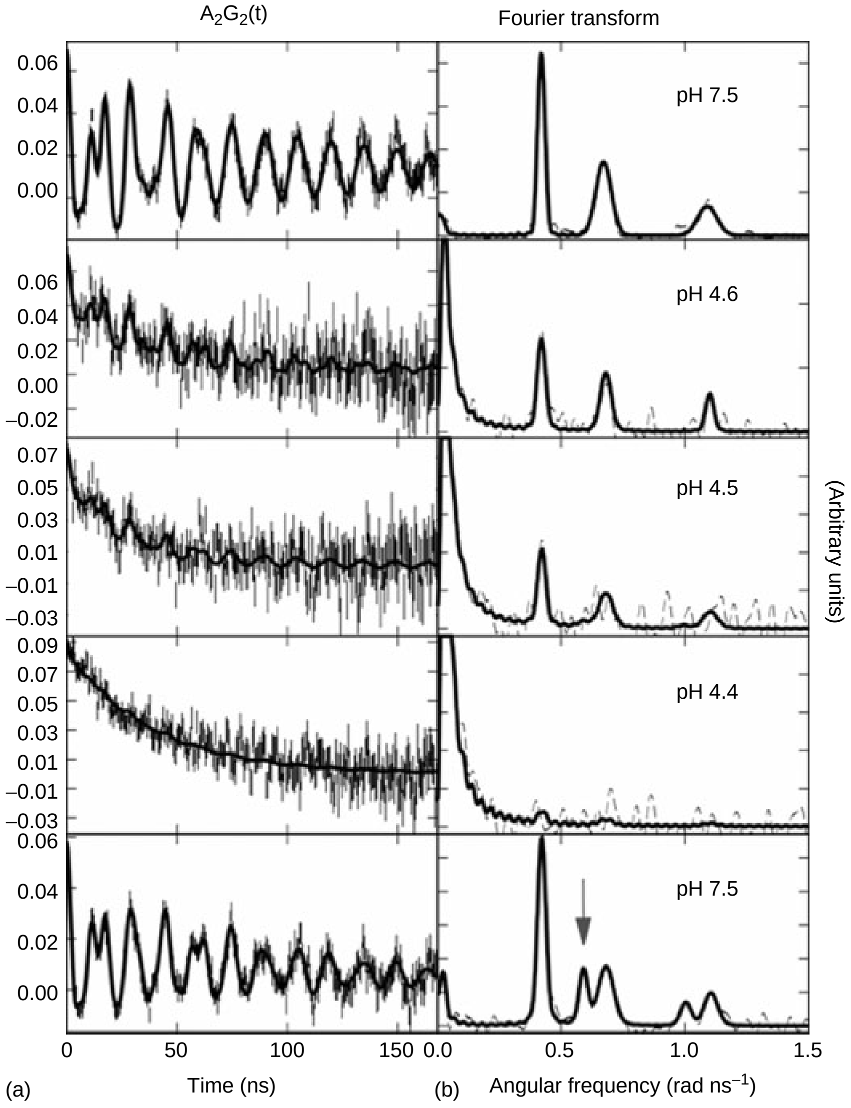

Figure 9 ^{111m}Cd PAC spectra for plastocyanin at different pH values. (a) Perturbation function (fit indicated by full line); (b) Fourier transform of the perturbation function (dotted line) and Fourier transform of the fit (bold line). On decreasing pH from 7.5, the signal from Cd(II) at the metal ion binding site is lost because it dissociates from the protein. Subsequently, on increasing pH the original signal at pH 7.5 is recovered, but surprisingly, an additional signal is present for hours (indicated by the arrow). (Reprinted with permission of Federation of the European Biochemical Societies from Sas, Hemmingsen and Danielsen[74])

function are completely lost and the perturbation function is simply described by an exponential decay. In the intermediate range it is also possible to calculate the perturbation function, although no analytical expression exists.[11,20,21] In order to limit the loss of signal due to rotational diffusion sucrose is often added to the sample (e.g., 55% w/w) to make it very viscous, and the experiments are carried out at 1 °C, or the proteins are immobilized by other means. However, in the first demonstration of the use of PAC spectroscopy to monitor protein–protein interactions, the immobilization was intentionally excluded. Two different PAC probes, ^{111}Ag and ^{111m}Cd were bound to plastocyanin, see top panels of Figure 10, in an attempt to model the two oxidation states of the copper ion bound in the native protein. The recorded perturbation function contained almost no periodic signal, indicating that the plastocyanin molecules were tumbling at a rate that obscured the signal that was observed in a quasi-static case (*see* Figure 9(a) for cadmium-substituted plastocyanin). Photosystem I (PSI) is the electron accepting physiological partner of plastocyanin. Adding PSI to the solution had practically no effect for the Cd(II)-substituted plastocyanin, but significantly affected the signal from Ag(I)-substituted plastocyanin. This indicates that the rotational diffusion of Ag(I) plastocyanin is significantly reduced and the periodic signal in the perturbation function is recovered because Ag(I) plastocyanin binds to photosystem I, whereas

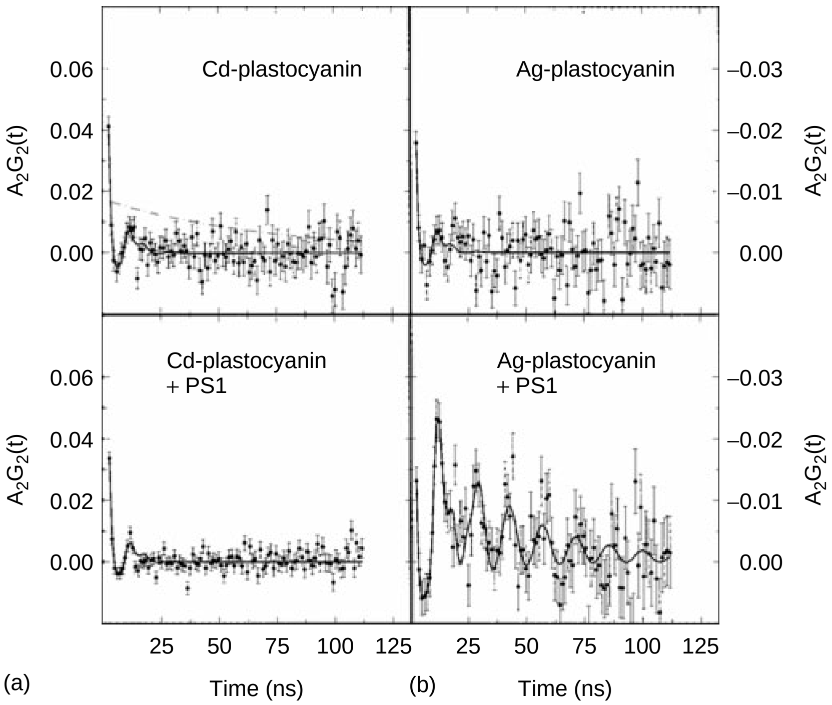

Figure 10 PAC perturbation functions for Cd(II)- and Ag(I)-substituted plastocyanin in the absence and presence of photosystem I. Experimental data with error bars and fit (full line). (a) For Cd(II)-substituted plastocyanin, there is no significant change upon addition of photosystem I (PSI), whereas for (b) Ag(I)-substituted plastocyanin the perturbation function changes dramatically. This indicates that Ag(I)-substituted plastocyanin binds to the large protein complex photosystem I, significantly reducing the rotational diffusion of plastocyanin, and thus shows that the association of these two physiological partners is regulated by the charge state of the metal ion in the manner expected. Cd(II) plastocyanin does not, under the given experimental conditions. This is an illustration of an application of PAC spectroscopy to the study of protein–protein interactions, and it is even possible to estimate the dissociation constant directly from the spectroscopic data. Note that in this example the perturbation function and not the Fourier transformed data, is displayed in the figure, as the perturbation function illustrates the effect of dynamics more clearly. Note that the data analysis is almost always carried out on the perturbation function.

It has been known for decades that it should be possible to detect exchange dynamics at the site of the PAC probe in analogy to NMR, but at shorter timescales.[22,23] The timescale on which exchange dynamics can be observed is dictated by the lifetime of the intermediate nuclear level of the PAC probe. Two coordination geometries in slow exchange will give two NQIs; in intermediate exchange a damped signal will be observed, and in fast exchange, one sharp weighted average signal (of the two NQIs) will be observed. Exchange dynamics has been suggested as the most plausible explanation of experimental data in a limited number of publications (Ref. 11 and references therein). Only recently, a temperature series on Cd(II) binding to de novo designed peptides has provided data which probably constitute the first clearcut observation of exchange dynamics with PAC spectroscopy on biological samples.[121]

The final example in this section describes global rotational diffusion, as well as internal dynamics in transferrins, in what is probably the most comprehensive study of a protein family carried out with PAC spectroscopy.[75–83] Transferrins are iron transporters, with two metal ion binding sites, one in the so-called N-terminal lobe and one in the C-terminal lobe. Using ^{181}Hf as PAC probe and varying the temperature from 0 to 45 °C, the dynamics was investigated for ovotransferrin and serum transferrin.[78] It was demonstrated that slow reorientation was a valid approximation in this study, and thus that the dynamics could be represented by an exponential damping of the perturbation function for the static case. Obviously, the rotational diffusion is temperature and viscosity dependent, and in a simple model $1/\tau_c$ is proportional to T/η (where T is the absolute temperature and η the viscosity of the liquid sample–not to be confused with the asymmetry parameter). Plotting $1/\tau_c$ against T/η, the slope provides information on the hydrodynamic volume of the molecule, a property that may also be determined by neutron scattering (*see* ***Neutron Scattering***). In addition, and perhaps more interestingly, on extrapolating the fit to $T/\eta = 0$, there was a residual value for $1/\tau_c$ indicating that internal dynamics on the nano- to

microsecond timescale of the proteins plays a significant role for these systems.

3.2 Inorganic Chemistry and Solid State Physics

In this section we focus on applications which provide information different from that illustrated by the examples in the section on bioinorganic chemistry. Thus the coverage of inorganic chemistry and solid state physics is not intended to be exhaustive, but to highlight the information that can be derived in addition to the local structure and dynamics at the PAC probe site (vide supra).

A seminal paper dealt with NQIs in metals and compounds for the purpose of the determination of nuclear quadrupole moments using reference moments.[8]

In the field of nuclear solid state physics the technique of TDPAC was first applied to the study of internal magnetic fields in ferromagnets and other magnetically ordered systems. The magnetic hyperfine field followed closely—but not exactly—the macroscopically determined magnetization. The deviations are likely due to the fact that the magnetic hyperfine field is determined at the site of an impurity atom where lattice relaxations and local modifications of the spin-polarized charge density play a role. Nevertheless, systematic studies of hyperfine fields in ferromagnets like iron and nickel for a large series of impurity probes gave a rather complete picture. Several studies were devoted to the determination of critical exponents near the Curie temperature.[122]

The study of NQI's on a large scale started with metals, especially defects trapped at the impurity probe atom like vacancies or other impurity atoms.[123,124] In cubic metals, the EFG at the nuclear site vanishes due to symmetry. This even holds for cases where the local lattice relaxation around an impurity atom is large, as long as the point symmetry remains cubic. As soon as there is a near-neighbor defect, the symmetry is broken locally and a finite EFG acts on the probe nucleus. In many cases, the impurity probe attracts defects or other foreign atoms—at least after annealing—such that extremely low concentrations become detectable. Of particular interest was radiation damage in cubic metals.[125] Temperature[126] and pressure[127] dependencies of EFG's were investigated. In many metals a $T^{3/2}$ temperature dependence was observed, which was related to the mean square lattice displacements due to vibrations. However, it turned out that the lattice expansion alone cannot explain the observed temperature dependence, but a local repopulation of conduction electron states is required. It should be mentioned that in a point-charge plus uniform background (of electrons) model, that is, representing the neighboring ion cores by point charges which produce the EFG via unscreened Coulomb potentials, lattice vibrations would not lead to a temperature dependence of the EFG at all. Thus far, no general theory on the temperature dependence of NQIs in metals is available.

Similarly, an attempt to separate the observed pressure dependence of the NQI in noncubic metals (mainly hexagonal closed packed) into a contribution due to the pressure dependence of the lattice constant ratio c/a and the volume V yielded an as yet unexplained $V^{-\alpha}$ dependence with α being more like three rather than one, as would be expected in a point-charge model.

Amorphous metals,[128] alloys,[128] and internal oxidation[129,130] have also been investigated. In amorphous systems, very broad frequency distributions, or in other words, heavily damped TDPAC spectra prevail, which do not readily yield more information other than that the local environment consists of a multitude of inequivalent geometries. The situation in alloys is more interesting as soon as local ordering occurs and intermetallic phases are formed. Here, TDPAC offers complementary information to X-ray diffraction because short-range order would clearly show up in the TDPAC spectra, whereas the phase analysis via X-ray diffraction requires long-range order. The same arguments apply to the case of internal oxidation. Due to the short-range nature of the NQI, molecule formation at a very early stage can be detected.

Of particular interest is the study of metal surfaces.[131,132] Probe atoms can reside on terraces or in the first surface layer or they can reside at steps, kinks, and so on. All these sites can be readily distinguished via their EFG strength, symmetry, and orientation. The deposition of probe atoms at low temperatures preferentially produces adatoms which, upon subsequent isochronous annealing, migrate to other sites. With the invention of surface techniques with atomic resolution like scanning tunneling microscopy or variants thereof, the TDPAC studies of surfaces got a strong competitor. Therefore, modern applications of TDPAC deal with magnetism on surfaces and at interfaces[133] where information with atomic resolution can be obtained, which is not accessible otherwise. It appears that the magnetic hyperfine field acting on the probe nucleus depends essentially on the coordination number of the magnetic neighbors rather than on the geometrical details.

After the ‘‘metal era’’ the studies of defects at impurity probe atoms were extended to semiconductors,[134] a field which is still active due to the relevance for applications. Doping of semiconductors is achieved by introducing donor or acceptor atoms, usually at extremely low concentrations. Frequently, the number of mobile charge carriers (electrons or holes) is much lower than expectations based on the doping levels. Here, the dopants can be passivated by impurities, for example, hydrogen or copper atoms. In addition, the dopant could reside on an interstitial or even bond-center site instead of being substitutional. In all these cases, TDPAC can be of valuable help due to its extreme sensitivity. The strength, symmetry, and orientation of the EFG tensor yields detailed information on the probe atom geometry on an atomic level. Again, interactions of the impurity atom with defects play a crucial role. The situation becomes particularly complicated in binary or ternary systems.

Further investigations dealt with structural phase transitions. In general, structural phase transitions are easily detected in diffraction studies or by differential thermal calorimetry. However, frequently such transitions are accompanied by local dynamics of atoms on sublattices prior to the transition which are not readily observed by diffraction techniques. Here, the lattice dynamics which shows up in the TDPAC spectra are of particular value in understanding the origin of the phase transition.

Particularly interesting cases are charge density wave (CDW) transitions in transition metal dichalcogenides.[135] In the commensurate CDW state, a superlattice is formed whose size and symmetry is given by diffraction studies. What is less obvious is the determination of the phase of the CDW with respect to the underlying lattice, that is, is the charge density maximum (or minimum) located on an atomic site or not. This has immediate consequences for the number of inequivalent lattice sites with certain populations. These are easily detected by TDPAC. Thus, in 1T-TaS_2 with octahedral metal coordination, a $\sqrt{13} \times \sqrt{13}$ superstructure is formed with the charge density maximum located on an atom site, thus forming a star-of-David structure with three inequivalent lattice sites with populations of 1:6:6 and axial symmetry at the central site (the strong coupling between adjacent layers leads to further small distortions; the undistorted 1:6:6 pattern is best observed in the 6R-modification where the CDW is formed in every second layer with octahedral coordination). On the contrary, in 2H-TaS_2 with trigonal prismatic metal coordination, a 3×3 superlattice is formed with the charge density maximum between three Ta-atoms. Hence, a sort of ‘‘snow-flake’’ with three inequivalent lattice sites and 3:3:3 populations, none of which exhibit axial symmetry, is formed (again, the coupling between neighboring layers leads to a further small distortion). A rather interesting situation is observed when the CDW is incommensurate with the underlying lattice. In this situation, there is no repeat period any more, that is, there is no unit cell. All metal atoms are subjected to slightly different EFGs due to slightly different charge densities, and line shapes characteristic of 1- or 2-dimensional incommensurate CDWs are observed. They manifest themselves in streaks in electron diffraction patterns. Hyperfine spectroscopies, in general, have elucidated this field of CDWs.[135]

TDPAC turned out to be ideally suited for the in situ study of intercalation reactions in 2H-TaS_2 and other host materials.[136,137] Metal ions, hydrated or solvated ions, as well as molecules can be intercalated between the layers which are held together with weak van der Waals forces only. These guest species can enter the host lattice only via the prism surfaces, that is, parallel to the layers. Upon intercalation, the lattice expands perpendicularly to the layers in order to accommodate the guest species. In the initial stage, strong elastic lattice deformations occur. The driving force which actually overcomes the energy barrier due to elastic lattice deformation is the charge transferred from the guest to the host. This has an immediate effect on the NQI at the host metal site (and also on the chalcogen site). It turned out that the NQI is a reliable measure of the charge transfer and also of the fraction of intercalated phase during the reaction. Electrochemical control of the reaction allows to keep the average prism current density constant, contrary to chemical reactions. In the latter case, nonequilibrium phases were observed when a critical current density was exceeded. This could be verified by electrochemical intercalation at high current densities.

Structure and bonding have been explored using the EFG as an experimental anchor that must be reproduced in theoretical studies of the electronic structure. For Cd(II), it has been demonstrated that both charge transfer from the ligands into the unfilled 5p cadmium orbitals and back-bonding involving the filled 4d cadmium orbitals, play a significant role in determination of the EFG at the site of the cadmium nucleus.[34] The contribution from the 5p electrons is dominating, and this forms the basis of the semiempirical BASIL model for calculations of NQIs in cadmium complexes.[29,35,37] A ‘‘calculator’’ for this model is available at http://www.matfys.kvl.dk/~eva/aom.html (we acknowledge Eva Danielsen for providing the code for this program).

Finally, in a single crystal experiment it is possible to extract all five independent elements of the traceless NQI tensor, usually chosen to be the orientation of the EFG principal axis system, in addition to the two parameters accessible for randomly oriented samples (η and ν_Q). This, of course, requires that it is possible to make a single crystal incorporating the radioactive mother nucleus, and is therefore limited to cases where the preparation can be completed within roughly the lifetime of the mother nucleus, for example, see Ref. 138.

4 ABBREVIATIONS AND ACRONYMS

ACE = angiotensin converting enzyme; AOM = angular overlap model; BASIL = Bauer's axially symmetric independent ligands model; CD = circular dichroism; CDW = charge density wave; EC = electron capture; EFG = electric field gradient; ENDOR = electron nuclear double resonance; EPR = electron paramagnetic resonance; EXAFS = extended X-ray absorption fine structure; NAD^+ = nicotinamide adenine dinucleotide; NADH = reduced nicotinamide adenine dinucleotide; NMR = nuclear magnetic resonance; NQI = nuclear quadrupole interaction; NQR = nuclear quadrupole resonance; PAC = perturbed angular correlation; PSI = photosystem i; SDS-PAGE = sodium dodecyl sulfate-polyacrylamide gel electrophoresis; TDPAC = time differential perturbed angular correlation.

METHOD SUMMARY

Acronyms, Synonyms

- Photoelectron Spectroscopy, PES
- Photoemission Spectroscopy, PES
- Ultraviolet Photoelectron Spectroscopy, UPS
- X-ray Photoelectron Spectroscopy, XPS
- Electron Spectroscopy for Chemical Analysis, ESCA
- Multiphoton Ionization Spectroscopy, MPI
- Resonantly enhanced Multiphoton Ionization Spectroscopy, REMPI
- Zero Electron Kinetic Energy Spectroscopy, ZEKE
- Auger Electron Spectroscopy, AES
- Penning Ionization Electron Spectroscopy, PIES

Measured physical quantities

- kinetic energy of electrons ejected from molecules or materials through excitation by one or more photons.

Information available

Depending on the photoelectron method and the particular sample:

- ionization energies to states related to ejection of core and/or valence electrons from neutral molecules or materials
- Koopmans' theorem, ionization energies related to the energy of core and/or valence orbitals
- electron configurations
- vibrational and rotational energies from fine structure on ionization bands
- spin-orbit coupling energies
- electron exchange energies
- charge distributions and bonding interactions
- substituent electronic effects
- information on the atomic character of molecular orbitals by analyses of photoionization cross sections
- information on geometry changes and reorganization energies associated with ionizations
- quantitative determination of elements present within about 10 nm of a sample surface

- electron affinity and related one-electron excited electronic states of the neutral molecule
- oxidation states of the elements present.

Information not available, limitations

- difficulty in resolving vibrational and/or rotational fine structure for gas-phase molecules larger than about 10 atoms without jet cooling
- possibility of contamination in the gas phase for neutral molecules
- solid-phase XPS detection limits in parts-per-thousand
- PES of solid materials surface sensitive, only probes about 10 nm deep
- must be performed in vacuum ($<10^{-5}$ torr for gas-phase studies, $<10^{-9}$ torr for solid-phase studies).

Examples of questions that can be answered

- What is the ionization energy of a molecule?
- What is the electron affinity of a molecule (negative-ion PES)?
- How much is the ionization energy of a molecule stabilized or destabilized by addition of substituents?
- What are the charge and orbital overlap interactions in a molecule?
- What is the inner-sphere reorganization energy of a molecule upon ionization?
- What is the oxidation state of the metal in a molecule?
- How ‘‘electron rich’’ is the metal in the molecule?
- How strong an electron donor or electron acceptor is a ligand?
- What is the exchange coupling in a bimetallic system?

Major advantages

- All one-electron ionizations are observed.
- Clearly defined measurement is a major contributor to thermodynamic relationships.
- An energy measure of electronic interactions can be obtained.
- The technique can be performed in some manner on essentially any molecule, in any phase.
- The lack of solvation effects in gas-phase spectroscopy makes the measurements amenable to theoretical calculations and provides solid benchmarks.
- Photoelectron spectroscopy is directly correlated to molecular orbital models via Koopmans’ theorem.

Major disadvantages

- All ionizations are observed; limited selection rules are present to help in assignments.
- The technique is not useful for cations (except in condensed phase).
- Valence photoelectron spectra are often very convoluted; individual ionizations are not resolved for large, low-symmetry molecules.
- Data collection requires substantial expertise and time.
- General access is limited.
- Commercial instruments are not available for gas-phase studies.
- Surface XPS instruments are expensive.
- Instrument maintenance is high.

Sample constraints

- For gas-phase studies of neutral molecules, samples must be sufficiently volatile.
- The technique is generally destructive of samples.
- The quantity of sample required is of the order of 10 mg or more.
- Valence photoelectron spectroscopy of solid molecular materials requires highly ordered thin films, typically prepared by epitaxial film deposition.

1 INTRODUCTION

Photoelectron spectroscopy is based on Einstein’s photoelectric effect.[1] A photon can remove an electron from a molecule or material if the photon has an energy greater than the electron binding energy, and any photon energy in excess of the electron binding energy is carried by the outgoing electron in the form of kinetic energy. The kinetic energy of the ejected photoelectron is measured by a photoelectron spectrometer. In the case of a neutral molecule, ejection of

the electron results in ionization of the molecule, and the difference between the photon energy ($h\nu$), which is known, and the electron kinetic energy (KE), which is measured, is the ionization energy (IE).

$$IE = \mathrm{E}(h\nu) - KE(e^-) \tag{1}$$

Ionization is explicitly defined in terms of transitions between the ground state of a molecule and ion states as shown in equation (2).

$$\mathrm{M} + \text{photon}(h\nu) \longrightarrow \mathrm{M_i}^+ + e^- \tag{2}$$

The information obtained from photoelectron spectroscopy is typically discussed in terms of the electronic structure and bonding in the ground states of molecules, with ionization of electrons occurring from bonding molecular orbitals, lone pairs, antibonding molecular orbitals, or atomic cores. These descriptions reflect the relationship of ionization energies to the molecular orbital model of electronic structure. The ionization energies are directly related to the energies of molecular orbitals by Koopmans' Theorem,[2] which states that the negative of the eigenvalue of an occupied orbital from the Hartree–Fock model of the electronic structure is equal to the vertical ionization energy to the ion state formed by removal of an electron from that orbital, provided the distributions of the remaining electrons do not change. While there are limitations to the applicability of Koopmans' theorem[3] in a first order approximation, each ionization of a molecule can be described as removal of an electron from an individual orbital. The ionization energies can then be considered as measures of orbital stabilities, and shifts can be interpreted in terms of orbital stabilizations or destabilizations due to changes in electron distributions and bonding.

Photoelectron spectroscopy remains among the most direct and comprehensive experimental probes of electronic structure. Photoelectron spectroscopy of neutral molecules in the gas phase has served as a particularly important basis for the bonding models used to describe inorganic molecules because the energetics of ion formation from the neutral ground state are directly related to the orbital electron configurations, oxidation states, charge distributions, and covalency. Photoelectron spectroscopy has become an established field over the last 40 years, with several books available on the subject.[4–6] There are also review articles on gas-phase photoelectron spectroscopy of neutral transition metal molecules,[3,7–9] which include case studies based on several well-characterized molecular systems. In addition to conventional photoelectron spectroscopy, additional photoionization spectroscopic techniques continue to be developed, which give additional types of experimental information and have different sample constraints. Examples include gas-phase photoelectron spectroscopy of anions and a variety of techniques using multiphoton ionization. This article considers examples of applications of photoelectron spectroscopy in bioinorganic chemistry and applications of newer photoelectron techniques to inorganic molecules.

2 TECHNICAL BACKGROUND

2.1 Photoionization

Considering the photoionization process in more detail for a neutral molecule in the gas phase, the photon ionizes the molecule (M) and leaves the molecule in a positively charged ion state ($\mathrm{M_i^+}$) according to equation (2). Rearranging equation (2) and considering the energy components of the process as in equation (3), shows that a measure of the ionization energy is also a measure of the difference in energy between the positive ion state $\mathrm{M_i^+}$ and the initial state of the molecule M.

$$\mathrm{E(M_i}^+) - \mathrm{E(M)} = \mathrm{E}(h\nu) - KE(e^-) = IE \tag{3}$$

Thus photoelectron spectroscopy measures the relative energies of the ground and excited positive ion states that are obtained by removal of single electrons from the neutral molecule.

The direct ionization transition is not restricted by any symmetry selection rules because the ejected electron can carry any necessary angular momentum to make the process electric dipole allowed, so ionization to any excited positive ion state obtained by removal of a single electron and within range of the photon energy can be observed. That is, ionizations that correspond to removal of electrons from any of the occupied orbitals can be observed. Additional states of these ions may also be observed, most commonly for core electron ionizations of metal complexes, corresponding to additional ''shake up'' of remaining electrons from occupied orbitals to virtual orbitals accompanying the ionization process. This lack of selection rules results in the photoelectron spectra of large molecules becoming congested and more difficult to analyze.

2.2 Ionization Band Shape

Photoionization is an electronic process that occurs on a timescale much faster than molecular vibrations, and therefore for each discrete ionization band the band maximum corresponds to the Franck–Condon vertical ionization energy. The ionization can be illustrated, as shown in Figure 1 for the hydrogen molecule, as the transition between the potential energy well of the initial state and the potential energy well of the state formed by removal of an electron. Removal of an electron changes the overall bonding in the molecule and results in a shift of the equilibrium internuclear separations. If the geometry changes are sufficiently great, the most probable transitions from the neutral ground state

are to excited vibrational levels of the final ion state, and the adiabatic ionization will be at some lower energy than the vertical ionization. When the vibrational levels are resolved, as shown for the photoelectron spectrum of hydrogen compared to the potential energy surface in Figure 1, the change in vibrational spacing from the initial state to the final state gives a measure of the change in vibrational frequencies and force constants associated with the excitation, while the intensity pattern (Franck–Condon factors) of the transitions to the excited vibrational levels gives a measure of the change in equilibrium bond distances. This information can also be used to give a measure of the inner-sphere reorganization energy of electron transfer, which is discussed in more detail in the applications section.

For large molecules the individual vibrational levels of the ionizations will typically not be resolved, but the overall shape of an ionization band is still governed by the difference in equilibrium geometry between the initial and ionized states. For example, if the vibrational levels for the ionization of hydrogen in Figure 1 were not resolved, the overall band shape would resemble the asymmetric Gaussian shown with a dotted line. The energy width and shape of the band will still be dependent upon the Franck–Condon factors of the unresolved vibrational structure. For large molecules with unresolved vibrational structure, it is often impossible to exactly measure an adiabatic ionization energy. Measurement of adiabatic ionization energies is further complicated by the fact that excited vibrational levels may be occupied in the

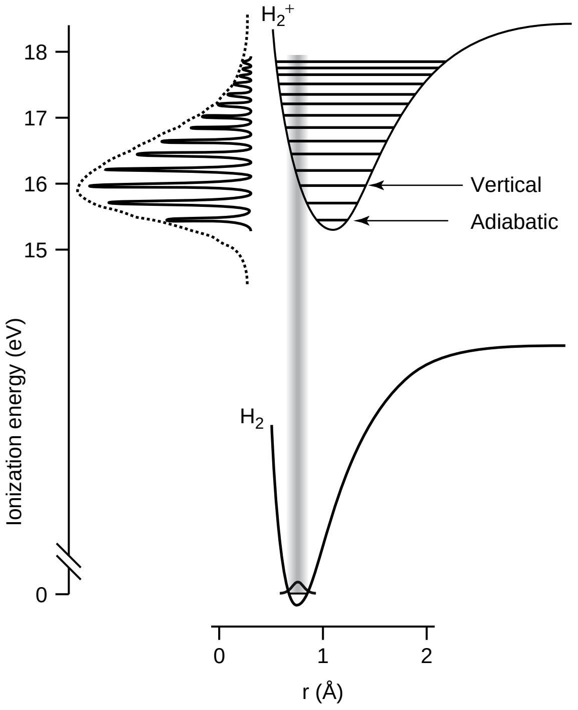

Figure 1 Transition between potential energy surfaces that describe the ionization of the hydrogen molecule

neutral ground state of the molecules, resulting in the presence of hot bands in the spectra. Vertical ionization energies are of most interest in the molecular orbital description of electronic structure as they are directly related to orbital energies by Koopmans' theorem.

2.3 Photoionization Cross Sections

In addition to the energy information that is contained in a photoelectron spectrum, the intensities of ionizations also give valuable information regarding electronic structure and the orbital origin of ionizations. The probability of ionization is dependent upon the energy of the ionizing photon and the character of the orbitals. The probability is also dependent upon the angle at which photoelectrons are collected and the polarized nature of the photons. These probabilities of photoionization are understood in terms of photoionization cross sections.

The dependence of photoionization cross sections upon the energy of the ionization photon and the character of the molecular orbital has been particularly useful in the assignments of the spectra of inorganic and organometallic molecules. The general trends that have been observed for photoionization behavior often lead to a clear and convenient differentiation between ionization from metal-based and ligand-based orbitals. Variable energy photon studies have become increasingly common since the advent of high intensity, tuneable synchrotron radiation sources. Synchrotron studies have led to a better understanding of the influences to cross-section behavior as photon energy changes.[10]

2.4 Core Ionization

Photons with energies in the kilo-electron volt (X-ray) range are able to ionize down to the core electrons of atoms and molecules. Core ionizations of molecules are associated with the individual atoms present and fall in characteristic energy ranges related to the specific elements. Core-ionization spectroscopy, most commonly carried out on solids, is therefore useful as an analytical tool, and Siegbahn coined the name *electron spectroscopy for chemical analysis* (ESCA) for the technique,[11,12] although X-ray photoelectron spectroscopy (XPS) is more commonly used today.[12,13] The exact ionization energy of a core level is influenced by the charge potential around the atom, and is useful for distinguishing between atoms in different chemical environments. The sensitivity for XPS is on the order of parts-per-thousand, so while XPS is the premier technique for analyzing oxidation states of transition metals in many systems, its use is limited by the concentration of the atom of interest. For example, XPS has not proven useful for the analysis for transition metal active sites in enzymes due to the low concentration of transition metal atoms present, but is often used for analyzing active-site models.

The influences of bonding/overlap and charge potential contributions to ionization energies also can be differentiated through use of the gas-phase core-valence ionization correlation approach of Jolly.[14,15] Core ionization energies are dependent on the charge distribution at atomic positions in a molecule, as well as relaxation effects. Valence ionization energies also respond to these factors, but in addition, are sensitive to bonding. The principle of core-valence ionization correlation states that, when comparing ionization spectra for two related molecules, the binding energy shift of a nonbonding valence orbital localized on an atom present in both molecules should be eight-tenths of the core binding energy shift for that atom between the two molecules.[16] A valence/core shift ratio differing from the benchmark 0.8 value indicates the contribution of bonding/overlap interactions to the valence shift.

2.5 Photoionization in the Solid Phase

Photoelectron spectroscopy of valence and core electrons in solids has been useful in the study of the surface properties of transition metals and other solid-phase materials.[12] When photoelectron spectroscopy is performed on a solid sample, an additional step that must be considered is the escape of the resultant photoelectron from the bulk. The analysis can only be performed as deep as the electrons can escape from the bulk and then be detected. The escape depth is dependent upon the inelastic mean free path of the electrons, determined by electron–electron and electron–phonon collisions, which varies with photoelectron kinetic energy. The depth that can be probed is on the order of about 5–50 Å, which makes this spectroscopy actually a surface-sensitive technique rather than a probe of the bulk properties of a material. Because photoelectron spectroscopy only probes such a thin layer, analysis of bulk materials, absorbed molecules, or thin films must be performed in ultrahigh vacuum ($<10^{-9}$ torr) to prevent interference from contaminants that may adhere to the surface.

2.6 Auger Electron Spectroscopy

Auger electron spectroscopy (pronounced ''O-Jay'' but with the softer J associated with French pronunciation) has similarities to photoelectron spectroscopy and is one of the most commonly used tools for probing the elemental composition of surfaces[13] because the energies of Auger transitions are also dependent on the characteristic atomic core level energies. The initial state in an Auger process is a core hole, which can be generated by photoionization, but is usually produced experimentally by impact from an electron beam to overcome the intensity limitations caused by the cross-section of photoionization. The core hole state produced then decays via an electronic transition from a higher lying orbital to the core orbital, with release of the resultant energy of relaxation by the ejection and kinetic energy of a secondary electron, referred to as an Auger electron. If the core hole was created in a K (1s) shell, and if the relaxing electron and ejected Auger electron are from valence orbitals, the overall process is referred to as producing a $\mathrm{K}V_1V_2$ Auger electron, where V_1 and V_2 are the valence levels. In the photoelectron process, the energy for the ejection and kinetic energy of the electron is provided by the photon, which is an essentially monoenergetic source. In the Auger process, the energy for ejection and kinetic energy of the electron comes from relaxation of a valence electron into the core hole. Because there are many different valence electron energy levels in the molecule, the source of energy for production of the Auger electrons is not monoenergetic.

Auger spectroscopy is also capable of probing the valence electronic structure of molecules and solids,[17–19] because the lineshapes of Auger transitions are dependent on the energies of the valence levels. The Auger lineshape can be considered as a superposition of a series of overlapping photoelectron spectra for the molecule, where each spectrum is shifted according to the energy of relaxation from the particular valence level V_1. A Koopmans' approximation for the energy of a particular transition, ignoring the ''repulsion'' between the two valence holes in the final state, is given by equation (4), where the ε values are the orbital eigenvalues of the valence and core levels.

$$KE\ (\text{Auger electron}) = \varepsilon(V_1) + \varepsilon(V_2) - \varepsilon(\mathrm{K}) \quad (4)$$

In the low kinetic energy region of the Auger line shape, there are many overlapping transitions, because electrons with high binding energies (high ε) that are ejected by relaxation of an electron from the highest occupied valence levels (low ε) have kinetic energies similar to electrons with low binding energies (low ε) that are ejected by relaxation of an electron from more stable valence levels (high ε). The ionizations on the leading edge of the Auger band at high kinetic energy correspond to ejection of electrons with the lowest binding energies (lowest ε) by relaxation of electrons from the highest occupied valence levels (lowest ε) to the core level. This leading edge of the Auger band provides the most useful electronic structure and bonding information.

Additional useful information is provided as a consequence of the way Auger spectroscopy couples the core levels and the valence levels. In simple terms, the intensity of a $\mathrm{K}VV$ Auger transition is a measure of the valence charge available for decay into the core hole. Because a core hole is localized on a particular atom, this can give an indication of the amount of electron density in a particular valence orbital around the atom where the core hole was made.

2.7 Penning Ionization

Penning ionization electron spectroscopy (PIES), also referred to as *metastable atom electron spectroscopy*

(MAES) or *metastable ionization electron spectroscopy* (MIES), is another spectroscopy related and complementary to photoelectron spectroscopy that has been used for the study of inorganic molecules.[20] In Penning ionization, electrons are ejected by collisions between target molecules and a beam of metastable atoms (atoms in an excited electronic state that have a long lifetime) such as He^* atoms in the (2^3S) excited state, which have an energy of 19.82 eV above the ground state of He. The Penning ionization process shown in equation (5) is interpreted in terms of an electron exchange, in which an electron of the target molecule transfers to a hole of the metastable atom and the excited-state electron from the metastable atom is ejected simultaneously.

$$M + He^* \longrightarrow M^+ + He + e^- \qquad (5)$$

The energy source for the ejection and kinetic energy of the electron is the energy of the metastable atom, which is essentially monoenergetic. The transition probability for the electron transfer depends largely on the spatial overlap of the relevant orbital of the sample molecule and the vacant orbital of the excited state, metastable atom. In other words, the intensity of a transition will be greater if the occupied orbital of the sample molecule has electron density on the periphery of the molecule, in contrast to photoelectron spectroscopy, where the intensity of an ionization is governed by the photoionization cross section. Comparison of the intensity of Penning ionization transitions to the intensities observed for the corresponding ionization bands in the photoelectron spectrum of the sample allows study of the spatial electron distribution of individual molecular orbitals, and is often also used to analyze solid materials.[21]

2.8 Photoionization of Anions

Gas-phase studies of neutral molecules are limited to molecules that can be sublimed in vacuo without decomposition, and therefore the majority of photoelectron spectroscopic studies of inorganic molecules have focused on organometallic molecules, many of which are reasonably volatile. Gas-phase photoelectron spectroscopy on negatively charged atoms or small ($<$10 atom) molecules has also been performed for many years.[22] Recent advances in instrumentation and sample introduction have opened these types of experiments to anionic species of interest to inorganic chemists.[23] The ionization energy of an anion is the electron affinity of the neutral molecule. This means that the ionization transitions observed when photoelectron spectroscopy is performed on anions, which are from the ground state of the anion to states of the neutral species, now give electron affinities and other information on the neutral molecule. Anion photoelectron spectroscopy has proven particularly useful in giving information on excited electronic states of neutral molecules that cannot be accessed by other spectroscopic techniques.

Neutral inorganic molecules have first ionization energies in the range of about 5–15 eV, meaning that photons in the vacuum UV range must be used to observe the ionizations of these molecules. The vacuum UV is a difficult energy region photons with usable intensity for experimentally producing, and the only practical laboratory sources use emission from noble gas discharge lamps; increasingly synchrotron radiation is used as a photoionization source for these experiments. In contrast to neutral molecules, the ionization energies of many anions are sufficiently low that ionization can be achieved using visible photons, which opens the use of commercially available, intense laser sources for performing photoelectron spectroscopy on these species. Anions can be introduced into the gas phase by techniques such as electrospray, or reactive anionic molecules such as clusters or molecular ions can be generated by pyrolysis, photolysis, or some other means. The anions can first be mass selected before being introduced into the photoelectron ionization area.

2.9 Multiphoton Ionizations

The cross sections for photoionization caused by simultaneous interaction with two or more photons are much lower than those for one-photon ionization, and consequently multiphoton ionization is not observed with the moderate intensity vacuum UV or soft X-ray sources used in conventional photoelectron spectroscopy. However, the availability of high-power tuneable laser sources has made the development of spectroscopic techniques associated with multiphoton ionization possible.[22] The use of two or more photons to reach an ionization threshold means that low energy lasers can be used to provide the excitation energy for multiphoton ionization of neutral molecules. The overall cross section of multiple photon events can be increased by using one photon that is in resonance with the transition energy to an excited state that effectively acts as an intermediate state; this intermediate transition will occur with the higher probabilities associated with normal photon absorption and increases the overall cross section of ionization. This technique, which typically uses two photons of different energy to cause ionization, is referred to as *resonantly enhanced multiphoton ionization* (REMPI) spectroscopy. The final ionization event gives information about the intermediate excited state.

Zero electron kinetic energy (ZEKE) spectroscopy was first introduced in 1984.[24] It is a subset of multiphoton spectroscopy, where the molecules are photoexcited to an ionization energy threshold level, from which electrons with very low or effectively zero kinetic energy will be produced. ZEKE spectroscopy combines the use of pulsed lasers and a delayed pulsed electrical field used for detecting the ZEKE electrons. The advantage of this technique is that extremely good resolution can be achieved, on the order of 1 cm^{-1} or greater, so vibrationally and rotationally resolved structure can be observed, and accurate adiabatic ionization energies can be obtained,[25,26] but to date this technique has only been

applied to the analysis of relatively small molecular systems. A variant of this technique uses the pulsed field to actually cause the ionization, and is referred to as ZEKE-PFI (pulsed field ionization) spectroscopy.

2.10 Additional Experimental Considerations

To summarize, photoelectron spectroscopy is a large field of study that has many subfields, and new techniques continue to be introduced. These different subfields all have different instrumental and sample constraints, but taken as a whole, photoelectron spectroscopic experiments can be performed on almost any system of interest in inorganic chemistry. The main physical constraints limiting the usage of different photoelectron techniques to different chemical problems have been summarized above.

One additional constraint to the widespread application of these techniques is the availability of spectrometers. Surface spectrometers are commercially available, although due to the need for ultrahigh vacuum technology, the purchase price and upkeep costs can be appreciable. Gas-phase spectrometers are not currently commercially available and must be custom built with the specific design dependent upon the type of samples and experimental information of interest. The most important components that control the key features of any photoelectron spectrometer are the sample handling and entry area, the photon source, and the electron kinetic energy analyzer. Ancillary components for vacuum production, vacuum measurement, and electron measurement are also required. Samples for gas-phase spectroscopy are typically introduced as a constant flow, with neutral molecules requiring heating to a sufficient vapor pressure; once in the gas-phase samples may be cooled by jet expansion to decrease thermal broadening of signals.

3 APPLICATIONS

The following section includes discussion of several applications of photoelectron spectroscopy to the study of bioinorganic model complexes. The ''Further Reading'' section at the end of this article lists previous reviews and articles and other applications in inorganic and organometallic chemistry that can be consulted for areas not covered here.

3.1 Metal–Sulfur Interactions in $CpFe(CO)_2(SPh)$

An important contribution of photoelectron spectroscopy to inorganic chemistry has been the use of this technique to understand the bonding capabilities of different ligands to metal centers.[27] If the bonding for a series of ligands is to be compared, the metal fragment to which those ligands are bound must be similar. The d^6 piano-stool complexes of the general form $CpM(CO)_2L$ have been useful for the comparison of a wide variety of metal–ligand interactions. The general electronic structure of the $CpM(CO)_2$ fragment is well understood,[28] and the large number of complexes of this general geometry available for study has allowed systematic characterization of the relative bonding capabilities of many ligands. While these molecules are of low molecular symmetry, the relatively high local electronic symmetry at the metal makes evaluation of the photoelectron spectra (PES) of these complexes straightforward. As one example, this molecular framework has been used to study iron–thiolate bonding, which is an important interaction present in many bioinorganic systems. The pseudo-octahedral geometry of $CpFe(CO)_2(SPh)$ and its formal d^6 electron configuration provide ideal molecular and electronic characteristics to observe the effect of filled–filled $d\pi$–$p\pi$ antibonding interactions between formally occupied metal orbitals and the thiolate ligand lone pair that is principally sulfur 3p in character.[29]

The gas-phase photoelectron spectra of piano-stool molecules shown in Figure 2 illustrate how information on metal–ligand bonding can be gained through application of this technique. The three occupied metal d orbitals of formal d^6 piano-stool complexes are closely related to the t_{2g} set for an octahedral molecule, and the relative energy of these three orbitals are related to the relative π interactions that the metal orbitals have with the CO and L ligands.[27] For example, the spectrum in Figure 2(a) is that of $CpMn(CO)_3$.[30] For this compound, each of the three metal-based orbitals are stabilized by back-bonding to two COs and the three resultant ionizations are grouped together at around 8 eV. The near-degeneracy of the ionizations reflects the pseudo-octahedral symmetry at the metal center. This spectrum also shows the Cp e_1''-symmetry, π-based ionization at about 10 eV.

The spectrum shown in Figure 2(b) is that of $CpFe(CO)_2H$.[27] For this compound, the H^- ligand now has no capability of undergoing π-interaction with the metal, and the metal ionizations split into a two-above-one pattern as two of the metal ionizations are destabilized away from the third due to loss of π-back-bonding to the third ligand (now the hydride). The energy splitting of the metal ionizations therefore acts as a benchmark for metal splitting in the absence of a π-interactive ligand.

The spectrum shown in Figure 2(c) is that of $CpFe(CO)_2(SPh)$.[29] This photoelectron spectrum is more complicated due to the presence of the additional ionizations from the Ph π and S 3p lone pair. The electronic structure of $CpFe(CO)_2(SPh)$ can be considered as the combination of the $[CpFe(CO)_2]^+$ and $[SPh]^-$ fragments, and the photoelectron spectrum of the $CpFe(CO)_2H$ and thiophenol (HSPh, shown in Figure 2d) can be used to model the ionizations of these fragments. The three lowest energy ionizations of thiophenol correspond to a mixture of sulfur lone pair and aryl π character, with the lowest energy (highest occupied molecular orbitals (HOMO)) ionization attributed to the orbital with the most sulfur lone pair character. For $CpFe(CO)_2(SPh)$,

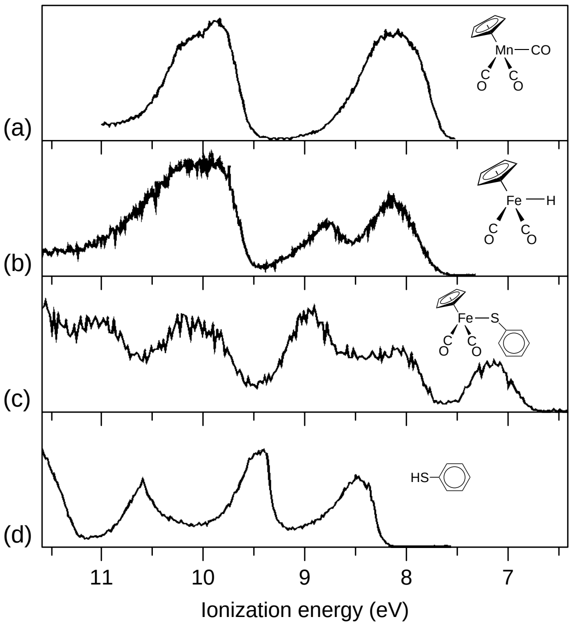

Figure 2 Valence photoelectron spectra of (a) $CpMn(CO)_3$, (b) $CpFe(CO)_2H$, (c) $CpFe(CO)_2(SPh)$, and (d) HSPh

the predominantly metal ionizations should occur in the region of 8–9 eV in analogy with the ionizations of other $CpFe(CO)_2X$ complexes.[30] The Cp π and aryl π orbitals give rise to additional ionization features at greater than 9 eV. The lowest energy ionization of $CpFe(CO)_2(SPh)$ at about 7 eV is metal–sulfur antibonding and principally sulfur in character, which would indicate that the thiolate lone pair orbital has been destabilized relative to thiophenol by about 1.3 eV. This destabilization is the result of two cooperating effects, the charge difference between H^+ and the $[CpFe(CO)_2]^+$ fragment and filled–filled interactions between the sulfur 3p lone pair and the occupied iron dπ orbitals.

3.2 Photoelectron Spectroscopy of Models for Active Sites in Molybdenum Enzymes

Molybdenum–sulfur bonding is also important in biology due to the large group of molybdenum-containing enzymes that catalyze a wide range of oxidation/reduction reactions in carbon, sulfur, and nitrogen metabolism. A common structural feature of the active sites of these molybdenum-containing enzymes is coordination by the sulfur atoms of one (or two) unique ene-dithiolate ligands derived from the side chain of a novel substituted pterin. Complexes with sulfur ligation of Mo centers often exhibit different spectroscopic behavior from those with alkoxide donors, and it is believed that the role of the ene-dithiolate coordination in molybdoenzymes is to buffer the influences of molybdenum oxidation state changes and the presence of strong π ligands.[31]

3.2.1 The ‘‘Electronic Buffering’’ Effect

The photoelectron spectra of model complexes for these molybdenum enzyme active sites have been investigated to gain a better understanding of their basic electronic structure and the role of the ene-dithiolate ligand.[31–33] For example, the metal coordination of model complexes such as Tp*MoO(tdt) are similar to the molybdenum center of sulfite oxidase, which possesses the basic structural core of a terminal oxo group cis to a 1,2-dithiolate.

The lower energy portion of the HeI photoelectron spectrum of Tp*MoO(tdt) is shown in Figure 3(a). The ionizations located from about 8 to 10.5 eV arise from the removal of electrons from orbitals primarily associated with the Tp* and oxo ligands. The large number of individual ionizations and the overlapping nature of these bands make it difficult to unambiguously assign any feature in this region to a particular ionization. The ionization band located at about 6.8 eV and labeled M_{ip} can be attributed to the ionization of the Mo d^1 electron from this formally Mo(V) complex; this

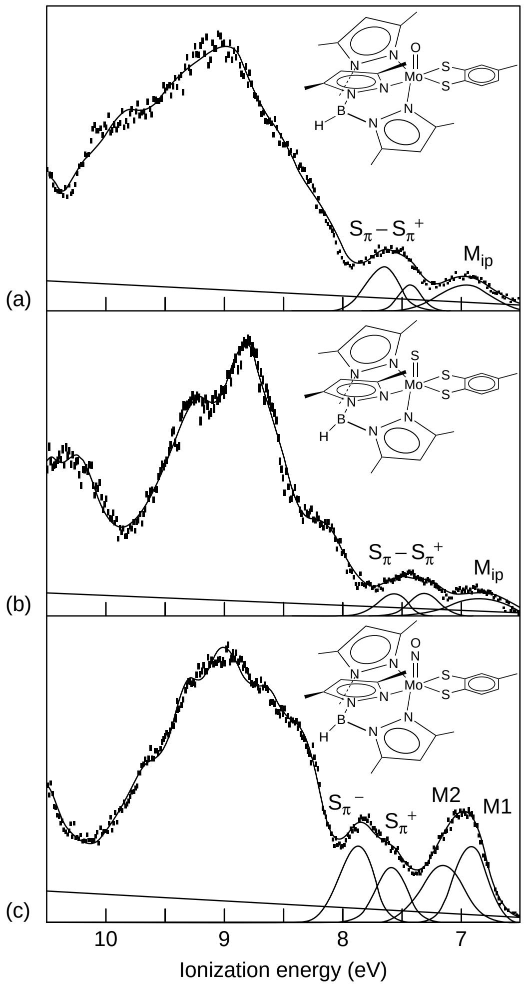

Figure 3 Valence photoelectron spectra of (a) Tp*MoO(tdt), (b) Tp*MoS(tdt), and (c) Tp*Mo(NO)(tdt)

electron resides in a Mo d orbital in the plane of the two sulfurs of the ene-dithiolate. The ionization bands located between about 7.25 and 8 eV are assigned to ionizations associated with symmetric (S_π^{+}) and antisymmetric (S_π^{-}) combinations of S 3p orbitals. The spectrum of Tp*MoS(tdt) is shown in Figure 3(b), and is very similar to that of the oxo complex. The spectrum of the nitrosyl complex Tp*Mo(NO)(tdt) is shown in Figure 3(c), with the first ionization feature fit with two Guassians labeled M1 and M2 assigned to ionization from the two nearly degenerate, primarily metal-based orbitals of the formally Mo(II) d^4 center.

The first ionization energies measured for these ene-dithiolate complexes, as well as those for analogous alkoxide complexes, are listed in Table 1. The first ionization energies of the Tp*MoE(tdt) complexes (E = O, S, or NO) are essentially independent of the E ligand present, even though the formal oxidation state of the Mo center in these complexes ranges from +2 to +5. In contrast, for analogous alkoxide complexes such as $TpMoE(OEt)_2$,[34] the formally Mo(II) nitrosyl complex was found to be almost 0.8 eV more difficult to ionize than the formally Mo(V) oxo analog. This counterintuitive behavior for the alkoxide complex is attributed to the strong π-accepting ability of the NO ligand.

The control that the ene-dithiolate ligand has upon the first ionization energy of these complexes illustrates the importance of this ligation to the reactivity found for molybdoenzymes. The ene-dithiolate ligand acts as an ''electronic buffer'', effectively dampening the harsh electronic changes that would otherwise be expected to take place with changes in the metal formal oxidation states and atom transfer reactions at the active site in these enzymes.

3.2.2 *Ene-Dithiolate Ligand Folding and Covalency*

The spectra discussed above indicate the presence of the ene-dithiolate electronic buffering effect, but not its cause. Insight into this cause can be gained by comparing spectra of a compound that have been collected with different photon energies to evaluate the photoionization cross sections. From previous experimental studies and calculations of atomic photoionization cross sections,[35,36] it is expected that ionizations from orbitals with significant Mo 4d contributions will increase in intensity compared to ionizations of primarily S 3p character when data collected with a HeII photon source are compared to data collected with a HeI photon source. Mixing of metal and sulfur character in orbitals will result in smaller changes in relative intensities of ionizations being observed.

Table 1 Comparison of first ionization energies for ene-dithiolate and alkoxide molybdenum complexes

Complex	First ionization energy (eV)	References
$Tp^*MoO(OEt)_2$	6.57	34
$Tp^*Mo(NO)(OEt)_2$	7.40	34
Tp*MoO(tdt)	6.95	32
Tp*MoS(tdt)	6.88	32
Tp*Mo(NO)(tdt)	6.90	32

The spectra of Tp*MoO(bdt) collected with HeI and HeII photons are compared in Figure 4.[37] The initial three ionizations in the spectra of Tp*MoO(bdt) are assigned as in the spectrum of Tp*MoO(tdt). Observation of only small changes in the relative intensities of the first three bands with different ionization source energy is evidence of substantial mixing of metal and sulfur character in these three orbitals.

The bent-metallocene ene-dithiolate compound $Cp_2Mo(bdt)$ provides access to the Mo d^2 electron configuration, with the added benefit that the sulfur ionizations can be more clearly observed because the Cp ionizations are more stable than Tp* ionizations. The spectra of $Cp_2Mo(bdt)$ in Figure 4 also show three low energy ionizations,[37] with the HeII data clearly showing an increase in the intensity of the middle band, and perhaps a slight decrease in intensity of the highest energy band. These results imply that the middle band is mainly metal-based, the lowest energy band is primarily S_π^{+} with some additional Mo 4d or C 2p character, and the highest energy band is S_π^{-}. While the spectra of Tp*MoO(bdt) indicate large amounts of covalency between the Mo and S orbital interactions, the spectra of $Cp_2Mo(bdt)$ indicate essentially none.

An explanation for this difference in covalency between the d^1 and d^2 systems lies in previous structural studies of molybdenum complexes, which have shown that the fold angle of the dithiolate metallocycle along the S···S vector varies in a way that is dependent upon the occupation of the d orbital that is in the equatorial plane. A larger fold angle is observed as the occupation of the metal orbital decreases, which can be ascribed to a stabilizing interaction of the filled p orbitals on sulfur with the metal orbital in the equatorial plane upon bending, as illustrated schematically in Figure 5. Folding of the dithiolate ligand enables the S electron density

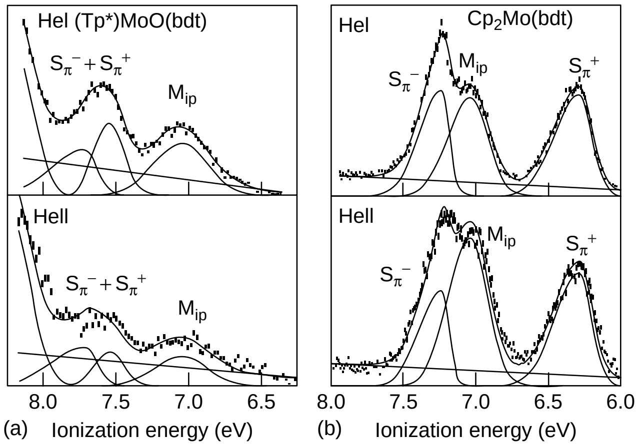

Figure 4 Comparison of the valence photoelectron spectra of (a) Tp*MoO(bdt) and (b) $Cp_2Mo(bdt)$ collected with HeI and HeII photon sources

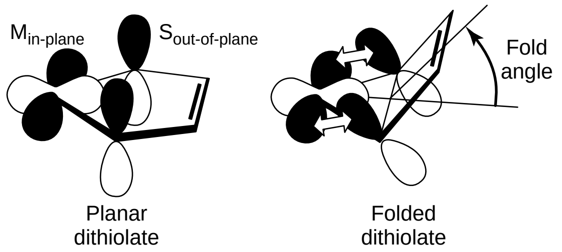

Figure 5 Schematic of metal–sulfur covalency that can occur upon dithiolate folding

to modulate the electron density in the equatorial plane of the metal and thus can play a very significant role in metal–sulfur anisotropic bonding. For the d^2 metal system $Cp_2Mo(bdt)$, the metal d orbital in the equatorial plane is fully occupied and the dithiolate metallocycle is essentially planar to avoid the filled–filled orbital interaction, with a fold angle in the solid state of 9.0°. For $(Tp^*)MoO(bdt)$, which has a formal d^1 electron configuration, the fold angle is intermediate at 21.3°, while for $(Tp^*)Mo(NO)(bdt)$, the fold angle is 41.1°. Although the metal center of $(Tp^*)Mo(NO)(bdt)$ is formally d^4, the strong π-acceptor character of the NO ligand results in an electron configuration in which the d orbital in the equatorial plane is empty.

The symmetric $S_{\pi}{}^{+}$ orbital has the right symmetry and energy to match the metal in-plane orbital upon folding of the dithiolate unit, and the substantial mixing of the out-of-plane $S_{\pi}{}^{+}$ orbitals and metal in-plane orbital upon folding is shown experimentally by the intensity changes observed in the HeI and HeII spectra of $(Tp^*)MoO(bdt)$. The S orbitals of dithiolate can therefore serve as an effective mechanism for the buffering of electron density at the metal center by either involving themselves in strong mixing with an empty metal orbital, or by localization of electron density on the S orbitals in the presence of a filled metal orbital. This ''dithiolate-folding-effect'' may be important in stabilizing the multiple oxidation states that result from the electron transfer or equatorial oxygen atom transfer (OAT) in pyranopterin Mo/W enzymes.

3.3 Photoelectron Spectroscopy of Porphyrins, Metalloporphyrins and Phthalocyanines

Porphyrins and metalloporphyrins have been studied extensively due to their importance in biology. The related phthalocyanine macrocycles are often considered for comparison to porphyrins and are also of interest because of their increased use in molecular electronic devices.[38] Much attention has been given to electronic structure calculations on porphyrins and metalloporphyrins,[39–41] and as discussed earlier, the quality of a computational method for describing the electronic wavefunction of any system can be judged by the method's ability to calculate accurate ionizations energies. Here we will specifically consider the experimental results that are referenced for theoretical calibration.

3.3.1 Analysis of Porphyrin and Metalloporphyrin Charge Potentials by XPS

XPS has been used extensively to analyze the donor ability of porphyrins and the charge potentials present throughout a metalloporphyrin molecule, particularly with regard to the electronic effects of substituents and changes at the central core. In a typical study, XPS is performed on a solid-phase sample of the molecule of interest that has been thinly distributed on a conductive substrate. The conductive substrate guarantees that the sample does not build up positive charge from the loss of photoelectrons, which can create difficulties with calibration. For XPS analysis, the sample can be deposited on the substrate by vacuum deposition to create a thin film, or can be simply spread and ground into a relatively soft substrate such as a gold foil. The core-ionization energies of the analyte are then internally calibrated to a core ionization of either the substrate or of a separate atom in the analyte.

The nitrogen 1s ionization energies that have been reported for tetraphenylporphyrin and various first row transition metal complexes of tetraphenylporphyrin are listed in Table 2. As can be seen, the values reported from different references for some of these molecules vary much more than the precision of ±0.1 eV that is typically reported for these measurements, so some care must be taken in comparing values from different papers. The overall shifts between molecules of these ligand-based core ionizations are also on the order of the precision of the measurements, so some caution must also be taken in their interpretation.

Table 2 Nitrogen core (1s) ionization energies for tpp complexes

Compound	N 1s (eV)	References
$tppH_2$	397.2, 399.1	42

Fe(tpp)Cl	398.6	42
$Fe(tpp)(pip)_2$	397.7	42
Mg(tpp)	397.8	45

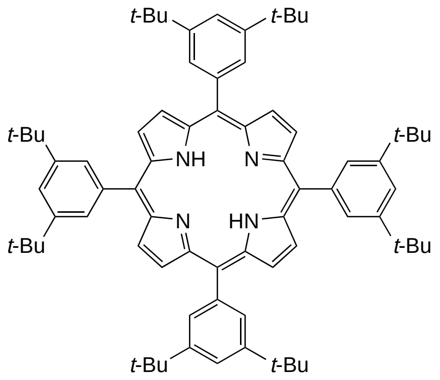
There are two distinct N 1s ionizations observed for free-base $tppH_2$, with the peak at lower ionization energy assigned to the two iminic (unprotonated) nitrogens and the peak at higher ionization energy assigned to the two pyrrolic (protonated) nitrogens. These two peaks are separated by about 2 eV, which indicates the lower charge potential at the pyrrolic nitrogens due to the presence of the protons. When the porphyrin is metallated the four nitrogens become equivalent, and the N 1s ionization energy is approximately the same as was observed for the iminic nitrogens in the free-base porphyrin. The N 1s ionization energy shifts when the central metal is varied, and this shift has been used as an indication that the charge potential at nitrogen is changing as the electronegativity of the metal varies. For example, the N 1s energies of M(tpp) are stabilized by 0.7 eV from Zn(II) to Ni(II).[45]

Core ionizations have also been used to analyze the electronic influence that substituents on the periphery of the porphyrin macrocycle have upon the donor ability of the central nitrogen atoms. Table 3 lists the N 1s ionization energies that have been reported for a series of substituted porphyrins, with the core levels of the unsubstituted porphine used for comparison.[47] The core ionizations of $oepH_2$ and $tppH_2$ are both destabilized from those of porphine, indicating the electron-donating nature of the ethyl and phenyl substituents in these common porphyrin ligands; the core ionizations indicate that tpp^{2-} should be a better donor than oep^{2-}. The core ionizations of tetraphenylporphyrins bearing electron withdrawing substituents on the phenyl rings, which have been of interest as a way of designing electron-poor porphyrins with bulky steric properties, are stabilized from those of $tppH_2$ to an extent that they are now similar to those of unsubstituted porphine.

The shifts of core ionization energies in bulk samples such as these just presented are typically interpreted in terms only of the molecular changes that influence the shifts. However, solid-state effects could also contribute to the experimental trends, particularly for molecules that have very strong intramolecular interactions in the solid phase. A recent paper[49] has addressed the possibility that the shifts that have been observed in the bulk phase XPS of porphyrins are actually due to solid-state packing effects rather than the inherent molecular electronic structure.

Table 3 Nitrogen core (1s) ionization energies for substituted porphyrins

Porphyrin	N 1s (eV)
porphine	398.1, 400.1
$oepH_2$	397.7, 399.8
$tppH_2$	397.4, 399.5
$TMeOPPH_2$	397.6, 399.7
TCl_2PPH_2	398.0, 400.05
$TCNPPH_2$	398.1, 400.2
TCF_3PPH_2	398.1, 400.2
TNO_2PPH_2	398.1, 400.2
TF_5PPH_2	398.2, 400.4



This study looked at the XPS of a series of metalloporphyrins for the sterically bulky phenyl-substituted porphyrin shown. The addition of the *tert*-butyl groups to the phenyl rings leads to large interplane distances between the porphyrin rings of about 7 Å in the crystal structures, meaning that there will be little electronic communication between neighboring molecules. The N 1s ionization energies of this free-base porphyrin were measured at 398.2 and 400.1 eV, essentially the same as those measured for $tppH_2$, although they would be expected to be destabilized by the addition of eight electron-donating *tert*-butyl substituents. When the N 1s energies are compared for different metal complexes of this bulky porphyrin, they are found to be effectively identical; that for the Zn(II) complex is 389.9 eV, for Cu(II) complex it is 399.0 eV, and for Ni(II) complex it is 399.0 eV. In comparison, the N 1s energies of M(tpp) have been reported to shift by 0.7 eV from Zn(II) to Ni(II) as mentioned above.[45] These results indicate that the degree of aggregation may have significant control over the relative core ionization energies of metalloporphyrins in the solid phase.

3.3.2 *Gas-phase Photoelectron Spectroscopy of Neutral Porphyrins*

Very few studies have been reported on the gas-phase photoelectron spectra of porphyrins, not due to lack of interest, but rather because acquisition of the spectra of these molecules is nontrivial with most spectrometers used for study of neutral molecules.

A molecular orbital treatment of the valence electronic structure of porphyrins indicates that the HOMO are two π orbitals that are close in energy to each other, but well separated in energy from all other occupied orbitals. The relative energy of these two orbitals is predicted to be dependent upon the substituents present. For metalloporphyrins, which are discussed in the next section, occupied metal orbitals may be in the same energy region as these ligand-based orbitals, and the specific metal or ancilliary

ligands will control exactly where the metal-based ionizations fall relative to the two porphyrin-based HOMOs.

As examples of the type of valence photoelectron spectra that are typical for these molecules, the gas-phase valence photoelectron spectra of oepH_2 and tppH_2 from 5 to 15 eV ionization energy are shown in Figure 6.[50] The ionizations located above about 10 eV for each compound arise from the removal of electrons from orbitals primarily associated with σ bonds and the most stable π bonds. The rather intense ionization at about 9 eV in the spectrum of tppH_2 is due to the π orbitals of the phenyl substituents that derive from the e_{1u} orbitals of benzene. The lowest energy set of ionizations, located between 6 and 7 eV for each of these molecules, has two distinct features that are characteristically a sharp first ionization, followed closely by a broad nondistinct ionization. As in the spectrum of simple pyrrole, the shape and intensity of the second ionization feature is dictated by vibronic coupling.[51] As mentioned, it is expected that two porphyrin π orbitals, which have labels a_u and b_{1u} in D_{2h} symmetry (a_{1u} and a_{2u}, respectively, in D_{4h} symmetry), should be separated from all of the other filled orbitals and close to each other in energy, giving rise to ^2A_u and $^2B_{1u}$ ion states that are also close to each other in energy. For comparison, the photoelectron spectrum of unsubstituted porphine has an ionization band at 6.9 eV that does not show two clear ionization features, because for porphine the ^2A_u and $^2B_{1u}$ ion states are essentially degenerate.[52] Addition of eight ethyl substituents in the β positions of the porphyrin pyrroles slightly separates the ^2A_u and $^2B_{1u}$ ion states due to hyperconjugative π interaction of the alkyl substituents. The a_u orbital has more electron density at the substituted sites than the b_{1u} orbital does, and the a_u orbital is therefore destabilized away from the b_{1u} orbital, causing the energy splitting seen in the photoelectron spectrum of oepH_2. The total destabilization of the ^2A_u state of oepH_2 from its position in unsubstituted porphine is about 0.7 eV.

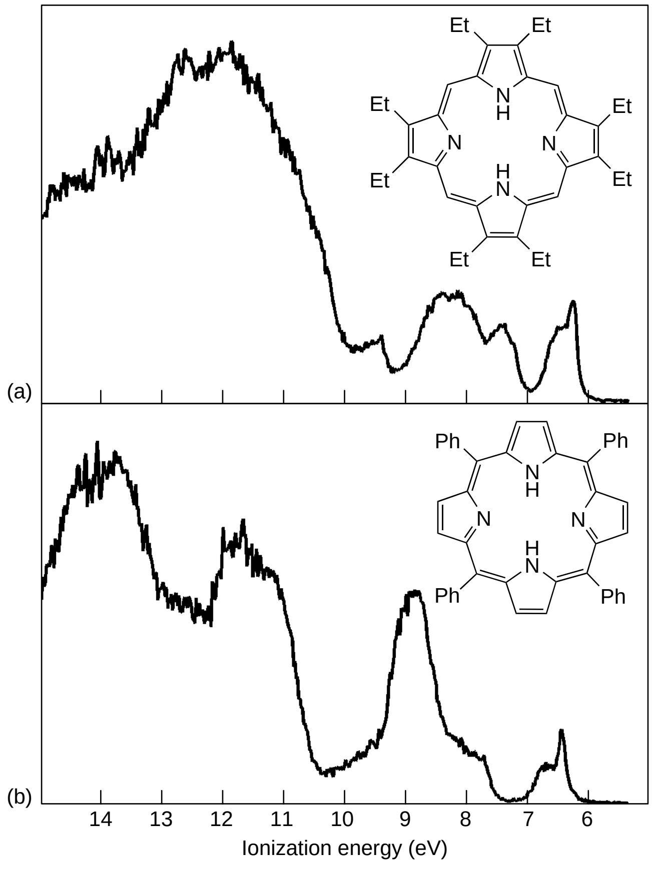


Figure 6 Valence photoelectron spectra of (a) oepH_2 and (b) tppH_2

The substituents in tppH_2 affect the relative energies of the ^2A_u and $^2B_{1u}$ ionizations in the opposite trend as the substituents in oepH_2. In tppH_2, the four electron-donating phenyl substituents are in the meso positions of the porphyrin; the a_u orbital has nodes passing through these positions, while the b_{1u} orbital has significant electron density at these positions and is destabilized relative to the a_u orbital. For tppH_2 the first ionization is then due to the $^2B_{1u}$ ionization, the opposite ordering observed for oepH_2. This assignment is also supported by the cross-sectional behavior of the ionizations with changing photon energy.[50]

A comparison of all of the ionization energies that have been reported for the ^2A_u and $^2B_{1u}$ ion states of oepH_2 and tppH_2 are listed in the Table 4. The two reports of tppH_2 are in good agreement, but the two studies of oepH_2 have given greatly different results. The paper that first reported a spectrum of oepH_2 also includes essentially identical spectra of several metalloporphyrins, raising the possibility of contamination of the samples during or between data collections. Cross contamination of samples in the vacuum chamber or decomposition are major concerns with gas-phase spectroscopy of neutral molecules. The latter report of the photoelectron spectrum of oepH_2 gives results that are fairly similar to spectra of etioporphyrin-I, -II, and -III, as would be expected for these similar octaalkylporphyrins.[52]

3.3.3 Photoelectron Spectroscopy of Metalloporphyrins

A question that is central to the chemistry of metalloporphyrin complexes concerns the energy of the metal-based ionizations and their relationship with respect to the porphyrin-based π ionizations. One example that

Table 4 Valence ionization energies for porphyrins

	Ionization energy (eV)		
Molecule	^2A_u ($^2A_{1u}$)	$^2B_{1u}$ ($^2A_{2u}$)	References
porphine	6.55		52

	6.39	6.83	53
tppH_2	6.70	6.43	50
	6.72	6.39	54

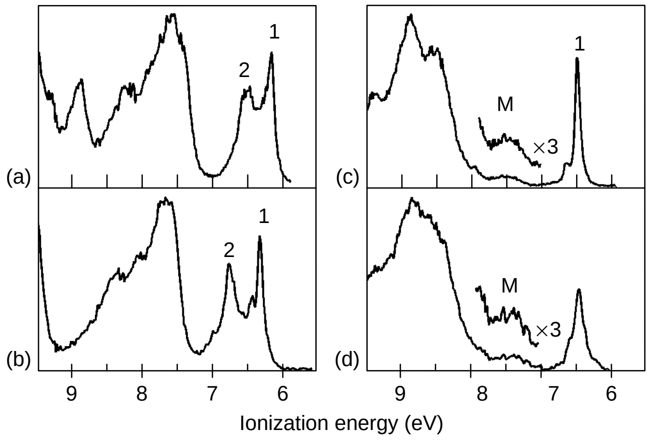

Figure 7 Valence photoelectron spectra of (a) Mg(oep), (b) VO(oep), (c) VO(pc) collected with HeI photons, and (d) VO(pc) collected with HeII photons. (Reprinted with permission from Westcott, Gruhn, Michelsen, Lichtenberger.[55] © 2000 American Chemical Society)

has been studied is VO(oep),[55] which is of interest due to its relationship to the reactive oxoiron(IV) porphyrinate intermediates in OAT. The spectrum of VO(oep) is compared to that of Mg(oep) in Figure 7. The assignment of the initial (6–7 eV) ionizations is straightforward for Mg(oep) because the porphyrin π electrons are the only low-valence electrons in this molecule. These ionizations shift slightly from 6.24 and 6.47 eV for oepH_2 to 6.16 and 6.52 eV for Mg(oep). For VO(oep), which should include an additional low energy ionization from the lone electron of the d^1 V(IV) metal center, the characteristic shapes of the two porphyrin-based ionizations are again observed. The similar relative intensities show that the two porphyrin π orbitals retain occupations of two electrons in the neutral molecule. The porphyrin-based ionizations of VO(oep) will be split into singlet and triplet states because of the unpaired V d electron, but the similar shapes of the ionizations in both spectra show that the spin-state splitting is less than the width of the ionizations and is not resolved in these spectra. Comparison of the ionizations of VO(oep) with those of oepH_2 and Mg(oep) show that the initial ionizations of VO(oep) do not correspond to removal of the single vanadium d electron from the d_{xy} orbital, and the specific location of this metal ionization is not apparent because of the porphyrin-based ionizations in this region.

To aid in locating the vanadyl d_{xy} ionization, the spectra of the related phthalocyanine complexes were also examined. Gas-phase spectra of Mg(pc) and other metallophthalocyanines have been reported.[56] The ionization of Mg(pc) that corresponds to band 2 of Mg(oep) is stabilized because of the extra nitrogen atoms of phthalocyanine, which opens a window of ionization energy to allow observation of other ionizations. The spectrum of VO(pc) is similar to that of Mg(pc), with band 1 located at 6.49 eV. Most significantly, the VO(pc) spectrum contains a broad ionization at 7.59 eV that is not seen in the spectrum of Mg(pc). The area of this ionization increases by 80% with respect to ionization 1 with HeII excitation, similar to the behavior observed for the vanadium-based ionizations of other vanadyl complexes. The band labeled M is therefore identified as the metal d_{xy} ionization. The HeII spectrum of VO(oep) suggests that the d_{xy} ionization of this molecule also is between 7.3 and 8 eV. However, because of the relatively low intensity of the d_{xy} ionization as seen for VO(pc) and because of the presence of other porphyrin π ionizations in this region, the d_{xy} ionization of VO(oep) cannot be clearly observed.

The observation that considerably less energy is required to remove electrons from filled orbitals than to remove an electron from a singly-occupied orbital indicates that the Aufbau Principle is being violated in these systems. Similar behavior has been observed for cobalt(II) and copper(II) phthalocyanines[56] and other metalloporphyrins with unpaired metal electrons.[53,54] Non-Aufbau electron configurations are occasionally invoked in theoretical calculations, but experimental observation of non-Aufbau behavior for transition metal molecules has been limited to the cases of porphyrins and phthalocyanines.

3.3.4 Multicharged Phthalocyanine Anions with Negative Ionization Energies

Only within the last few years has gas-phase photoelectron spectroscopy of multicharged anions been reported.[57] Electrons are bound in neutral molecules or stable anions by a coulombic potential, and due to coulombic repulsions few species with multiple negative charges are stable in the gas phase. Some of the first examples observed and studied by photoelectron spectroscopy were copper phthalocyanines that contain three or four negatively charged sulfonate ($-SO_3^-$) substituents.[58] Gas-phase ions of the molecules of interest were generated using electrospray from solutions of sodium salts of the anions; the gas-phase anions produced were then accumulated and stored in a quadrupole ion trap, separated by mass/charge ratio by a time-of-flight mass spectrometer, and then analyzed by photoelectron spectroscopy using photons of either 6.424 eV (193 nm wavelength) or 4.661 eV (266 nm wavelength).

The photoelectron spectra of $[CuPc(SO_3)_4]^{4-}$ (a, b) and $[CuPc(SO_3)_4]^{3-}$ (c, d) are shown in Figure 8. The negative charge of the molecules leads to a substantial decrease of ionization energy as compared to the neutral porphyrin and pthalocyanine molecules discussed in the previous section. Also, there is a further destabilization of the first ionization energy of $[CuPc(SO_3)_4]^{4-}$ as compared to $[CuPc(SO_3)_4]^{3-}$ as the negative charge on the anion increases. Most surprisingly, the spectrum of $[CuPc(SO_3)_4]^{4-}$ shows that the lowest energy ionization band has a threshold energy of *−0.9 eV*, indicating that in the gas phase the tetra-anion is actually unstable with respect to loss of an electron. The fact that this species can indeed be isolated is due to a coulombic barrier. This barrier,

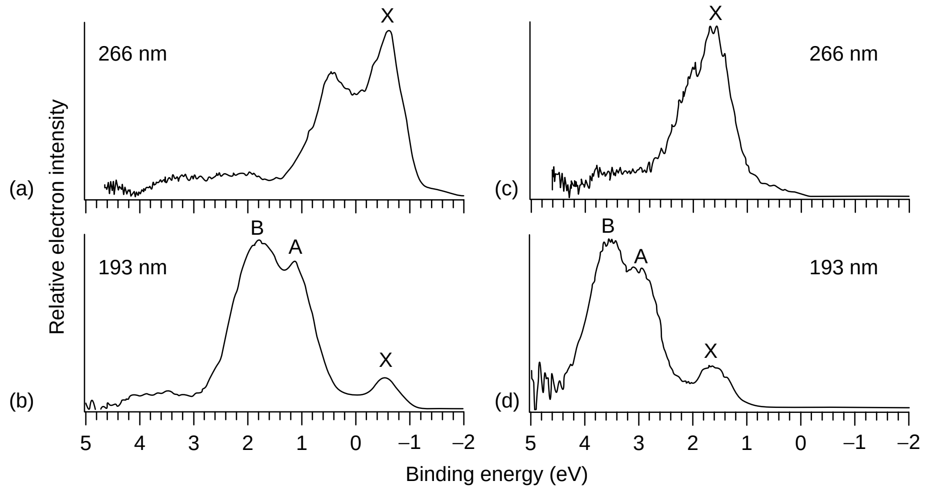

Figure 8 Photodetachment spectra of $[CuPc(SO_3)_4]^{4-}$ at (a) 266 nm and (b) 193 nm and of $[CuPc(SO_3)_4]^{3-}$ at (c) 266 nm and (d) 193 nm. (Reprinted by permission from Macmillan Publishers Ltd: *Nature*, Wang and Wang,[58] © 1999)

estimated to be 2.5 eV for the tri-anion and 3.5 eV for the tetra-anion species, is caused by long-range repulsive forces located at the exterior of the molecule that the electrons, even though energetically unstable for binding, must overcome if they are to be removed from the molecule. The unstable electron is essentially held in an electrostatic ''corral'' by the negative charges by which it is surrounded, until the photon provides the energy to overcome the barrier. If energy is not put into the system, this barrier is not overcome and the tetra-anion exists as a metastable species. The lifetime of this metastable species is at least as long as the 400 s for which the anions were stored in the quadrupole during the process of the experiment.

3.4 Measures of Inner-Sphere Reorganization Energies

Electron-transfer processes are key steps in a vast array of chemical and biological transformations. Ionization itself is an electron-transfer process. According to semiclassical theory, the rates of these reactions in solution are governed by three fundamental parameters: the reorganization energy, λ (where $\lambda = \lambda_i + \lambda_o$, the inner-sphere and outer-sphere contributions); the electronic coupling matrix element, H_{AB}; and the standard free energy change, ΔG^0. Both theoretical and experimental investigations suggest that the solvent contribution λ_o to the reorganization energy is much larger in most cases than the inner-sphere contribution (λ_i). It also has been shown that the ratio λ_o/λ_i decreases with decreasing solvent polarity. The limiting case is a reaction in the absence of bulk solvent, as occurs in the gas phase. Several recent papers have demonstrated that it is possible to obtain inner-sphere reorganization energies of isolated molecules from band-shape analyses of ionizations obtained by gas-phase photoelectron spectroscopy.[59–61] Compared to other experimental methods used to analyze reorganization energies, gas-phase photoelectron spectroscopy has the advantage of allowing direct measure of λ_i without contribution from λ_o.

The total inner-sphere self-exchange λ_i for a neutral molecule is the sum of the reorganization energy of the initial neutral molecule, λ^0, and the reorganization energy of the radical cation, $\lambda^{\bullet+}$. These energies are illustrated in Figure 9 in terms of a general distortion coordinate that prepares a molecule for electron transfer. If the distortions are sufficiently small that the transitions occur near the bottom of the potential wells, where the wells are essentially harmonic, λ^0 and $\lambda^{\bullet+}$ are similar in magnitude. Photoelectron spectroscopy of a neutral molecule directly measures the transition from state 1 to state 2 as the vertical ionization energy, and the width, vibrational structure, and contour of the ionization band give information on the distortion energy $\lambda^{\bullet+}$.[59]

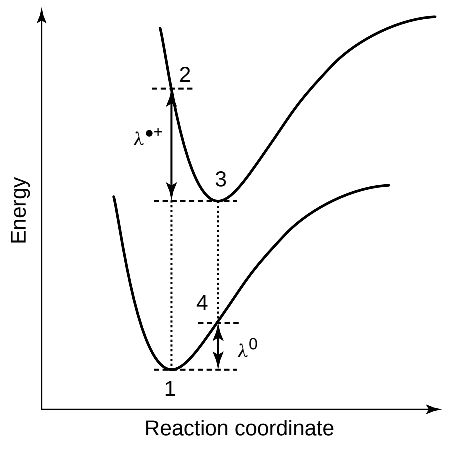

Figure 9 Potential energy surfaces for neutral and cation states that define λ^0 and $\lambda^{\bullet+}$

3.4.1 Reorganization Energies of Metalloporphyrins

As previously discussed, the first two ionizations of free-base porphyrins correspond to the two highest occupied π orbitals and are close in energy. If the second ionization is too close in energy to the first, it can obscure the profile associated with the lowest positive ion state. However, with the proper choice of porphyrin substituents and metal, these two ionizations are separated appropriately for band-shape analysis of the first ionization.

As an example, the portion of the photoelectron spectrum of Zn(oep) that contains the first two ionization bands is shown in Figure 10.[61] The Gaussian labeled A on the low binding energy side of the first main ionization is due to a hot band. The intensity of this Gaussian is consistent with the relative intensity expected from population of excited vibrational levels in the ground state of the molecule at the temperature at which the data were collected (280–320 °C). The vertical ionizations of the two π ionizations are associated with the two maxima on the overlapping band structure, which are modeled with the Guassians labeled 1 and 5. There is a splitting of about 0.4 eV between these two maxima, which leaves room for observation of the ionization intensity on the high binding energy side of the first ionization due to a partially resolved vibrational progression. This structure is modeled with the Gaussians labeled 2 and 3. The spacing of these Guassians is about 0.11 eV (≈900 cm^{-1}), which is in the energy region expected for vibrational modes associated with the C−C and C−N bonds of the porphyrin ring. Of course, this vibrational structure is most likely the result of many vibrational modes rather than one particular mode, but the regular spacing of the Guassians can be used to represent an average of many vibrational contributions by mode averaging.

The experimentally measured reorganization energy for formation of a radical cation, $\lambda^{\bullet+}$,

$$\lambda^{QM} = \sum_k h\upsilon_k S_k \tag{6}$$

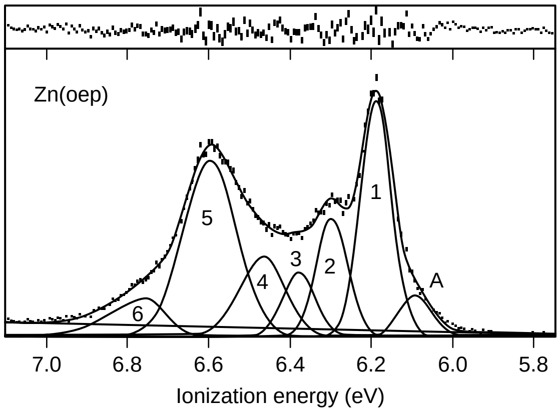

Figure 10 Photoelectron spectrum of Zn(oep) and residual of fit. (Reprinted with permission from Amashukeli, Gruhn, Lichtenberger, Winkler, Gray.[61] © 2004 American Chemical Society)

can be considered as the sum of λ^{QM} and λ^{SC}, the reorganization energies obtained from quantum-mechanical (QM) and semiclassical (SC) band-shape analyses of photoelectron data for the first ionization of a molecule.[59] QM analysis of any resolved vibrational fine structure in the ionization band yields distortion parameters (S), which are related to λ^{QM} according to equation (6) (h is Planck's constant and υ_k is the vibrational frequency of mode k). With the assumption that the geometry changes upon ionization are small enough that a harmonic oscillator model is appropriate, the intensities of the individual symmetric Gaussian bands in the vibrational progression can be considered to follow a Poisson distribution (where I_n is the intensity of the nth vibrational band) as shown in equation (7). For Zn(ppix) and Zn(oep),

$$I_n = \frac{S_n}{n!} e^{-S} \tag{7}$$

only the first two vibrational bands are well resolved, and the values of S are extracted from the ratio of I_1 to I_0. The fit of the data for Zn(oep) gives a value for λ^{QM} of 55 ± 3 meV.

Distortions along low-frequency modes and small frequency changes between the neutral and cation states, if present, contribute to the width of the vibrational lines in the photoelectron spectra after taking into account instrumental line broadening. Such band profiles can be treated semiclassically using equation (8), where IE is the ionization energy and D is related to the transition moment. The Gaussian functions used to fit the experimental spectra can be described

$$G = |D|^2 \exp \frac{-(h\nu - IE)^2}{4k_b t\lambda^{SC}} \tag{8}$$

as a convolution of G and another function defined by the resolution of the instrument. The Guassians used to model the band shape of Zn(oep) are quite narrow, and the value of λ^{SC} is fairly negligible (3 ± 2 meV) compared to the λ^{QM} value, showing that very low-frequency modes contribute very little to $\lambda^{\bullet+}$. Taken together, λ^{QM} and λ^{SC} indicate an overall $\lambda^{\bullet+}$ for Zn(oep) of 58 ± 3 meV, while the $\lambda^{\bullet+}$ reorganization energy for Zn(ppix) is about 10 meV greater.

The small values of $\lambda^{\bullet+}$ obtained for Zn(oep) and Zn(ppix) indicate that the assumption that λ^0 is approximately the same as $\lambda^{\bullet+}$ should be reasonably valid for these molecules. The self-exchange λ_i in the gas phase can then be experimentally estimated to be about 120 meV (Zn(oep)) to 140 meV (Zn(ppix)). For comparison to studies by other methods, an analysis of electron-transfer kinetics in Ru-Zn-cytochrome produced an estimated upper limit of 300 meV for the innter-sphere contribution to the Zn-porphyrin self-exchange reorganization energy. These photoelectron spectroscopy measurements indicate that this quantity is likely to be ≤ 120 meV, and that the outer-sphere contribution to the total reorganization energy in Ru-Zn-cytochrome is some 90 meV greater than the earlier estimate.

3.4.2 *Reorganization Energy of the Fe^{+2}–Fe^{+3} Redox Couple in Rebredoxin*

Negative-ion gas-phase photoelectron spectroscopy has also recently been used to evaluate the reorganization energies of tetrahedrally coordinated Fe^{+2} anions that serve as models for the active sites of mononuclear iron–sulfur proteins such as rubredoxin that cycles between high spin Fe^{+2} and high spin Fe^{+3}.[62,63]

The electronic structure of several model complexes for mononuclear iron proteins has been evaluated by gas-phase photodetachment photoelectron spectroscopy. Molecules of interest are negatively charged, such as $Fe(SCN)_3^-$, $Fe(SCN)_4^-$, and $Fe(SCN)_4^{2-}$. The anions were transported into the gas phase by electrospray ionization; isolated $Fe(SCN)_4^{2-}$ was not detected in the gas phase, but rather was trapped as the stabilized ion pair $Na^+[Fe(SCN)_4^{2-}]$.

The spectra of some of these molecules are shown in Figure 11. The spectra of each of these molecules shows a broad feature centered at around 6 eV, which for the Fe^{+3} and Sc^{+3} molecules is the lowest energy ionization feature. The spectrum of the d^0 Sc^{+3} complex serves as a reference to assign the Fe 3d and ligand ionizations in the spectra of the corresponding Fe complexes, and corroborates that the lowest energy ionizations for $Fe(SCN)_4^-$ are from ligand-based ionizations. For the Fe^{+2} molecules $Fe(SCN)_3^-$ and $Na^+[Fe(SCN)_4^{2-}]$, the spectra each contain a weak low ionization energy feature near 5 eV that is assigned to the Fe d ionization.

The lowest energy iron-based ionization of these and similar Fe^{+2} complexes are clearly observed in the photoelectron spectra, but the lack of distinct vibrational structure means that the quantum-mechanical method used to analyze reorganization energies for the porphyrins described earlier cannot be used. However, the difference between the vertical detachment energies (VDE) and adiabatic detachment energies (ADE) ionization energy can also be taken as an estimation of λ_{ox}. The VDE is measured directly from the peak maximum, while the ADE can be estimated by drawing a straight line along the leading edge of the threshold band and then adding a constant to the intersection with the energy axis to correct for experimental resolution and thermal broadening. In the case of large geometry changes (large reorganization energies), the adiabatic transition may not actually be observed in the photoelectron spectra, so the adiabatic values obtained by this method are upper limits.

The reorganization energies measured for Fe(II) molecules are shown in Table 5. There is a clear trend that λ_{ox} increases as the size of the molecule and number of vibrational modes increases. It is interesting to note that λ_{ox} for Na^+ $[Fe(S_2\text{-o-xyl})_2^{2-}]$ is significantly smaller than λ_{ox} for Na^+ $[Fe(SCN)_4^{2-}]$, most likely because the chelated ligands of $Fe(S_2\text{-o-xyl})_2^{2-}$ make the molecule more rigid. Also note that these reorganization energy values are significantly larger than those measured for Zn(oep) and Zn(ppix).

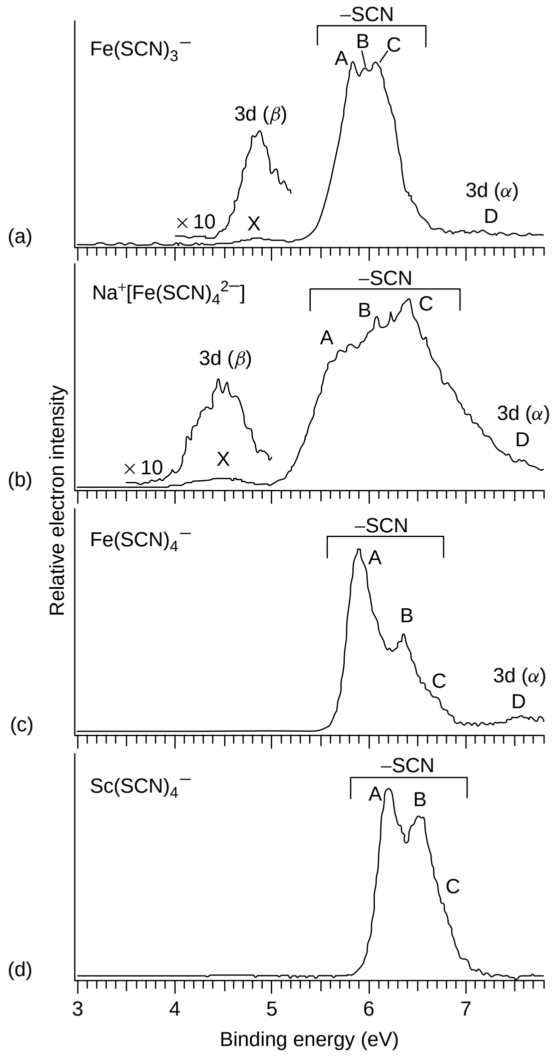

Figure 11 Photoelectron spectra of (a) $Fe(SCN)_3^-$, (b) $Na^+[Fe(SCN)_4^{2-}]$, (c) $Fe(SCN)_4^-$, and (d) $Sc(SCN)_4^-$ collected with a 157 nm laser. Note that the energy scale is reversed compared to all other spectra shown here. (Reprinted with permission from Yang, Wang, Fu, Wang.[62] © 2003 American Chemical Society)

4 CONCLUSION

Development of new photoionization methods and instrumentation, along with advances in supporting electronic structure calculations, have allowed photoelectron spectroscopy to be progressively applied to larger and more complicated chemical systems. The applications presented here are just a few examples of the uses of photoelectron spectroscopy to the study bioinorganic model complexes. Studies to this point have provided many unique and in several cases surprising insights into the electronic structure properties of metal active sites in biology. There is much promise for the future in a wide array of applications of photoelectron spectroscopy in this area.

Table 5 Adiabatic detachment energies (ADE), vertical detachment energies (VDE), and reorganization energies of Fe^{+2} complexes

Molecule	ADE (eV)	VDE (eV)	λ_{ox} (eV)
$FeCl_3^-$	4.10(6)	4.36(6)	0.26
$Fe(SCN)_3^-$	4.64(5)	4.96(8)	0.32
Na^+ $[Fe(SCN)_4{}^{2-}]$	4.12(5)	4.56(8)	0.44
$Fe(SCH_3)_3^-$	2.80(6)	3.08(5)	0.28
Na^+ $[Fe(S_2\text{-o-xyl})_2{}^{2-}]$	2.30(5)	2.60(5)	0.30

METHOD SUMMARY

Acronyms, Synonyms

- Solid-State luminescence, fluorescence, or phosphorescence.
- Electrogenerated chemiluminescence.

Measured physical quantities

- Photons of light emitted by the solid sample following creation of an excited state via irradiation (photoluminescence) or application of a potential (electroluminescence).

Information available

- direct measurement of bandgap energy
- presence of excitons, dopants, or point defects in the sample material
- indirect measurement of excited state lifetime.

Information not available, limitations

- The sample must be inherently luminescent to successfully utilize the technique.
- Sample morphology (differences in crystal structure between samples) is not provided.
- No structural information is provided.
- The exact nature of excitons, dopants, or point defects in the sample material may not be determined without additional techniques.

Examples of questions that can be answered

- What is the bandgap energy of this material?
- Does the addition of a dopant or introduction of point defects in the material alter the bandgap energy?
- What is the threshold voltage needed to produce luminescence?
- Will this material be suitable for the development of a photonic device (e.g., solid-state laser, light emitting diode, photovoltaic cell)?

Major advantages

- very sensitive when compared to other analytical methods
- large linear concentration range
- more selective when compared to other molecular spectroscopic methods.

Major disadvantages

- less applicable than other molecular spectroscopic methods since not all samples are inherently luminescent (or require extreme conditions to be luminescent);
- instrumentation more complicated than molecular absorption spectroscopy.

Sample constraints

- Luminescence may be quenched by other nonradiative processes, which can be minimized by cooling the sample.
- The irradiation angle and sample geometry can have a large effect on the observed spectrum.
- The application and conduction of voltage through the sample can have unanticipated effects.

1 INTRODUCTION

Emission spectroscopy has been used to study both atomic and molecular systems for the last 75 years. However, with the rise of materials science and surface chemistry there has been interest in studying the luminescent properties of such solid-state systems, as evidenced by the large number of publications in the 1960s and 1970s focusing on semiconductor luminescence. Recent interest in solid-state luminescence focuses on the usage of semiconductors for light sources and active lasing materials in solid-state lasers. When considering luminescence in semiconducting materials (a major focus of this article), many radiative transitions can be observed, as shown in Figure 1. These transitions focus on (i) direct band-band recombination of the electron and hole, (ii) luminescence from an exciton as described below, (iii) luminescence from a donor (identical to ii) or to an acceptor impurity, and (iv) direct donor-acceptor interaction.

The information obtained from solid-state luminescence is electronic in nature. The most common information available from such measurements revolves around excited-state energy levels. This parameter is particularly important in considering semiconductor materials, as this technique provides a direct measurement of the material bandgap energy (E_g). Furthermore, the presence of defects and/or dopants in the material can be observed through the presence of additional emission peaks. Excitation of the material into its excited state can be achieved via photolytic or electrolytic stimulation, thus providing ‘‘real world’’ conditions for the material, depending on its ultimate application (e.g. photodiode, light-emitting diode, etc.). Stability of the system in its excited state can also be indirectly assessed through the measurement of the emission lifetime (which directly relates to the lifetime of the excited state).

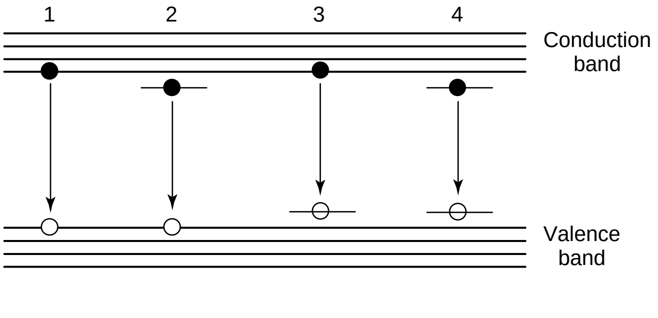

Figure 1 Typical transitions in semiconductors that produce luminescence (see text for details)

Since only the electronic levels of the sample are probed with this technique, many parameters of interest to the material cannot be directly assessed. For example, morphology or structural information of the material cannot be determined through luminescence measurements. In addition, the specific nature and location of the observed defects described above cannot be determined without more sophisticated luminescence microscopy measurements. Also, the material must be inherently luminescent to provide any useful information from this technique. This luminescence may not be visible at ambient temperatures, however; some sample cooling might be required to obtain usable data. With these limitations in mind, however, the solid-state luminescence technique has many benefits. Many of these advantages are also commonly profiled in molecular or atomic emission spectroscopy treatments.[1] Luminescence is one of the most sensitive of analytical techniques, with a large linear concentration range and very low limits of detection.

2 TECHNICAL BACKGROUND

2.1 Luminescence Instrumentation

If the researcher has commercial molecular luminescence instrumentation (e.g., a spectrofluorometer) available, then solid-state luminescence data should not be difficult to obtain. Many good references are available discussing the basic theory of luminescence,[1–3] so the focus herein will be on its use in solid-state applications. Instrumentation normally consists of an excitation source, excitation wavelength selector, sample compartment, emission wavelength selector, and detector. The largest issue for conducting measurements on

solid-state samples involves the sample presentation. While molecular luminescence spectrometers are typically designed with perpendicular excitation and emission beam paths to minimize light scatter at the detector, this geometry presents problems for a solid-state sample. Since the excitation source cannot pass through the sample (indeed, many such materials are opaque to light and perform such emission processes at or near the surface), it must be positioned at an angle to the excitation and emission light paths. As the obtained emission intensity is geometry dependent, care must be taken to utilize the same angle for all samples, should quantitative data be necessary (e.g., quantum yields). Alternately, the sample compartments of some commercial spectrophotometers already contain additional optics to allow the researcher to select an emission beampath either perpendicular (''right angle'') or only 10 to 15° offset (''front face'') from the excitation beampath. Any emission geometry, other than perpendicular, greatly increases the chance of excitation light reaching the detector. Therefore, judicious filtering is normally necessary to obtain relevant data.

Another issue to consider with sample presentation is temperature. Many materials are not luminescent at room temperature, due to other nonradiative processes precluding the luminescent radiative energy deactivation pathway. Since the population of energy levels that lead to nonradiative pathways is normally thermally dependent, lowering the sample temperature can eliminate these pathways and, in essence, ''turn-on'' sample luminescence. Sample cooling is typically conducted in commercial optical cryostats that provide transparent windows to the observed luminescence, either to liquid nitrogen (77 K) or helium (4 K) temperatures. Such cryostats can be wired with electrical pass-through leads to facilitate electro-generated luminescence as well. Furthermore, studies can be performed on samples under the influence of a magnetic field. This experiment will allow the degeneracy of any electronic levels involved in the emission to be lifted (the Zeeman effect), thus altering the observed spectrum.[4–6] For materials studies, this measurement can provide some structural information with respect to the presence of defect centers. Cooling can be performed through immersion in or evaporation of the cryogen. The former method provides better electrical insulation, should high voltages be needed for the experiment, but cavitation from the cryogen can lead to poor spectral resolution.

2.2 Luminescence Measurements

As with other molecular luminescence measurements, three methods of recording spectra are normally used. In *emission spectra*, the excitation wavelength is held constant while the emission wavelength is swept during data acquisition. This spectrum shows the wavelengths where the sample emits light, and is commonly reported in the chemical literature when luminescence is reported. However, to obtain the complete spectral waveform *excitation spectra* are also recorded. In these measurements, the emission wavelength is held constant while the excitation wavelength is swept during data acquisition. The resulting spectrum shows what wavelengths of light produce the emission observed in the first measurement. Normally, this spectrum will correspond to any available absorption spectrum of the material, after taking instrumentation differences into account. Agreement of these two spectra can confirm that the absorption and emission transitions are directly related. The presence of additional bands in the excitation spectrum indicates the presence of some mediary in the energy manifold between excitation and emission (e.g., a defect in the material).[3] Lastly, *synchronous spectra* scan both the excitation and emission wavelengths (normally with a small offset to prevent significant scattering interference) during data acquisition. This technique is utilized more for the measurement of scattering phenomena, although the presence of significant peaks can indicate extreme heterogeneity in the material sample (e.g., presence of aggregated clumps of material on the surface). This technique is also referred to as *resonance light scattering*.[7–9] Commercial spectrophotometers typically have instrumentation profiles to perform all three experiments.

Luminescence of materials can normally be considered under two broad categories: semiconductor materials and point defects in insulating materials. Examination of the latter can be analyzed and interpreted using methodologies adopted for solution-based molecular luminescence.[1] For semiconducting materials (the major focus of this discussion), the groundbreaking work of Van Roosebroek and Shockley[10] determined that band–band recombination (path 1 in Figure 1) can be described based on its lifetime (τ_{BB}) and spectral bandshape ($I(\omega)$), as shown in equations (1) and (2):

$$\tau_{BB} = C\mathrm{e}^{\frac{E_g}{k_B T}} \tag{1}$$

$$I(\omega) = C'\alpha(\omega)\mathrm{e}^{\frac{\hbar\omega}{k_B T}} \tag{2}$$

where ω is angular frequency and T is the temperature. The presence of the absorption constant $\alpha(\omega)$ indicates the direct connection between the absorptive and emissive properties of the material of interest. Also, the lifetime of the emission is directly tied to the magnitude of the bandgap.

Another common parameter measured in luminescence spectroscopy is the *quantum yield*. This value indicates the efficiency of the system to radiative decay and typically is the ratio of the emitted energy to the total energy imparted upon the system. There are various mathematical treatments to determine this value, many utilizing actinometer references.[1] However, a recent study by Palsson and Monkman[11] provides a methodology where the film is excited both directly and

through the use of a integrating sphere. Comparing the integration of these two spectra can provide a direct measurement of the quantum yield.

2.3 Observation of Excitons

As noted above, a primary piece of data obtained from solid-state luminescence spectra is the bandgap energy, observed as a single peak. However, a simple bandgap measurement can only occur if the material sample is relatively defect free and in a single phase. Should multiple phases or defects occur, isolated electronic states, or *excitons*, are likely to be observed. Exciton formation has been theorized and interpreted since the 1930s and is particularly common when mixed semiconductors or multiple-domain materials are examined. The presence of excitons in a sample produces a series of quantized emission peaks. The observed energies (E_n) based on quantum number n can be explained using effective mass theory, as shown in equations (3) and (4):

$$E_n = E_g - \frac{\mu^* e^4}{2\varepsilon^2 \hbar^2}\frac{1}{n^2} + \frac{\hbar^2 k_B^2}{2(m_e^* + m_h^*)} \qquad (3)$$

$$\frac{1}{\mu^*} = \frac{1}{m_e^*} + \frac{1}{m_h^*} \qquad (4)$$

where m_e^* is effective mass of electron, m_h^* is effective mass of electron hole, ε is the dielectric constant of sample, e is elementary charge, k_B is the Boltzmann constant, h is the Planck constant and $\hbar$ is the Planck constant/2π. Based on the composition of the material, several emission progressions can be observed in a single measurement. In addition, should the defect concentration or illumination intensity become high, *excitons* can interact and form biexcitons, which readily lead to the observance of nonlinear optical properties.[12,13]

Should a system contain donor and acceptor moieties, an exciton like behavior can be observed when the charges recombine. Again, effective mass theory can present us with the energy of the observed transition, as shown in equation (5):

$$h\upsilon = E_g - (E_D + E_A) + \frac{e^2}{\varepsilon R} \qquad (5)$$

where E_D is ionization energy of donor in semiconductor, E_A is ionization energy of acceptor in semiconductor and R is distance between donor and acceptor in semiconductor. Application of this equation can produce distances between donor and acceptor sites within the material lattice (R). Indeed, energy transfer can commonly be observed between donor and acceptor moieties. Parameters controlling the observation of such transfer include the separation in space of the involved centers and the energetic separation of their energy levels. Since the probability of energy transfer decreases with the sixth power of the distance between the two centers (Förster energy transfer), the distribution of the donor and acceptor defects in the material is crucial.

2.4 Deep Level Centers and Site-Selection Spectroscopy

In addition to excitons, ‘‘deep level’’ centers can be observed in the system, especially if lanthanide or transition metal ions are present in the material. These centers occur at a localized state removed from the fundamental band gap of the material. Observation of these centers can provide information pertaining to the electronic structure of defects present in the material, vibronic states associated with the ion in question, and/or the existence of energy transfer within the material. Observation of these centers can be obtained with *site-selection spectroscopy*, where only a specific moiety of the material is probed. This technique is particularly useful if the deep center has a particularly weak emission that is normally overpowered by the bulk material. A system that takes advantage of this process needs a defect center with excitation and emission energies slightly lower than the corresponding bulk material energies. Assuming that the excitation waveform is sufficiently narrow, the bulk and defect can be selectively probed, producing emission spectra exclusively exhibiting the system components in question. This technique has been successfully utilized to probe Mn^{2+} defect sites in ZnS semiconductor crystals.[14,15]

2.5 Electroluminescence Measurements

As noted previously, electroluminescence can be performed using commercial spectrophotometers provided the researcher has the necessary instrumentation to provide an electric bias to the material sample. The most reliable means for obtaining these data is through thin film electroluminescence, where the material is placed between two electrodes. This sample geometry reduces problems caused by electrical diffusivity in the material. At least one of these electrodes must be optically transparent to provide for the emission of visible light (typically indium tin oxide, ITO). The layering of multiple materials with varying electrical properties will ultimately lead to increased luminescence intensity and duration (*vide infra*). The electric bias can be either constant or pulsed, with each producing different electronic effects and light intensities. In addition to the spectra measured previously, the major parameter of interest is the *turn-on voltage*, or the bias necessary to obtain an observable emission. Typically materials exhibit a reasonably linear voltage/emission intensity relation. However, extremely high biases will lead to dielectric breakdown between the electrodes and deformation of the material. Also commonly reported is the effective lifetime of the observed emission at a given bias. Naturally, the observed emission lifetime exhibits an inverse relation to the applied bias, so a balance between emission intensity, lifetime, and applied bias must be determined.

3 APPLICATIONS

3.1 Temperature Dependence of Emission

One study performed by Omary and Patterson[16] observed luminescence as a function of temperature. The particular system is a thallium–silver complex, $Tl[Ag(CN)_2]$, that demonstrates interesting behavior over a range of temperatures. Upon heating, the wavelength of maximum emission undergoes a slight redshift as the temperature is raised. This is not surprising, but the intensity of the luminescence is. As the temperature is raised from 10 to 76 K, the band intensity increases (Figure 2a). However, as the system is heated from 76 to 195 K, the intensity drops dramatically, with no observable luminescence at room temperature (Figure 2b). By utilizing site selection spectroscopy (*vide supra*), the authors successfully probed the different transitions associated with the thallium centers.

Another study relating emission intensity to temperature was performed by Assefa *et al.*[17] The system under examination involves Eu^{3+} and gold and silver cyanide complexes. This study is similar to that of Omary[16] in that the intensity of the emission from [EuAu] decreases as temperature increases from 10 to 150 K. In contrast, the opposite is observed with [EuAg]; the intensity increases as temperature increases from 78 to 200 K. This study also demonstrates the excited state energy transfer from donor $Au(CN)_2^-$ and $Ag(CN)_2^-$ to acceptor Eu^{3+} ions.

3.2 Light-Emitting Diodes

Perhaps the most promising application of solid-state luminescence, and certainly recognizable by the general public, is the area of light emitting diodes (LEDs). Numerous articles are available regarding this application, depending on the specific type or function of concern. DenBaars[18] provides a detailed review of LED materials and their general emission properties. Table 1 summarizes various properties of some commercially available inorganic LED materials. The review also provides information on data calculation and manipulation, describing equations for radiative and nonradiative recombination rates, internal quantum efficiencies, and electron-to-hole injection ratios. The author also explains various methods to construct the material and device of choice, and gives a description of the process of injection luminescence and other physical properties of LEDs.

Thin film electroluminescent (TFEL) materials are similar to LEDs, in that they are completely solid-state materials. The difference lies in the application of charge and a higher level of defects. Therefore, TFEL devices require a much higher electrical field than the injection electroluminescence observed in LEDs. However, devices in this category typically possess the possibility of multicolor emission. Mach[19] provides a review similar to that of DenBaars[18] on the application, construction, and properties of various materials in this application.

A good example of the concomitant study of photoluminescence and electroluminescence in a materials study involves the blue emission observed from siloles as reported by Tang *et al.*[20] The photoluminescence (Figure 3) and electroluminescence (Figure 4) of the thin films were compared, and similar emission profiles were noted. Current-voltage-brightness curves are presented, illustrating the typical correlation between the current density and brightness. Band gaps of these materials were determined using the luminescence data to be around 3 eV, slightly lower than their acyclic cousin.

Composite materials have been examined for LED work with the intention of producing dual emission as described above. A recent study by Ding *et al.*[21] blended a violet–blue emitting polymer with a green emitting polymer in a single device. A comparison of the absorption and emission of the blends both in solution and in the solid-state was presented. Although the weight ratios of the blends were varied, the authors noticed only the green emission of the blends. Their conclusion was that this suggested a Förster energy transfer in the double layer LEDs instead of their independent operation. They also noted a decrease in

Table 1 Standard LED materials. (Adapted from DenBaars.[18] With kind permission of Springer Science & Business Media)

Material	Color range	Peak emission (nm)	Luminous efficiency (lm W^{-1})	External quantum efficiency (%)	Growth technique	Device type

the turn-on voltage and an increase in efficiency when p-phenylenevinylene (PPV) and polyethylene dioxythiophene (PEDOT) were used as hole-transport layers (common materials utilized in multilayer devices to improve electron and hole mobility).

3.3 Other Luminescence Application Examples

Many materials are designed to luminesce when exposed to relatively low-energy radiation, such as visible, ultraviolet, or possibly infrared light. A recent report by Issler and Torardi[22] focuses on inorganic phosphors specifically designed to luminesce when exposed to higher energy X-ray radiation (in particular, X-rays in the 15–100 keV range). These measurements obviously require certain instrumental precautions beyond those necessary for typical luminescence measurements. The films studied show strong absorption in the X-ray region and high emission efficiency in the visible region. These materials will likely play an important role in medical imaging.

Up-conversion and down-conversion luminescence, scintillator materials, and photonic crystals are other topics of recent interest.[23] Up-conversion is the ability of a material to convert low-energy excitation light into higher energy

emission light due to multiple energy transfer processes (as shown in Figure 5).[24] One necessary characteristic of these materials is the existence of multiple long-lived ($>10^{-6}$ s) excited states. Previous systems focused on trivalent lanthanide systems due to their multiple long-lived excited states. However, several instances involving transition metal systems have been reported. One such system incorporates Re^{4+} into a Cs_2ZrCl_6 matrix to convert near-IR radiation into intense visible light.[24] Another up-conversion example uses Yb^{3+} doped $RbMnCl_3$ to obtain orange luminescence upon excitation with near-IR radiation.[25] The system is not ideal, however, as the up-conversion is only viable at low (10 K) temperatures. The system utilizes Yb^{3+} to absorb radiation in the near-infrared region to ultimately produce Mn^{2+} emission in the visible region.

Down-conversion is another useful technique that has applications in lighting and plasma flat panel displays. The process involves the input of a vacuum ultraviolet photon and the output of multiple visible photons. This down-conversion was recently reported with Eu^{3+} doped $LiGdF_4$.[26] Upon absorption of a high-energy photon by Gd^{3+}, two visible photons were emitted through an energy transfer between Eu^{3+} and Gd^{3+} with a quantum efficiency near 200%. This research has an environmentally interesting application as an alternative to mercury-vapor lamps.

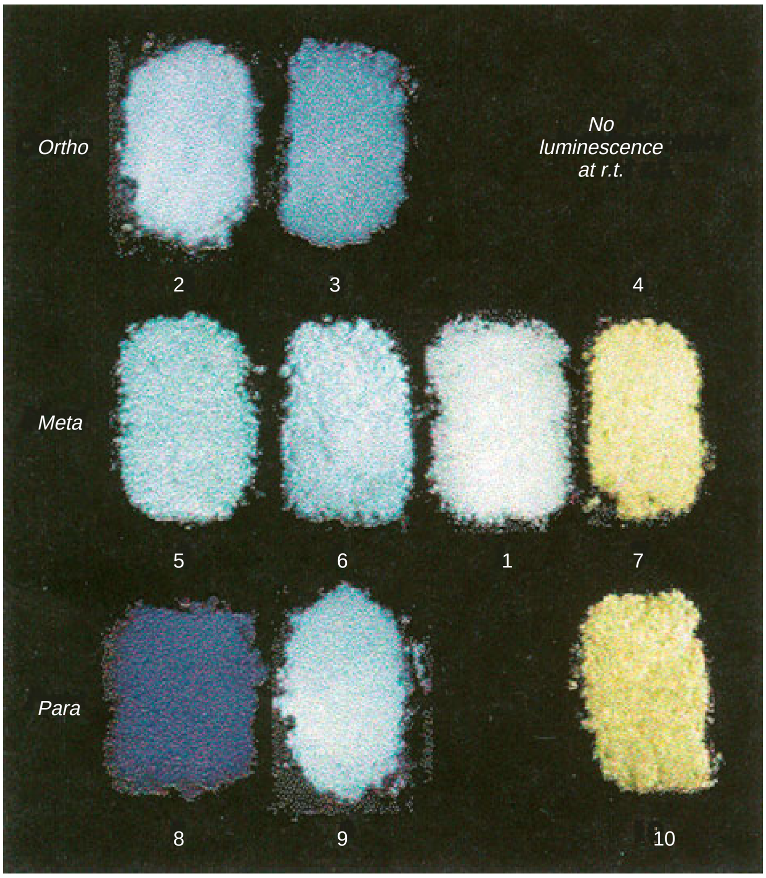

Figure 6 Gold(I) benzenethiolate complexes exhibiting room temperature luminescence. (Adapted from Watase, Nakamota, Kitamura, Kanehisa, Kai and Yanagida.[28] Reproduced by permission of The Royal Society of Chemistry)

Scintillator materials have been used for many years as a way to detect high-energy radiation (X- and γ-rays). Due to the nature of the application of these materials, the selection criteria are very strict, requiring high conversion efficiencies. These systems have historically been limited to Tl^{+}-doped NaI and CsI, until recent advances using Ce^{3+}-doped chloride and bromide systems.[23] As with the previously mentioned Issler study,[22] high-energy radiation is converted to visible light. However, instead of using phosphors, $LaBr_3$ is doped with a small percent (0.5%) of Ce^{3+}.[27]

Although many solid-state systems require cooling to make luminescence feasible (*vide supra*), Watase *et al.*[28] provide an example of a system that exhibits luminescence at room temperature. The system is a series of gold(I) benzenethiolate complexes that reportedly emit light from 450 to 530 nm. The excited states that produce the luminescence are suggested to be caused by metal-to-ligand charge-transfer or ligand-centered transitions. Figure 6 is a photograph of the complexes studied when excited by a xenon lamp.

4 ABBREVIATIONS AND ACRONYMS

CVD = chemical vapor deposition; DH = double heterostructure; H = homojunction device; ITO = indium tin oxide; LEDs = light emitting diodes; LPE = liquid phase epitaxy; MBE = molecular beam epitaxy; MOCVD = metal organic chemical vapor deposition; PPV = p-phenylenevinylene; PEDOT = polyethylene dioxythiophene; TFEL = Thin film electroluminescent; VPE = vapor phase epitaxy.

METHOD SUMMARY

Acronyms, Synonyms

- Rapid-Scan Stopped-Flow Kinetics
- Rapid-Mixing
- Stopped-Flow

Measured physical quantities

- Changes in absorbance, fluorescence, circular dichroism, light scattering, or luminescence, as a function of time after mixing

Information available

- Time course at a single wavelength and time-resolved spectra
- Kinetic parameters (e.g. the observed rate constants (k_{obs}))
- Activation parameters (e.g. the activation enthalpies and entropies)
- The possible pathway of reactions.

Information not available, limitations

- It is difficult to obtain the true spectra of the isolated intermediate.

Examples of questions that can be answered

- What are the values of rate constants for ligand binding and ligand dissociation?
- Are there any intermediates formed during a reaction?
- How do factors such as temperature, pH, or concentration affect the rate constant?
- Does the binding reaction constitute a one- or two-step mechanism?

Major advantages

- Obtains the kinetics of fast reactions (e.g. k_{on} and k_{off} for ligand substitution)
- Detects and characterizes reaction intermediates
- Defines reaction pathways and proposes a kinetic model
- Provides thermodynamic insight into rapid reactions
- Has lower sample consumption compared with continuous-flow techniques
- Is able to couple with a wide range of detection modes.

Major disadvantages

- Reactions completed within the dead time of stopped-flow instruments cannot be measured; dead times are on the order of milliseconds for conventional instruments but can be somewhat shorter if special mixers are used.
- It requires the availability of optical signals to monitor changes (in conventional instruments).

Sample constraints

- Samples must be in solution
- Reactions must produce detectable signal changes.

1 INTRODUCTION

In order to elucidate the mechanism of any reaction, be it chemical or biochemical, a binding process, or a macromolecular conformational change, we need to determine the time-dependent evolution of the molecular species involved. Kinetic techniques fall into two broad categories, equilibrium, and relaxation methods. Equilibrium methods extract rate information without physically or chemically perturbing a system, for example, by measuring dynamic effects on the spectral line shape (optical, electron paramagnetic resonance (EPR) or nuclear magnetic resonance (NMR)), or by observing molecular fluctuations. Relaxation techniques generally rely on a rapid change of an extrinsic variable (e.g. temperature, pressure or solvent composition) to perturb the system and follow its response as it evolves toward a new equilibrium position. Rapid mixing of two (or more) solutions is an example of a relaxation method.

Rapid-mixing techniques play a particularly prominent role in kinetic studies of fast reactions. In 1923, Hartridge and Roughton developed the first rapid-mixing kinetic techniques to follow chemical and biochemical reactions.[1] Chance introduced the stopped-flow (SF) modification in 1940.[2] Since then it has undergone extensive modification by Chance, Gibson, and others. Occasionally stopped-flow has been used to follow anaerobic reactions. This necessitates the development of deoxygenating systems that are suited to adaptation to rapid-mixing techniques.

In the past, mainly as a consequence of the advances in computer technology, instrumentation for kinetic investigations has improved dramatically. For example, a stopped-flow unit in the late eighties consisted of a large number of different parts, which included the syringe system, a lamp together with a monochromator, an oscilloscope for viewing the data, and a transient recorder for collecting the data and for their transfer to a computer for data fitting. Many problems occurred during these measurements and they were time consuming because programs for analyzing the data were still slow once absorbance versus time traces that could not be fitted to a single exponential function were observed. Furthermore, only measurements at single wavelengths were possible, therefore making it often necessary to repeat the analysis at different wavelengths.

Today a stopped-flow instrument consists of only the unit itself combined with a diode array detector and a computer allowing fast kinetic measurements of time-resolved UV–vis spectra under anaerobic, high pressure and/or low temperature conditions. Improvements have been made as well, for example, syringes are installed vertically instead of horizontally (to avoid problems with gas bubbles) and polyetheretherketone (PEEK) is used instead of Teflon for valves and flow tubes to improve the anaerobic capabilities of the instrument. Further, the syringe drives setup was optimized. Application of ''rapid-scan'' devices (usually, but not exclusively, diode arrays) allows complete spectra to be collected at very short time intervals during a reaction.

Extreme experimental conditions (low temperature and high pressure) have been successfully applied to rapid kinetic analysis. High-pressure techniques have been recognized to be very important for the elucidation of chemical reaction mechanisms. Since a high-pressure stopped-flow apparatus was first reported in the 1980s, a slightly modified apparatus was constructed by several researchers. Low-temperature stopped-flow methods together with diode array instrumentation have become extremely useful for studying reactions that are too fast at ambient temperatures and/or for detecting reactive intermediates that can only be observed at low temperatures. For example, the low-temperature stopped-flow kinetic method is an approach used successfully in copper-dioxygen chemistry.[3,4]

Stopped-flow, one of the most frequently used rapid kinetics techniques, is a simple and elegant technique for monitoring reaction kinetics in solution. Examples include ligand substitution, binding reactions, organic and inorganic oxidation and reduction reactions, proton exchange, metal–ligand complex formation, and surfactant aggregation to form micelles.

In general, stopped-flow methods provide a reasonably inexpensive means of determining a large number of fairly fast reactions. Stopped-flow mixing is usually coupled with real-time optical observation using absorbance (UV through IR; *see*, ***Vibrational Spectroscopy***), fluorescence emission, or circular dichroism (CD) spectroscopy. In addition, the stopped-flow technique has been implemented in conjunction with many other biophysical techniques, such as EPR, NMR (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy***

of Inorganic/Organometallic Molecules, ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Metallobiomolecules***), and small-angle X-ray scattering. A number of commercial stopped-flow instruments are now available that provide fast reaction analysis capability. Examples include instruments from Applied Photophysics Ltd. (Leatherhead, UK), Bio-Logic-Science Instruments SA (Claix, France), Hi-Tech Scientific (Salisbury, UK), and Olis Incorporated (Bogart, GA, USA).

2 TECHNICAL BACKGROUND

2.1 Features of the Basic Instrument

Stopped-flow methods constitute commonly used tools for investigation of mechanisms of molecular kinetic processes in the time range from milliseconds to hundreds of seconds. In stopped-flow experiments, two or more reactants are expelled from a set of pneumatically or stepper motor-driven syringes. The reactant solutions meet in a mixer where the reaction is initiated. The fresh reaction mixture is rapidly transferred into an observation cell while the previous contents of the cell are flushed out. Then the liquid flow is stopped by a stopping syringe or a valve at the exit of the cell. The kinetics are monitored by recording an optical signal (e.g. absorbance, fluorescence, or CD) as a function of time. The most common mixing options for stopped-flow include single mixing and multi mixing (also known as *double mixing* or *sequential mixing*) where more than two solutions are mixed together. This is schematically illustrated in Figure 1.

2.2 Data Collection by Stopped-flow Methods

Data acquisition in the stopped-flow mode requires rapid sampling of the signal at intervals shorter than the dead time. Data associated with monitoring a molecular process to completion comprise a progress curve. An analysis of the progress curves for a second-order reaction, in terms of rate constants of the underlying molecular processes, is generally not simple because usually the observed reaction starts far from the final equilibrium state and the kinetic equations cannot be linearized. Therefore the solution is not just a simple exponential function (or a sum of such functions) except under special conditions called pseudo-first-order reactions, when one reactant is greatly in excess over the other reactant. Therefore kinetic studies are most commonly carried out under pseudo-first-order conditions.

Kinetic traces acquired under pseudo-first-order conditions can be fitted to exponential functions, and the observed rate constants, k_{obs}, can be calculated. The second-order rate constants can be obtained from the slopes of the linear plots of k_{obs} versus [ligand] (e.g. the ligand-binding reactions). The activation parameters can be determined through a systematic variation of temperature and pressure. The activation enthalpies and entropies, $\Delta H^{\neq}$ and $\Delta S^{\neq}$, are calculated using the Eyring equation (1), and the volumes of activation, $\Delta V^{\neq}$, calculated from the slope of $\ln k_{obs}$ versus pressure (under certain conditions).

The Eyring equation is

$$k = \frac{k_B T}{h} \exp\left(\frac{-\Delta G^{\neq}}{RT}\right) \quad (1)$$

where R is the gas constant, k_B is the Boltzmann constant, h is the Planck's constant, k is rate constant, and T is absolute temperature.

For the stopped-flow spectroscopy method, one can monitor the kinetics of a reaction by capturing and analyzing time courses at a single wavelength using a photomultiplier as detector. In contrast to this a diode array detector can register simultaneously absorbance changes at a large number of wavelengths. This feature is valuable when a complex

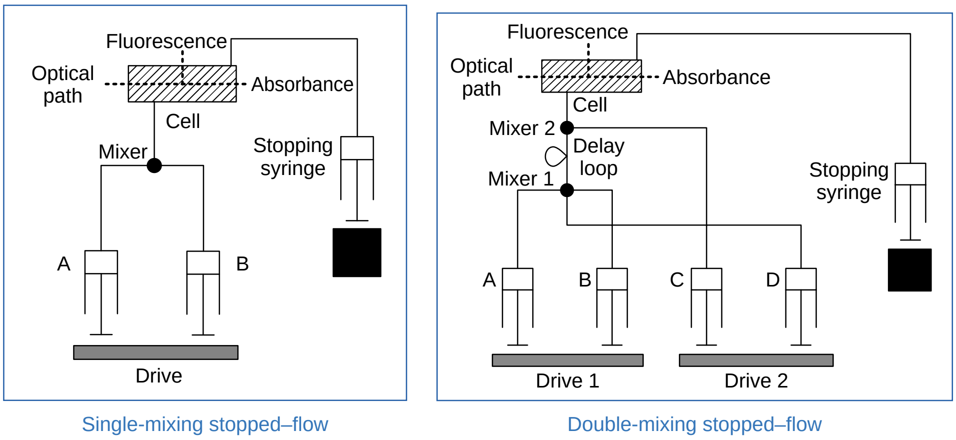

Figure 1 Schematic diagram of stopped-flow single-mixing (a) and double mixing (b). (Adapted from a diagram downloaded from http://www.hitech-inc.com)

reaction, involving a number of spectral species, is to be analyzed. The data set generated by a single rapid-scan experiment is large. Analysis of these data uses matrix algebra methods to filter signal from noise and to assess the number of linearly independent spectral components, which contribute to the total spectral change accompanying the reaction, and to extract the spectra and their time courses. Inherent to these methods is great data compression, thus permitting economic and efficient data storage. Once the number of components and their time courses are known, global analysis of the data allows one to fit the kinetic process to a chemical model by solving the differential equations which describe it. By so doing, not only can the rate constants be extracted but also the spectra of any intermediates (model-dependent) on the reaction pathway. These analytical techniques are powerful and easy to implement. However, they can mislead and it is important to retain one's chemical/biochemical common sense when examining the output.

2.3 Dead Time of a Stopped-flow Instrument

The interpretation of stopped-flow data requires a careful calibration of the instrumental dead time by measuring a pseudo-first-order reaction tuned to the time scale of interest (i.e. a single-exponential process with a rate constant approaching the expected dead time) and an optical signal matching the application. The dead time of a stopped-flow instrument is the time that elapses between mixing and observation, and is usually determined by employing a pseudo first-order reaction of 2,6-dichlorophenolindophenol (DCPIP) with ascorbic acid. Commercial instruments can routinely reach dead times of a few milliseconds. Recent improvements in mixer and flow-cell design by several manufacturers of stopped-flow instruments resulted in dead times well under 1 ms. The upper end of the time scale that can be reliably measured in a stopped-flow experiment is determined by the stability of the mixture in the flow cell, which is limited by convective flow or diffusion of reagents in and out of the observation volume.

2.4 Samples for a Conventional Stopped-flow Instrument

Because stopped-flow techniques are widely used with optical detection, samples should be prepared in solution and produce detectable signal changes after mixing into the cell. In some situations, if the reaction of some samples is very rapid and complete within the dead time of the stopped-flow instruments, the majority and indeed the entire kinetic time course may be lost. Selected adjustment of concentration, solution conditions, temperature, and so on, may be able to slow the reaction into an accessible time range, but this is not always possible or desirable. Such systems are not amenable to the stopped-flow technique. In general, other techniques will have to be used, and these will be dependent on the availability of a signal for monitoring of the reaction.

3 APPLICATIONS

The goal of a comprehensive kinetic analysis is to identify each step in the reaction pathway, define the rate and equilibrium constants for each step, identify all conformational and chemical intermediates, identify the rate-limiting steps, and ultimately establish the basis for mechanisms. Various techniques are needed to attain this goal. In this section, applications of stopped-flow techniques in contributing to this goal in the fields of inorganic and bioinorganic chemistry are presented. The most common detection methods for following the kinetics are absorbance or fluorescence spectrometry, which are mainly described in this part.

3.1 General Procedures

In order to provide kinetic and thermodynamic insight into new reaction systems, the following steps are frequently followed in applications of stopped-flow techniques.

1. Spectra or rapid-scan spectra are obtained by the stopped-flow method establishing also a suitable wavelength at which kinetic measurements could be performed.
2. Progress curves at a single wavelength are monitored. The time courses are the average of several independent kinetic runs. Usually these studies are performed under pseudo-first-order conditions that allow the experimenter to analyze the kinetic time courses as a sum of exponential functions. The single wavelength can be chosen from the time-resolved spectra, and is always selected close to the absorbance maximum (or fluorescence emission maximum) of reactant, intermediate, or product.
3. The observed rate constants (k_{obs}) and second-order rate constants (if possible) are calculated. The traces are fitted to a single-exponential or to a sum of exponentials model. The validity of the fitting is evaluated by an inspection of residuals and normalized variation parameters. The software that runs stopped-flow spectrophotometers provides fitting programs to extract rate constants. Other commercial software is also available. The operator must decide the likely form of the curve and the time range over which the curves should be fitted. Reactions are generally monitored for at least several half-lives ($6 \sim 9$ is common in the literature). In practice, the time is decided by the experimental conditions. It is often the case that time courses are not simple but comprise more than one exponential phase. The trace is easily fitted, but in order to do so the user must select the time range over which the fitting should take place. This selection should be made to

ensure that approximately equal numbers of data points representing the kinetic process are collected. It is best to be aware that rather different values for rate constants may be obtained depending on the ''fit-range'' one chooses.

4. The influence of variables such as pH, concentration, buffer, solvents, and different reactants on the observed rate constants or rapid-scan spectra is examined.
5. The influence of temperature can be studied, and the activation parameters (e.g. the activation enthalpies and entropies) can be calculated. If necessary, the high-pressure stopped-flow technique can be used to study the pressure dependence of reactions, and the corresponding volumes of activation may be calculated.
6. On the basis of multiple experimental results (kinetic and steady-state) and the kinetics analysis, a global analysis or singular value decomposition (SVD) can be used to extract spectra for species (intermediates and product) and a possible reaction mechanism can be proposed.

It is good practice to check from time to time that the stability of the instrument is within the manufacturer's specification. It is necessary to test the reliability of the stopped-flow instrument using control experiments that test a range of parameters such as the dead time, mixing efficiency and signal output. In general, these tests will be the same for the instrument in the configuration for fluorescence studies as that for absorbance studies.

3.2 Ligand Substitution

3.2.1 Substitution Reaction of Fe(III) Complexes with Thiocyanate

Seven-coordinate three-dimensional metal complexes are considered to be quite unstable and kinetically labile species, and their solution chemistry is largely undefined. Over the last few years it was shown that these species exhibit extremely interesting chemical properties and catalytic activity. They can catalyze disproportionation of deleterious superoxide radicals, even faster than natural enzymes, and therefore this became a challenging research area. Recently, Rudi van Eldik[5] reported a detailed rapid-scan stopped-flow kinetic study of the substitution behavior of the seven-coordinate [Fe(dapsox)(L)$_2$]ClO$_4$ complex with thiocyanate as a function of the thiocyanate concentration, temperature, and pressure in protic and aprotic organic solvents.

Kinetic data were obtained by recording time-resolved UV–vis spectra using a stopped-flow instrument combined with a thermostat and equipped with a high-speed diode array spectrometer. At least 10 kinetic runs were recorded under all conditions, and the reported rate constants represent the mean values. All kinetic measurements were carried out under pseudo-first-order conditions; that is. the ligand concentration was in large excess (complex concentration 5×10^{-5} M).

Kinetic traces in ethanol clearly showed two subsequent reaction steps over the whole SCN$^-$ concentration range (Figure 2), similar to that observed in MeOH solution,

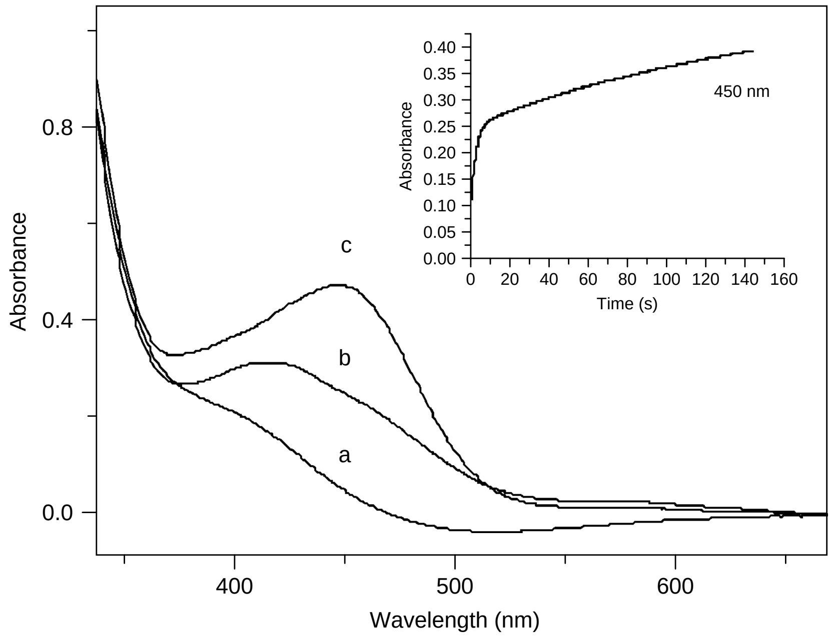

Figure 2 UV–vis spectra obtained from the time-resolved spectra of the reaction in nonacidified MeOH at −50 °C of [Fe(dapsox)(OMe)(MeOH)] (a), intermediate [Fe(dapsox)(NCS)(MeOH)] (b) and [Fe(dapsox)(NCS)$_2$]$^-$ (c). Experimental conditions: [Fe(III)] = 5×10^{-5} M, [SCN$^-$] = 0.3 M. Inset: corresponding kinetic trace fitted to a double-exponential function

and they were fitted to a double-exponential function that resulted in k_{obs} values for the first and second reaction steps. Plots of k_{obs} versus $[SCN^-]$ for both reaction steps at 5 °C show a linear increase in k_{obs} with increasing $[SCN^-]$ over the whole concentration range without a significant intercept, indicating that there is no reverse solvolysis or parallel reaction. From the slopes of the linear plots of k_{obs} versus $[SCN^-]$ the second-order rate constants can be calculated. Measurements under high pressure were carried out using a homemade high-pressure stopped-flow instrument. Values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ were calculated from the slopes and intercepts of plots of $\ln(k/T)$ versus $1/T$, respectively, and values of $\Delta V^{\neq}$ were calculated from the slope of plots of $\ln k$ versus pressure in the usual manner.

On the basis of the reported activation parameters, a dissociative mechanism for the first substitution step and a dissociative or dissociative interchange (I_d) mechanism for the second substitution step are suggested for the reaction in MeOH and EtOH.

3.2.2 *Substitution Reaction of Fe(III) Complexes with Hydrogen Peroxide*

A detailed kinetic investigation of the reaction between $[Fe^{III}(edta)H_2O]^-$ and H_2O_2 has been reported.[6] The reaction was found to consist of two steps and resulted in the formation of the already characterized high-spin Fe(III) side-on bound peroxo complex.

For the investigation of the first reaction step, the kinetics of this reaction was studied by stopped-flow spectrometry. The effect of five different buffers on k_{obs1} was investigated. Kinetic data were obtained under pseudo-first-order conditions, $[H_2O_2] \gg [Fe(edta)^-]$. Kinetic traces recorded in the presence of an excess of H_2O_2 showed a two-step behavior that could be fitted by two exponential functions. The time scales of the two steps were different enough for the reaction to be separated into two steps by selecting different time scales and fitting each step to a single-exponential function. Typical kinetic traces and the corresponding fits for the two reaction steps are shown in Figure 3. Plots of k_{obs1} versus the H_2O_2 concentration at different buffer concentrations were found to be linear with a significant intercept. The rate law for this reaction based on the first reaction step is $k_{obs1} = k_{-1} + k_1[H_2O_2]$. The overall spectral changes increased significantly with increasing hydrogen peroxide concentration, from which it followed that coordination of hydrogen peroxide is a reversible process. Under conditions where the dead time of the stopped-flow instrument (ca. 4 ms) does not interfere with the spectral changes observed during the kinetic traces, an apparent thermodynamic equilibrium constant of $38 \pm 3\,M^{-1}$ was calculated from the spectral changes observed for the first step in this reaction. The temperature dependence of k_{obs1} as a function of $[H_2O_2]$ at selected pH values was used to construct Eyring plots for k_1 and k_{-1}, from which the activation parameters $\Delta H^{\neq}$ and $\Delta S^{\neq}$ were determined. The volume of activation, $\Delta V^{\neq}$, was determined from the slope of a plot of $\ln k_{obs}$ versus pressure.

For the second reaction step, the observed rate constant of this reaction (k_{obs2}) was independent of the hydrogen peroxide concentration. As described above, the temperature dependence of k_{obs2} was used to construct a linear Eyring plot from which $\Delta H^{\neq}$ and $\Delta S^{\neq}$ were obtained. The volume of activation was derived from the slope of the linear plot of $\ln k_{obs2}$ versus pressure at 25 °C in the pressure range 10–170 MPa. The reported volumes of activation can be used to construct a volume profile for the overall reaction. The positive activation volume, $\Delta V^{\neq} = +6.8 \pm 0.4\,cm^3\,mol^{-1}$, suggests a dissociative interchange (I_d) mechanism for the ligand substitution reaction on $[Fe(edta)OH]^-$ with hydrogen peroxide.

The results clearly indicate that the reaction of Na[Fe(edta)] with hydrogen peroxide occurs in a two-step process. In combination with all the other kinetic data available, a detailed reaction mechanism could be presented.

3.2.3 *Substitution Reaction of Pt(II) complexes with Nucleophiles*

Kinetic studies on reactions of Pt(II) complexes with biologically relevant nucleophiles have been reported.[7] The substitution of both coordinated water molecules by a series of nucleophiles (namely, thiourea (tu), L-methionine (L-Met), and guanosine-5′-monophosphate (5′-GMP)) was investigated as a function of concentration, temperature, and pressure using stopped-flow techniques and was found to occur in two subsequent reaction steps. The activation parameters for all reactions suggest an associative substitution mechanism.

The spectral changes of the reactions were first recorded over the wavelength range of 190–500 nm to establish a suitable wavelength at which the kinetic trace could be followed. The ligand substitution reactions were studied under pseudo-first-order conditions with respect to either the Pt(II) complex or the nucleophile to force the reactions to go to completion. This was achieved by using at least a 10-fold (1:1 complex formation) or 20-fold (1:2 complex formation) excess of the nucleophile or the complex. All reported rate constants represented an average value of at least three to five independent kinetic runs for each experimental condition.

A linear dependence of the observed rate constants on the tu concentration was found for the Pt(amp) complex. k_{obs1} and k_{obs2} can be expressed by equations (2) and (3). All of the reactions studied do show a zero intercept; therefore, the reactions are irreversible, and k_{-1} and k_{-2} are zero.

$$k_{obs1} = k_1[Nu] + k_{-1} \approx k_1[Nu], \quad Nu = \text{L-Met, tu, 5}'\text{-GMP} \tag{2}$$

$$k_{obs2} = k_2[Nu] + k_{-2} \approx k_2[Nu], \quad Nu = \text{tu, 5}'\text{-GMP} \tag{3}$$

Kinetic traces for reactions with L-Met gave excellent fits to a double-exponential function. The obtained constants, k_{obs1} and k_{obs2}, were plotted against the concentration of the entering L-Met molecule. In the case of k_{obs1}, a linear

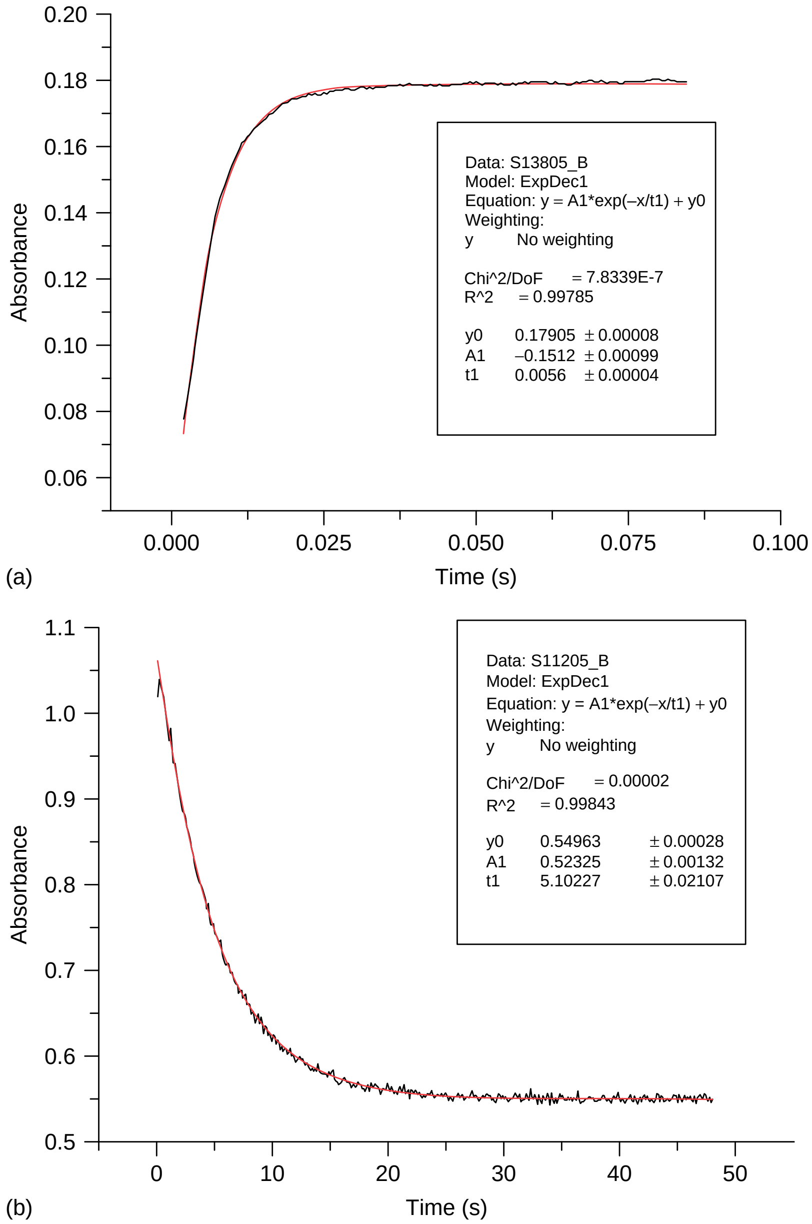

Figure 3 (a) Typical absorbance-time trace for the first reaction step in TAPS as buffer. Experimental conditions: $[Fe(edta)^-] = 0.001$ M, $[H_2O_2] = 0.020$ M, I = 0.5 M, pH = 9.1 (b)Typical absorbance-time trace for the second reaction step in glycine as buffer. Experimental conditions: $[Fe(edta)^-] = 0.001$ M, $[H_2O_2] = 0.020$ M, I = 0.5 M, pH = 10.75, T = 25 °C

dependence on the nucleophile concentration was observed for all the complexes studied; k_{obs2} was found to be independent of the L-Met concentration, suggesting a chelate formation process. The results for the reactions with L-Met imply that k_{obs1} and k_{obs2} can be expressed by equations (2) and (4).

$$k_{obs2} = k_2, \quad \text{Nu} = \text{L-Met} \qquad (4)$$

The k_{obs} values for all reactions increased with increasing pressure and showed a linear dependence. The acceleration of the reactions by pressure indicates an activation process that is consistent with an associative substitution mechanism and is dominated by bond making. This is also supported by the negative $\Delta S^{\neq}$ values calculated from the temperature dependence of the reactions. The values for the activation entropy, $\Delta S^{\neq}$, and the activation volume, $\Delta V^{\neq}$, are significantly negative for all reactions studied. The second substitution step in the reaction with L-Met, which involves chelate formation, shows a more negative activation entropy and activation volume compared to the first step.

3.3 Complex Formation

3.3.1 Nitric Oxide Binding and Dissociation with Iron(III) Porphyrin Complex

The rates of ligand binding and ligand dissociation (k_{on} and k_{off}) can be determined by stopped-flow methods. For example, the kinetics of the binding and release of NO with an iron(III) porphyrin complex was studied as a function of pH, temperature, and pressure by stopped-flow and laser flash photolysis techniques.[8] The diaqua-ligated form of the porphyrin complex binds and releases NO according to a dissociative interchange mechanism based on the positive values of the activation parameters $\Delta S^{\neq}$ and $\Delta V^{\neq}$ for the ''on'' and ''off'' reactions.

The kinetics of the reaction was followed at 427 nm (pH 7) or 432 nm (pH 11) under pseudo-first-order conditions with at least a 10-fold excess of NO. The k_{obs} values determined under such conditions by fitting the kinetic traces to a single-exponential function depend linearly on [NO] according to equation (5). The rates of NO binding and release (k_{on} and k_{off}) were determined from slopes and intercepts of linear plots of k_{obs} versus [NO], respectively. The overall equilibrium constant calculated from the kinetic data, $K_{NO} = k_{on}/k_{off}$, was in reasonable agreement with the corresponding thermodynamic value of K_{eq} determined from a combination of UV–vis and electrochemical measurements. In general, the values of k_{on} and k_{off} can be checked against the value of the equilibrium constant (K) if it is known.

$$k_{obs} = k_{on}[NO] + k_{off} \qquad (5)$$

To determine the activation parameters $\Delta H^{\neq}$, $\Delta S^{\neq}$, and $\Delta V^{\neq}$ for the binding and release of NO, the kinetics was studied at different temperatures (6–30 °C) and hydrostatic pressures (0.1–170 MPa). The k_{on} and k_{off} values determined from linear dependences of k_{obs} versus [NO] at each temperature and pressure allowed the construction of Eyring plots for the ''on'' and ''off'' reaction. Activation parameters can be calculated from the plots. Because of the small intercepts in the plots of k_{obs} versus [NO] in the pressure-dependent study, the activation volume for the ''off'' reaction could not be determined accurately in this way. This value, however, could be measured in a stopped-flow experiment using the NO-trapping method.

Activation volumes determined in these studies enabled the construction of volume profiles for the binding of NO to the diaqua and monohydroxo forms of the complex, respectively. On the basis of these data, a feasible explanation for the significant kinetic and mechanistic differences observed in the reactivity of these two species was offered.

3.3.2 Kinetics of the Formation of Lead(II) Complexes

For new compounds, the stopped-flow method is one important approach to study kinetics. For example, three lead(II) complexes were synthesized, and stopped-flow kinetic measurements enabled the unraveling of the formation process of the three lead(II) complexes on the basis of thermodynamic and kinetic studies.[9]

Formation and proton-assisted dissociation kinetic studies were performed under pseudo-first-order conditions. The kinetic traces, recorded at the maximum of the UV absorption band assigned to the lead complexes (274 nm) by single-wavelength stopped-flow spectrophotometry, were averaged from at least six replicates and then processed on-line with the fitting routine software. This program fits up to three-exponential functions to the experimental curves by the Marquardt nonlinear least-squares algorithm. The goodness of fit was judged in terms of the statistical parameter χ^2 (in general, values less than 0.1 were obtained) and by visual inspection of the residual plots. The pseudo-first-order rate constants were thus derived. Linear regression and nonlinear least-squares calculations were performed with Origin 6.0 (Microcal Software, Inc., Northampton, MA USA).

The time course of the complex formation was studied under pseudo-first-order conditions with excess ligand. Concentrations after mixing were at least 10 times larger than those of lead(II). Under such conditions the reaction proceeded to completion in a single rate-limiting step with no more initial loss of spectrophotometric amplitude than that expected from the dead time of the employed instrument. The process was found to be of first order with respect to lead(II). Indeed, the recorded signal could be fitted with excellent statistical confidence to a single-exponential function by nonlinear least squares.

A combination of potentiometric and absorption spectroscopic data allowed the authors to characterize the formation and the dissociation mechanism of octacoordinated lead(II) complexes of primary and tertiary tetrakiscarbamoyl-methyl cyclam derivatives.

3.4 Redox Reactions

Noncomplementary redox reactions between halogen and oxyhalogen species often exhibit complex kinetic patterns which can be understood in terms of multistep kinetic models. The corresponding mechanisms are centered on the formation and subsequent reactions of reactive intermediates such as XO_2 (X = halogen) and related compounds. Stopped-flow techniques can be used to provide insights into the redox reactions. Several examples of redox reaction are also described in Section 3.5.

Stopped-flow spectroscopy was used to relate the rate constants, activation parameters, and mechanisms of the oxidation of ClO_2^- and BrO_2^- by O_3.[10] Ozone reactions with XO_2^- (X = Cl or Br) are studied under pseudo-first-order conditions with excess XO_2^-. The kinetic traces were obtained observing the loss of O_3 at 260 nm and fitted to an exponential equation to give the pseudo-first-order rate constants. The O_3/XO_2^- reactions are first order in $[O_3]$ and

[XO_2^-]. The proposed rate-determining step is an electron transfer from XO_2^- to O_3 to form XO_2 and O_3^-. Subsequent rapid reactions of O_3^- with general acids produce O_2 and OH. The OH radical reacts rapidly with XO_2^- to form a second XO_2 and OH^-. However, for X = Br, kinetic spectra show that small but observable concentrations of BrO_2 form within the dead time of the stopped-flow instrument. Bromine dioxide is a transitory intermediate, and its observed rate of decay is equal to half the rate of the O_3/BrO_2^- reaction. Variation of rate constant values with temperature gives $\Delta H^{\neq}$ and $\Delta S^{\neq}$. The positive $\Delta S^{\neq}_{Br}$ value is attributed to the loss of coordinated H_2O from BrO_2^- upon formation of an $[O_3BrO_2^-]^{\neq}$ activated complex.

3.5 Observation of Intermediates

3.5.1 Methods for Collecting Spectral Data

The spectra of reaction intermediates may be reconstructed either by collecting a series of single-wavelength kinetic traces over the wavelength range of interest, or by rapidly collecting individual spectra during the course of a single reaction. The method used depends primarily on the capabilities of the available instruments, and also on the chemical properties of the system being investigated.

Absorbance stopped-flow data are most commonly collected at a single wavelength with a monochromator and photomultiplier or photo-diode detector. By repeating a reaction across the wavelength range of interest, data for spectral analysis can be collected. Spectrophotometers capable of acquiring hundreds (or more) of spectra each second are available in commercial stopped-flow systems. These are most often based on an array of photodiodes. An alternative method for rapid scanning uses a subtractive double grating monochromator with intermediate slits that are mounted on a rapidly spinning disk. This initial technology contributed the name ‘‘rapid-scan’’ kinetics, even though kinetic spectra are more often now collected with no spectral scanning at all by photo-diode arrays.

An isosbestic point is a wavelength where the absorbances of two light-absorbing forms are equal. The isosbestic point is useful in both quantitative and qualitative work. Where a clear isosbestic point occurs during the course of a reaction, it is often taken as evidence that only two species are involved, since it is considered unlikely that a third absorbing species would also have an identical absorbance at the same wavelength. It is more likely that a third species may simply have no absorbance at this wavelength.

3.5.2 Example of a Two-step Reaction Mechanism

The observation of intermediates is important because it can help to provide useful information to describe a detailed reaction pathway for the reaction. Rapid-scan experiments can directly show whether the change in absorbance at all wavelengths is monotonic or not, and how many well-defined isosbestic points are observed in this process.

The intermediate formed may or may not show a UV–vis spectrum. If it does, it is easy to make a decision that an intermediate is formed. For example, Stanbury *et al.*[11] found that the aqueous reaction of acidic Cl_2 with excess SCN^- rapidly generates a UV-absorbing intermediate. Sometimes, the reaction investigated proceeds rapidly, generating an unstable intermediate within the dead time of all stopped-flow instruments used for kinetic analysis. In order to obtain confirmative evidence on the structure of the intermediate, additional approaches are required to provide evidence. Researchers can gain significant insight into the reaction mechanism through combined stopped-flow kinetics and UV–vis, EPR, and resonance Raman spectroscopic studies, etc., as well as information about the structures of intermediates.

In our previous work,[12] it was found that an absorbance peak at 526 nm appeared within the first seconds, then decreased slowly, upon mixing of perphenazine with potassium persulphate (Figure 4). Both perphenazine and potassium persulphate have no absorbance peak in the range between 390 and 700 nm (spectrum not shown), so their spectral changes do not interfere with the spectrum of intermediate. Therefore time-resolved spectra in Figure 4 provided clear evidence for the formation and decay of an intermediate, the visible spectrum of which was characterized by an absorbance maximum at 526 nm.

The spectra (recorded between 280 and 705 nm and between 1.3 ms and 16.4 s) were analyzed by Pro-Kineticist global analysis/simulation software (Applied Photophysics Ltd., Leatherhead, UK). Singular values, which are a measure of the contribution of the corresponding basis spectra to the observed spectra, indicated that the number of colored components present in this system was three. Before simulating with Pro-Kineticist global simulation software program, a possible model was entered in the form of two-step reaction mechanism ($A \rightarrow B \rightarrow C$). Global analysis of the spectrum (Figure 5a) indicated the presence of three species assigned as perphenazine (A), the intermediate (B), and the final oxidized product of perphenazine (C). The concentration changes of the compounds A, B, and C with time are displayed in Figure 5(b), the curve for B possesses a typical characteristic of successive reaction and is similar to the time course at 526 nm in the experimental results. We also tried other possible models, such as $A + B \rightarrow C \rightarrow D$, or $A \rightarrow B \rightarrow C \rightarrow D$; the synthesized spectra and concentration-time curves were not consistent with the experimental results. These results calculated by the software in Figure 5(a) and (b) were consistent with the experimental data, proving that the two-step reaction model ($A \rightarrow B \rightarrow C$) was the most reasonable mechanism. The chemical identity of this intermediate is still under investigation.

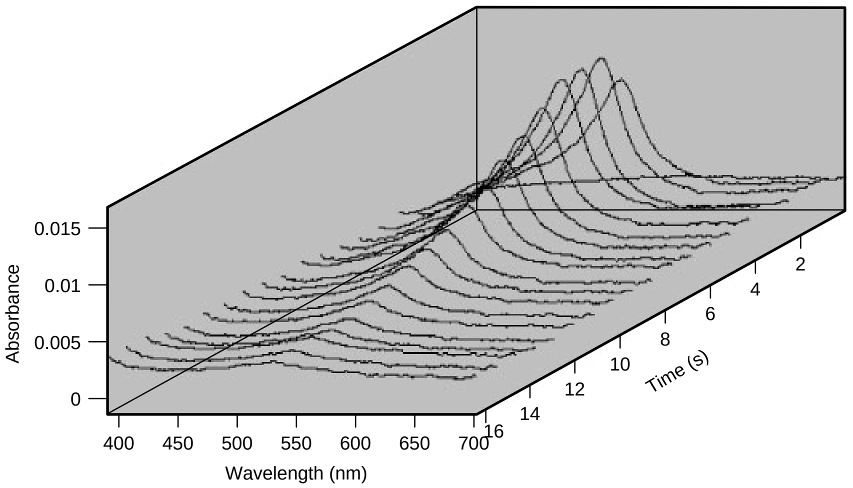

Figure 4 Time-resolved spectra (800 spectra are acquired in the 390–705 nm range per shot. Only 19 spectra are present for clear observation.) of 6.0×10^{-5} M perphenazine mixed with 2.0×10^{-2} M $K_2S_2O_8$ in 0.3 M H_2SO_4 buffer at 25.0 °C The reaction was monitored by photodiode array detector (PDA) attached to the stopped-flow instrument

3.5.3 Example of a Three-step Reaction Mechanism

Rapid-scan UV-vis spectra of the nitrite-catalyzed reaction between HbFe(II)NO (Hb = hemoglobin) and peroxynitrite were obtained.[13] The analysis of the spectra with singular-value decomposition/global analysis demonstrated that the spectral changes follow a three-exponential process (A → B → C → D) and are indicative of the formation of HbFe(III)NO and HbFe(III)NO_2 as intermediates. The observed rate constants for the first two reaction steps were determined by global analysis of the rapid-scan stopped-flow spectrophotometric data. The calculated spectra of three species were obtained from singular-value decomposition and global analysis of the rapid-scan data as shown in Figure 6. The rate-determining step was determined from kinetic data, and the step changed depending on the conditions.

3.6 Double-mixing Stopped-flow

The double-mixing stopped-flow method is a convenient and powerful tool to generate a labile component transiently, for example avoiding anaerobic conditions for investigating interprotein electron transfer. Studies of interprotein electron transfer require the rapid mixing of a reduced (donor) and oxidised (acceptor) protein. A requirement of single-mixing approaches is that the donor protein is pre-reduced (e.g. with a reducing substrate or artificial reductant) before being introduced into the stopped-flow analyser. Reduced enzymes are often sensitive to oxidation by O_2, making the approach technically demanding since anaerobic conditions are often required to prevent reoxidation of the protein. However, double mixing can be used to reduce transiently the donor protein prior to mixing with the acceptor. The following two examples show the applications of double-mixing mode, as well as the disadvantages of double mixing.

Lippard *et al.*[14] presented the results of detailed double-mixing stopped-flow kinetic studies of the reaction of diiron(II) compounds ($Fe_2(\mu\text{-}O_2CAr^{Tol})_4(4\text{-CNPy})_2$) with water and the subsequent interaction of the aqua species with dioxygen.

This reaction $Fe_2(\mu\text{-}O_2CAr^{Tol})_4(4\text{-CNPy})_2$ with water was investigated at −60 °C with different excess amounts of water. A plot of $\ln k_{obs}$ versus $\ln[H_2O]$ was fitted to a linear equation, which had a slope of 0.99, indicating a first-order dependence on water. The pseudo-first-order rate constant is also linearly dependent on the concentration of water, with an intercept, which corresponds to the reverse reaction rate constant, near zero. This result indicates the reaction to be irreversible under these conditions.

After $Fe_2(\mu\text{-}O_2CAr^{Tol})_4(4\text{-CNPy})_2$ was mixed with water, the solution was further allowed to react with excess dioxygen in a second push using the double-mixing stopped-flow apparatus (Figure 1). The 460 nm absorbance arising from the aqua adduct decreased with time, a change that could be nicely fitted to a pseudo-first-order expression. The derived rate constants are comparable to those obtained from a previous competition experiment, which indicates that aquation was completed prior to oxygenation.

The second example is the measurement of the kinetics of a substrate binding to extracted FeMo-cofactor of nitrogenase by a double-mixing stopped-flow approach.[15] In a typical experiment, solutions of FeMoco-L and CN^- are rapidly mixed and held together for a known length of time. Subsequently, this solution is mixed with a solution of $[NEt_4]SPh$ whereupon the thiolate reacts with the cofactor.

In principle, the double-mixing approach can be used to monitor the binding of any substrate to extracted

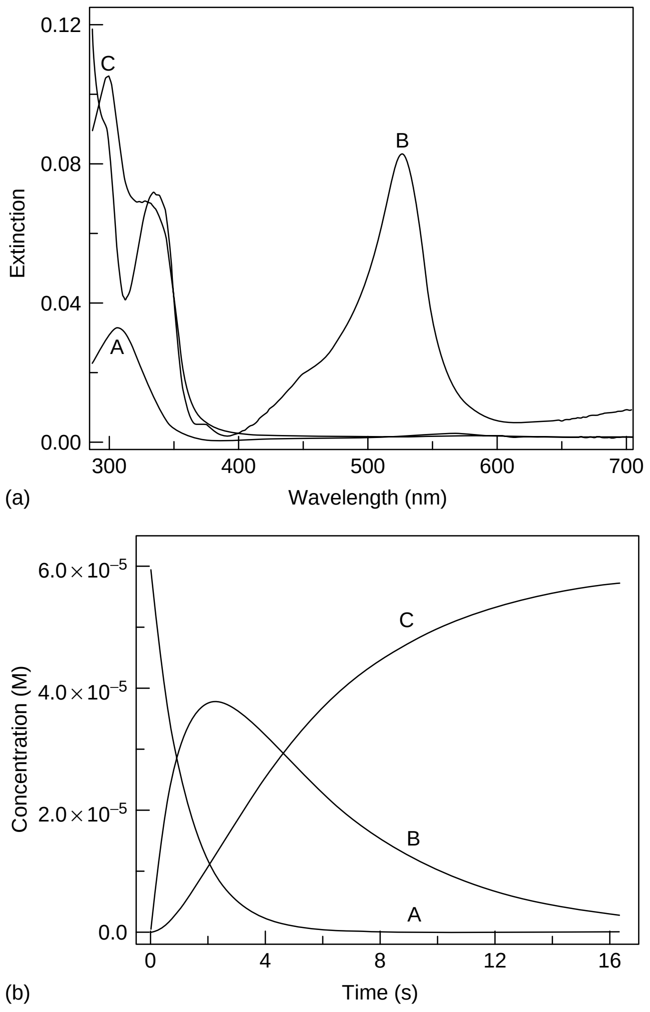

Figure 5 (a) Calculated spectra of the perphenazine (A), intermediate (B) and product (C); (b) Change of concentrations of different substances in the course of reaction. Results in (a) and (b) were calculated by Pro-Kineticist global simulation program, which was used for spectral analysis of intermediates using a set of spectral data from the reaction of 2.0×10^{-2} M $K_2S_2O_8$ with 6.0×10^{-5} M perphenazine in 0.3 M H_2SO_4 buffer at 25.0 °C obtained by PDA

FeMo-cofactor; in practice, its application is limited. During the double-mixing experiments, the cofactor solution is diluted fourfold before it is analyzed; initial equivolume mixing with the solution of CN^- is followed by equivolume mixing with the PhS^- solution. Consequently, the solution of the cofactor being analyzed is only half the concentration of a conventional stopped-flow experiment, and thus, the absorbance-time curves are only half the magnitude. (This can be somewhat improved by using syringes of different volume.) In addition, when configured in the double-mixing mode, the dead time of the apparatus is about 3–4 ms, which is more than double that of the stopped-flow configuration and leads to loss of some of the absorbance change for more rapid reactions. The consequence of both these limitations is that (compared to conventional stopped-flow spectrophotometry) the data from double-mixing stopped-flow experiments are associated with a poorer signal-to-noise ratio.

3.7 Low-temperature Stopped-flow

Low-temperature stopped-flow methods have become extremely useful for studying reactions that are too fast at ambient temperatures and/or for detecting reactive intermediates that can only be observed at low temperatures. The low-temperature stopped-flow technique has been well documented as a useful tool for the detection of unstable copper-dioxygen intermediates. The kinetic and thermodynamic behavior of O_2-binding to Cu(I) complexes can provide fundamental understanding of copper(I)/dioxygen chemistry, which is of interest in chemical and biological systems. As an illustration of low-temperature stopped-flow in inorganic chemistry, the reaction of dioxygen with the tripodal copper(I) complex was studied by Siegfried *et al.*[16] For example, low-temperature stopped-flow studies of the least oxidizing copper(II) complexes reacting with $O_2^{\bullet-}$ provided evidence of a CuO_2 intermediate.[3] The low-temperature technique was applied to study the reactions between copper(II) complexes and H_2O_2, which enabled the researcher to detect a mononuclear Cu^{II}-peroxo complex.[4]

Zuberbühler *et al.* reported stopped-flow kinetic investigations of the oxygenation reactions of a series of tetradentate copper(I) complexes in propionitrile, tetrahydrofuran, and acetone.[17] The formation of $[(L^{MeO})Cu^{II}(O_2^-)]^+$ can only be followed below 203 K because at a higher temperature it occurs faster than the stopped-flow instrumental limit. On the basis of experimental results, the authors proposed a reaction mechanism, which involved four steps, at least three intermediates. On the basis of the kinetics analysis, spectra for species (intermediates and product) could be calculated.

3.8 High-pressure Stopped-flow

Chemical reactions are often highly pressure-dependent. As a matter of fact, high pressure is an elegant way to perturb reversibly chemical equilibria and reactions. Another advantage of using the pressure parameter is that reactions are slowed or accelerated depending on the type of chemical interaction involved. For instance, pressure weakens electrostatic interactions, but stimulates some hydrophobic interactions, such as stacking between aromatic residues. Similarly to the activation enthalpy, $\Delta H^{\neq}$, obtained from kinetics as a function of temperature, experiments under pressure yield an activation volume, $\Delta V^{\neq}$. When the activation volume is positive, the reaction is slowed, and when it is negative, the velocity is increased by pressure. From the pressure-dependent kinetic constants (k_{obs}) the activation volumes ($\Delta V^{\neq}$) were determined according to $(\mathrm{d}\ln k_{obs}/\mathrm{d}P)_T = -\Delta V^{\neq}/RT$ where P is the hydrostatic pressure, T the absolute temperature and R the gas constant.

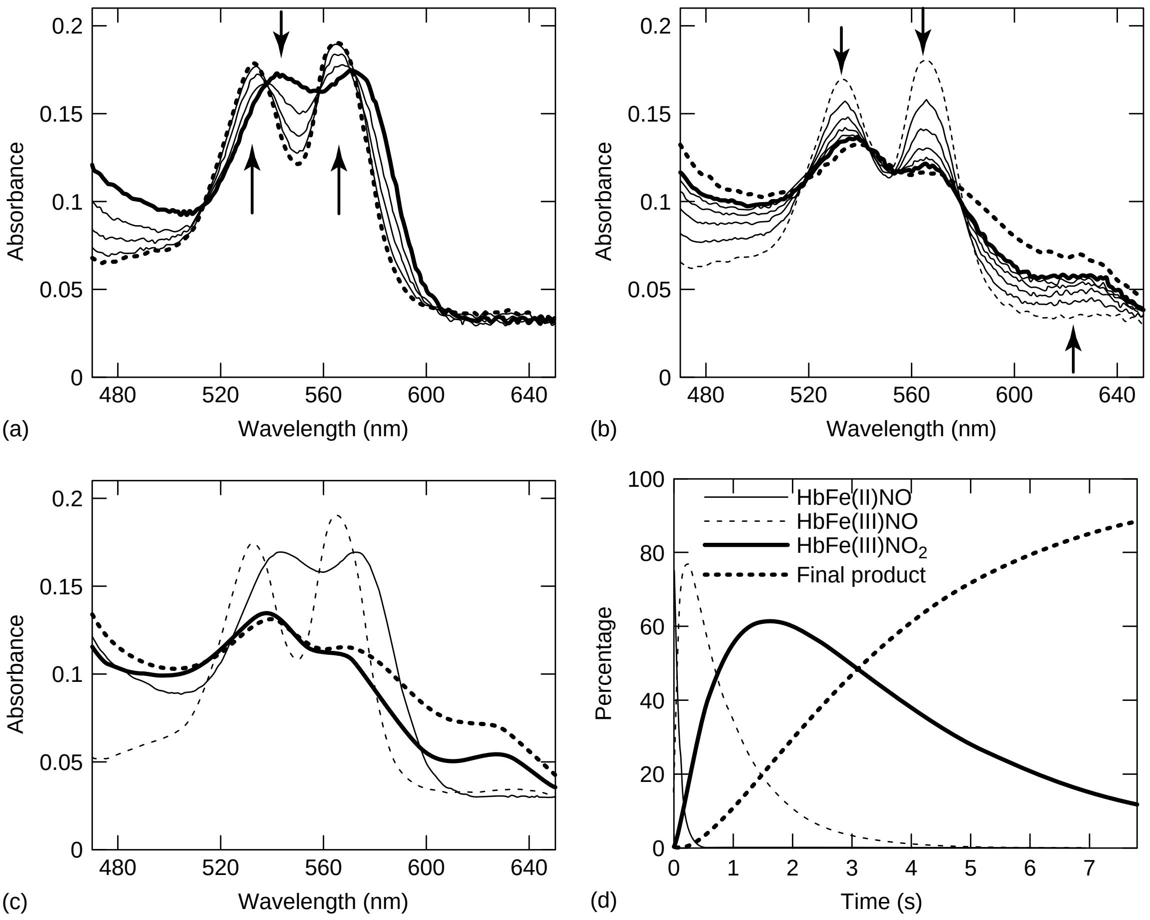

Figure 6 Rapid-scan UV–vis spectra of the nitrite-catalyzed reaction between HbFe(II)NO (14 μM) and peroxynitrite (400 μM) in a 0.05 M phosphate buffer at pH 7.0 and 20 °C, $[NO_2^-] = 175$ mM. Absorbance spectra were collected every millisecond, but to improve the signal-to-noise ratio, each curve shown represents the average of two measured curves. (a) Oxidation of HbFe(II)NO (bold line) to HbFe(III)NO (bold dotted line): the traces depicted were recorded every 40 ms up to 160 ms. (b) The dissociation of $NO^{\bullet}$ from HbFe(III)NO (dotted line) and the binding of nitrite to metHb generates $HbFe(III)NO_2$ (bold line, ∼2.2 s). The traces depicted were recorded every 400 ms. The dotted bold line represents the final spectrum after a total of 7.8 s. (c) The three species obtained from singular-value decomposition and global analysis of the data from parts (a) and (b). The data were fitted to a three-exponential expression (A → B → C → D), and the values of the three observed rate constants obtained are $11.6 \pm 0.2\ s^{-1}$, $1.2 \pm 0.1\ s^{-1}$, and $0.31 \pm 0.06\ s^{-1}$, respectively. (d) Time courses for the four species involved (see legend, which also applies to c) obtained from singular-value decomposition and global analysis of the data from parts (a) and (b)

High-pressure stopped-flow techniques were also widely used to monitor fast reactions with gaseous fluid as reactants. For example, Bailey *et al.*[18] developed a high-pressure stopped-flow apparatus in their laboratories and used this apparatus to follow the reaction of dioxygen with bovine cytochrome *c* oxidase. This technique was also applied to study the reaction of nitric oxide synthase with oxygen, which is fast and takes place within several steps, separated by ephemeral intermediates. These experiments under high pressure indicated that oxygen binding occurred in more than one step.[19] The use of extreme experimental conditions, such as low temperature and high pressure, associated with rapid kinetic analysis, has proven to be a convenient tool to study complex reactions.

3.9 pH-jump Stopped-flow

The pH-jump technique can be used in the conventional stopped-flow mode in order to elucidate the kinetics of the reaction at different pH. In such experiments, a pH-dependent equilibrium is perturbed by mixing the system equilibrated at one pH in a weak buffer with a strong buffer at a different pH.

For example, the kinetics of Fe dissociation from Fe^{3+}nFbp(X) (nFbp = recombinant ferric binding protein from *Neisseria meningitides*, X = PO_4^{3-}, citrate) driven by H^+ were studied by pH-jump stopped-flow methods. Researchers used this technique to induce Fe^{3+} dissociation from Fe^{3+} nFbp(X) (X = PO_4^{3-}, citrate), which enabled researchers to study the mechanism in the absence of

a competing chelator.[20] A low buffer concentration was maintained to enable a pH jump during the stopped-flow experiment. The kinetics of Fe^{3+} release from Fe^{3+} nFbp(X) via a pH jump were investigated by fast mixing of the Fe^{3+}-loaded protein at near neutral pH (6.65) with $HClO_4$ of the desired concentration (0.001–0.05 M). The rapid pH jump results in successive dechelation events and complete dissociation of Fe^{3+} from the protein.

3.10 Analysis of Stopped-flow Data

Kinetic data in most cases are complex and hence best analyzed by computational methods that make no assumptions in fitting the data, except for the model chosen by the investigator. Comprehensive data treatments are often required for kinetic studies, and finally kinetic models are proposed based on these results.

The kinetic traces are obtained from stopped-flow experiments and fit to a single-exponential or to a sum-of-exponentials model. Strictly speaking, one does not know beforehand how many exponentials will be required to describe adequately a particular kinetic curve, so that one has to perform several separate fits, each using a different number of such terms. We therefore need criteria to use in choosing which model best describes the data. The standard ones are the form of: (i) the residuals; (ii) the autocorrelation function values; and (iii) the χ^2 value (statistical goodness-of-fit parameter).

3.10.1 Ligand–Binding Reaction; Data Analysis

The observed rate constant, k_{obs}, can be determined from the exponential function. When the plots follow a linear dependence of k_{obs} against initial concentration of ligand, equation (6) is adopted:

$$C + L \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} C - L \tag{6}$$

where C is the compound, L is the ligand, $C - L$ is the compound-ligand complex, and k_{+1}, k_{-1} are the transient-phase kinetic rate constants. If the initial concentration of ligand, $[L]$, is greater than $[C]$, k_{obs} is then expressed as equation (7):

$$k_{obs} = k_{+1}[L] + k_{-1} \tag{7}$$

The values of k_{+1} and k_{-1} are determined from the slope and the intercept of the plot of $[L]$ versus k_{obs}, respectively. The dissociation constant of $C - L$, K_{-1}, can be calculated from equation (8):

$$K_{-1} = \frac{k_{-1}}{k_{+1}} \tag{8}$$

In contrast, when the plots of $[L]$ versus k_{obs} are nonlinear, equation (9) is applied:

$$C + L \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} C - L \underset{k_{-2}}{\overset{k_{+2}}{\rightleftharpoons}} C^* - L \tag{9}$$

where $C - L$ is an intermediate (loosely bound) form and $C^* - L$ is a more tightly bound isomerized form, and k_{+1}, k_{-1}, k_{+2} and k_{-2} are the transient-phase kinetic rate constants. In this mechanism, the reciprocal of the slower relaxation time, k_{obs}, is expressed as equation (10) when $[L] \gg [C]$

$$k_{obs} = \frac{k_{+2}[L]}{K_{-1} + [L]} + k_{-2} \tag{10}$$

where $K_{-1}(= k_{-1}/k_{+1})$ is the dissociation constant for the intermediate $C - L$ complex. The k_{-2} value can be estimated by linear extrapolation in the low $[L]$ region of k_{obs} versus $[L]$ plot. The k_{+2} and K_{-1} values are obtained with the k_{-2} value determined above, by the reciprocal of the intercept and the slope/intercept of the secondary plot of $1/(k_{obs} - k_{-2})$ versus $1/[L]$, respectively. In the two-step mechanism, the overall dissociation constant, K_d, for the $C - L$ complex can be calculated from equation (11).

$$K_d = \frac{K_{-1}}{[1 + (k_{+2}/k_{-2})]} \tag{11}$$

3.10.2 Calculating Spectra

Two approaches may be used to extract the spectra of species (as well as the kinetics of the reaction scheme) from data collected by stopped-flow experiments: SVD and global analysis. For SVD, the data set is reduced to a matrix representation that allows the spectral and kinetic parameters to be calculated. For global analysis, each absorbance trace is fit to an equation to obtain rate constants and extinction coefficients. For example, SVD results provide information on the number of reaction components and hence the minimum reaction complexity. The interested reader is directed to more thorough reviews listed at the end of this chapter (Section 5 Further Reading).

3.10.3 Examples of Analysis and Simulation

Transient-state kinetic data are typically fit with multiple exponentials and not with analytically derived equations. This procedure yields observed rate constants and amplitudes, each of which is typically assigned to one process. These amplitudes can be complex functions of rate constants, extinction coefficients, and intermediate concentrations. It can be difficult to extract meaningful parameters from them without the use of a full model for the reaction and corresponding mathematical analysis.

The next example shows how to choose a kinetic model. The unusual kinetic curves observed by stopped-flow spectrophotometry have been successfully simulated for all levels of iron loading of human H-chain ferritin. The presence of an additional intermediate, postulated to be a hydroperoxo diFe(III) complex, was suggested by a detailed analysis of the kinetic data of 48Fe/protein samples. A mathematical model for catalysis was developed that explains the observed kinetics. The model consists of two sequential mechanisms.[21]

When 48 equiv Fe(II) was mixed with the apoprotein in a multiwavelength stopped-flow experiment, a family of UV–vis reaction spectra was obtained. Absorbance maxima occur at ~305 and ~650 nm. The result shows the series of spectra for the first 50 ms of the reaction where the concentration of the peroxo intermediate ($\lambda_{max} \sim 650$ nm) increases and reaches a maximum; the series of spectra for the decay of the intermediate occupy the time interval of 50 ms to 14 s. A pure isosbestic point is not obtained in the spectra, indicating the presence of more than one decay product of the peroxo intermediate. After the authors tried several kinetic models, the 650 nm data for the 48Fe(II)/protein sample were best fitted according to a sequential reaction of the type

$$A \rightarrow B \rightarrow B' \rightarrow C$$

At least two intermediates, B and B′ can be consistently resolved in the rate data. A significantly poorer fit to the data and a correspondingly large residual were obtained with the simpler scheme, $A \rightarrow B \rightarrow C$. Similarly, the reaction scheme $A \rightarrow B$ plus $B \rightarrow C$ and $B \rightarrow C'$ or $A \rightarrow B \rightarrow C$ plus $A \rightarrow B' \rightarrow C'$ was found to either give poorer fits to the kinetic data or resulted in physically meaningless values of the rate constants with 10- to 1000-fold errors and negative molar absorptivities for some species with similarly large errors, indicating strong correlation between the fitting parameters and inappropriateness of these models. Nevertheless, the fitting results reported here do not preclude the possibility that the data, while appearing to conform to $A \rightarrow B \rightarrow B' \rightarrow C$ very well, are in fact due to another kinetic process not yet considered. The model fits the observed kinetics very well, and good correspondence is obtained between the rate constants from the data for the two wavelengths.

If the wrong kinetic model is used in analysis, the spectra obtained may not be meaningful. Indeed, one possible use for spectral analysis is to assist in deciding between rival mechanisms; if the spectra generated for one mechanism are unlike anything ever observed for the prosthetic group, while the alternate mechanism gives known spectra, the latter mechanism should be preferred. Statistical criteria are not adequate to distinguish between some rival mechanisms.

In another example, the kinetics of the protonation of Re(O)I(2,7-nonadiyne) by CF_3SO_3H in CH_3CN were monitored by visible spectroscopy. Two second-order rate constants and presumably successive protonations were observed.[22] Global fits gave calculated spectra for the starting material, the intermediate, and the product that best fits the observed stopped-flow traces in an $A \rightarrow B \rightarrow C$ sequence.

3.10.4 Examples of Computer Fitting Programs

The kinetics of most reactions is studied under pseudo-first-order conditions. However, large excess of one of the reactants might result in association processes too fast for this technique, because stopped-flow measurements are capable of following processes with observed rate constants, k_{obs}, not exceeding 1000–1500 s^{-1}. All these make numerical methods of analysis of the progress curves potentially very useful because they are not limited by any assumptions. A promising numerical integration approach to analyze progress curves obtained in stopped-flow experiments was described by Frieden and Dang.[23] Their programs KINSIM and FITSIM are applicable for any reaction mechanism and can treat simultaneously up to 20 real data files and mechanisms with up to 100 species and 100 reaction steps. One must keep in mind that a given experiment may only be sensitive to a small subset of the kinetic parameters; this situation is handled by varying only the kinetic parameters that are sensitively defined by a given experiment, while holding all others fixed.

A method for extracting kinetic and optical parameters from progress curves for protein–ligand association, obtained by stopped-flow experiments, was described by Antosiewicz *et al.*[24] The method is limited to one-step and two-step association kinetics, but it allows concentration of protein and offset of the signals to be adjustable parameters during an interactive nonlinear least-squares fitting procedure. The method was tested on simulated pseudo-experimental data and applied to progress curves obtained in a stopped-flow spectrofluorimeter.

A multitude of mathematical software is available that can simultaneously fit several traces to a single set of rate constants. Data fitting can be performed using the software supplied for the operation of the stopped-flow apparatus, the integrated J&M software Kinspec, Origin (OriginLab Corporation, Northampton, MA) or Igor (WaveMetrics, Inc., Lake Oswego, OR) for simple exponential functions. Several commercial and homemade software are frequently used for stopped-flow data analysis, such as, Specfit (Spectrum Software Ass.), Globfit (MATLAB), and Pro-Kineticist global simulation program (Global Analysis for Spectra, Kinetic Data) from Applied Photophysics.

3.11 Stopped-flow Fluorescence Spectroscopy

For fast reactions with observed fluorescence signal changes, stopped-flow fluorescence spectroscopy is a better choice for kinetic investigation. Stopped-flow fluorometry measurements have been widely employed to study the kinetics of protein interactions. A typical stopped-flow system is assembled from modular components of a conventional spectrophotometer/fluorimeter, a device permitting rapid mixing of the components of a reaction and a data recording system with fast response. Commercially available instruments offer facilities for the observation of changes in absorbance and/or fluorenscence emission after rapid mixing of the reagents. These measurements can be made simultaneously due to the different optical requirements of the two spectroscopic techniques as illustrated in Figure 1. The change in light absorption at a certain wavelength is detected at 180° relative to the light beam. Changes in fluorescence intensity are detected at 90 degree relative to the excitation

light beam via a second monochromator, a narrow bandpass filter or a cut-off filter to select the emission wavelength.

3.11.1 *Example of Nucleotide Binding to 3α-Hydroxysteroid Dehydrogenase*

This example shows how to determine whether a binding reaction constitutes a one- or two-step mechanism. Transient-phase kinetic studies using the fluorescence stopped-flow method were conducted with 3α-hydroxysteroid dehydrogenase (3α-HSD) to characterize the nucleotide binding mechanism.[25] The time course for oxidized nucleotide binding demonstrated that binding of not only NAD^+ but also $NADP^+$ was apparent by the fluorescence kinetic transients. From the relationship of k_{obs} against the respective initial concentrations of NAD^+ and $NADP^+$, the linear dependence of k_{obs} against both [NAD^+] and [$NADP^+$] indicated that the oxidized nucleotide cofactor binding is in accordance with a simple one-step mechanism. The nicotinic acid adenine dinucleotide ($NAAD^+$) binding also showed a one-step mechanism (equation 6).

In the case of reduced nucleotide binding, the dependence of k_{obs} on the initial concentration of NADH showed a hyperbolic curve. Different from oxidized nucleotides, the kinetic feature of the NADH binding was consistent with a two-step mechanism, which involves a fast bimolecular association process followed by a slow unimolecular isomerization process (equation 9). In conclusion, the binding of oxidized nucleotides, NAD^+, $NADP^+$ and $NAAD^+$, agreed well with a one-step mechanism, while that of reduced nucleotide, NADH, showed a two-step mechanism as described in Section 3.10.1.

3.11.2 *Example of Fluoride Binding to Tyrosinase*

Stopped-flow fluorescence spectroscopy was used to obtain insight into the interaction of fluoride with tyrosinase (Ty) under pseudo-first-order conditions, as well as to validate the use of fluorescence quenching in studying ligand-binding kinetics.[26]

Ty fluorescence was detected using a photomultiplier tube equipped with an optical cut-off filter of 320 nm supplied with the stopped-flow system, thus resulting in the detection of all emitted light above 320 nm. Fluoride binding traces were fitted to a single-exponential decay function of the form $F_t = F_\infty + A\exp(-k_{obs}t)$, where F_t denotes the fluorescence at time t; F_∞ is the fluorescence level at completion of the binding reaction; A is the signal amplitude. The fitting was performed using the least-squares fitting algorithm implemented in the stopped-flow software.

Representative fluoride binding traces obtained by mixing 2.5 µM resting Ty with various [F^-] (0–120 mM) at pH 6.80 in 1:1 volume ratio at 21 °C are represented in Figure 7, where a decrease in fluorescence is observed upon binding of F^-. The plots of k_{obs} versus [F^-] at a given pH

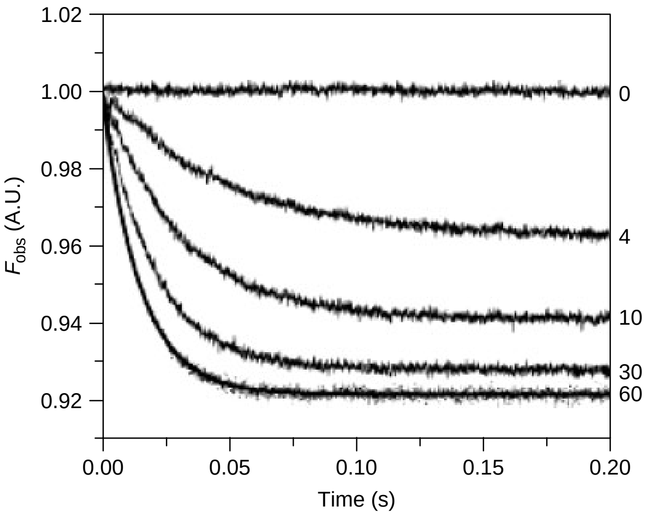

Figure 7 The kinetics of fluoride binding to Ty_{met}. Stopped-flow fluorescence traces of fluoride binding obtained by mixing 2.5 µM resting Ty in air-saturated 100 mM Pi at pH 6.80 with solutions containing various concentrations of fluoride made up in the same buffer. The fluoride concentrations (in millimolar) indicated with each trace represent end concentrations in the observation cell. Data could be fitted to single-exponential decay functions (as indicated for the trace with [F^-] = 60 mM) yielding values for the observed binding rate k_{obs} and the fractional fluorescence quenching amplitude F_∞/F_0 at each [F^-]

are linear in all cases, in agreement with a two-state binding scheme where a single fluoride ion binds to the enzyme. The apparent first-order fluoride binding rate (k_{on}) and the $Ty_{met}F$ fluoride dissociation rate constant (k_{off}) can be determined from the slope and intercept of k_{obs} versus [F^-], according to $k_{obs} = k_{on}[F^-] + k_{off}$.

The use of Ty fluorescence quenching as a probe provides a direct spectroscopic probe of fluoride binding to Ty_{met}. Stopped-flow fluorimetric experiments can be performed with high sensitivity and speed, thereby avoiding the need for large amounts of protein and the experimental difficulties arising from the intrinsic instability of the enzyme, the latter being important especially at the lower pH values.

In addition, many examples of binding systems were investigated by stopped-flow fluorescence spectroscopy, such as the binding of calmodulin to calcineurin, the binding of guanine to calf spleen purine nucleoside phosphorylase, the nucleotide cofactor binding to the *Escherichia coli* PriA Helicase, etc.

3.12 Stopped-flow Circular Dichroism

If some or all of the reactants or products of chemical and biological processes are chiral, then circular dichrosim (CD) detection may be the ideal tool for monitoring the kinetics of a reaction, and if the half-life of the reaction is of the order of milliseconds to seconds or even minutes then

stopped-flow mixing of the reagents will almost certainly be the appropriate choice of sample handling method.

CD is very commonly used method for studying protein conformational change. The combination of stopped-flow mixing and CD provides an important tool for protein investigation. The advantage of CD measurements over the other optical methods is that the far-UV signals monitor changes over the entire protein (i.e. its secondary structure). A disadvantage is that CD instruments are moderately expensive and less available than absorbance and fluorescence detectors. As one of the main applications of stopped-flow CD is in the study of protein folding and unfolding, samples are often viscous, have significant absorbance due to buffers, and the experiments often require wide and variable mixing ratios. For further information and examples the reader may consult references.[27]

3.13 Other Stopped-flow Detection Methods

It is a serious limitation that all these optical techniques can only be used for reactions that are accompanied by significant chromophoric changes. It is an additional limitation of all these techniques that optical spectra tend to be broad and often show considerable overlap. Therefore reactive species can often not be monitored individually, even in cases where all of them have distinct spectral properties. Optical methods also provide little structural information about the various species in the mixture. The use of traditional stopped-flow is dependent upon the availability of optical signals to monitor change in fluorescence, absorbance or CD that occur upon binding or chemical conversion of substrate to product. In order to overcome these limitations of traditional stopped-flow optical techniques, various detection methods have been developed, such as stopped-flow mass spectrometry (MS), stopped-flow NMR, and stopped-flow EPR.

3.13.1 Stopped-flow EPR

Stopped-flow instruments with optical detection have been established since 1952, and stopped-flow techniques with EPR detection were first introduced in 1960. Stopped-flow EPR accessories with improved driving systems have been available since 1980. A stopped-flow experiment with EPR detection allows the observation of a time-dependent change of the amplitude of an EPR signal at a distinct field value (usually at the maximum of first derivative) during the reaction of two reactants in the liquid state by time-sweep acquisition (kinetic display). The result of such a measurement is a rate constant for formation, decay, or conversion of a paramagnetic species, for example a radical occurring in the reaction mixture. The procedure is analogous to the well-established case of stopped-flow operation with optical detection in which a time dependence of the optical absorption at a distinct wavelength is observed.

Typical applications of stopped-flow EPR instruments have been reported in chemistry and biochemistry, and the kinetics of transient radicals occurring in typical redox reactions with life-times down to milliseconds have been published. Examples are the decay of stable nitroxide radicals during reduction by ascorbate[28] or dithionite,[29] and formation and decay of semi-dehydro ascorbate radicals during the oxidation of ascorbate by Ce^{4+}.[30] Recently, a novel EPR stopped-flow accessory was described which allows time-dependent cw-EPR measurements of rate constants of reactions involving paramagnetic species after rapid mixing of two liquid reagents. This EPR stopped-flow design represents a state-of-the-art, computer controlled fluid driving system, a miniresonant EPR structure with an integrated small ball mixer, and a stopping valve.[31]

3.13.2 Stopped-flow Fourier Transform Infrared Spectroscopy

Stopped-flow mixing coupled with time-resolved Fourier transform infrared (FTIR) spectroscopy (*see* ***Vibrational Spectroscopy***) represents a new experimental approach to explore kinetic events, which has become possible only recently with the development of appropriate techniques. Thorneley *et al*. developed stopped-flow FTIR as a probe of the dynamics of metalloenzyme-substrate interactions, such as the binding of CO to molybdenum nitrogenase,[32] the binding chemistry of NO to cytochrome c' from *Alcaligenes xylosoxidans*., the hydroxylation of a substrate by diiron-(IV) intermediate, and the reaction between hydrogen and the [NiFe]-hydrogenase from *Allochromatium Vinosum*.[33]

The strongest advantage of the FTIR approach as a structure-specific probe is that a complete spectrum is available for each time point of measurement. Methods to study protein folding by stopped-flow FTIR have been reviewed.[34] In this way, several spectral windows are accessible simultaneously for the observation of the formation of different secondary structure elements and also events that can be attributed to changes in tertiary structure. One specific advantage of the infrared technique is the ability to monitor directly the kinetics of processes involving β-sheet structures, which is exceptionally difficult to do with other techniques.

3.13.3 Stopped-flow Conductivity

Many fast reactions do not result in measurable changes in absorbance or fluorescence. A large number, however, do exhibit a change in conductivity as the reaction progresses. The use of a stopped-flow system equipped with conductivity measurement facilities can, therefore, considerably extend the scope of this already powerful technique. Conductivity measurements offer greater signal-to-noise and a much better dynamic range than spectrophotometric measurements. Reactions are generally characterised before the kinetic study is carried out to ensure that conductivity changes are due solely to the reaction of interest. Conductivity measurements can be made in

the presence of a large, but constant background signal, so it is possible to work with comparatively large buffer concentrations and to use nonaqueous ionising solvents such as ethanol and acetone. One example involves the oxidation of ferrocyanide by birnessite studied by stopped-flow conductivity measurements. Two processes were detected by the stopped-flow experiments.[35]

3.13.4 *Stopped-flow Light Scattering*

Kinetic recordings of light scattering can be obtained in a conventional stopped-flow spectrometer. For example, the kinetics of the interaction between DNA and cationic vesicles were followed using stopped-flow light scattering techniques.[36] Stopped-flow scattering was used as a tool for the characterization of solution structures of DNA-cationic vesicle complexes. The combination of light scattering, fluorescence and small-angle neutron scattering measurements provided information about the minimum number of stages and time scales for the formation of DNA-cationic vesicle complexes, as well as information about the structures of intermediates.

3.13.5 *Additional Modes*

A highly useful application of fluorescence spectroscopy is the technique known as fluorescence resonant energy transfer (FRET). The basic principle is to have a pair of chromophores attached to a molecule. One chromophore, the donor, absorbs the excitation energy and transfers this excitation energy to the second chromophore, the acceptor, through a dipole–dipole interaction mechanism. FRET can potentially give more specific information on the changes in average distance between fluorescence donors and acceptors. For example, the combination of stopped-flow and FRET is available for kinetic investigation of GAAA tetraloop-receptor docking and monitoring the rate of DNA bending.[37,38]

Luminescence measurements can also be carried out by using a conventional stopped-flow apparatus. In additional, stopped-flow techniques are used in conjunction with NMR (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Inorganic/Organometallic Molecules***), MS, and electrospray ionization mass spectrometry (ESI-MS).

3.14 Additional Considerations

3.14.1 *Limitations of Stopped-flow Techniques*

Transient-state kinetic analysis is most commonly based upon stopped-flow methods where an optical signal is used to follow the time dependence of a reaction; however, it is often difficult or impossible to rigorously interpret the optical signal. For example, if the absolute extinction coefficients and concentrations of species contributing to the optical signal are not known, then the reaction pathway cannot be determined unambiguously. Some fast reactions do not result in measurable changes in absorbance or fluorescence. These problems can also be solved by use of chemical quench-flow methods. Quench-flow methods do not require a chromophore and is a complementary alternative technique for traditional stopped-flow. In these experiments a reaction is initiated by rapid mixing of two or more reactants, followed by mixing with a quenching reactant (e.g. acid, base, or liquid nitrogen) after a specified period of time. This step abruptly stops the reaction. Subsequently the reaction mixture is analyzed off-line using methods such as chromatography, NMR, or MS. Quench-flow experiments require that the quenched reaction mixture be stable during the off-line analysis, which often presents a problem. The difference between these approaches is that in stopped-flow, an optical signal is produced and observed during a reaction, while in quench flow, the reaction is stopped by a quenching solution and the reaction mixture is analyzed by chemical methods.

The time resolution in optical stopped-flow experiments is typically in the millisecond time range; sub-millisecond resolution can be achieved by using specially designed mixers. In optical experiments using pulsed-flow or continuous-flow methods a time resolution in the microsecond range can be achieved. Continuous-flow measurements can achieve shorter dead times compared to stopped-flow, but this comes at the expense of sample economy. For a very rapid reaction that is complete within the mixing time of the stopped-flow instrument, the majority and indeed the entire kinetic time course may be lost. Some rapid reactions can be followed at lower temperature, lower concentration, or different pH. For example, if the reactions are too rapid to allow measurement of rate constants under pseudo-first-order conditions using the stopped-flow technique, the rate constants can be measured under second-order conditions; in order to measure such high rate constants on the stopped-flow instrument, second-order reaction conditions and low concentrations of both reaction partners may be selected to obtain conditions where the reaction is slower than the dead time of the stopped-flow instrument. Obviously, lower concentrations also reduce the signal intensity.

3.14.2 *Sample Preparation*

Sample preparation is critical to the success of any spectrophotometric experiment whether using absorbance or fluorescence detection systems. Even the rapid mixing of two samples of buffer in a sensitive instrument can result in what appears to be a reaction curve. This may be caused by simple effects such as the rapid compression and decompression of an air bubble in the flow path, the mixing of two solutions at different temperatures or the effect of the stopping process upon small dust particles present in the solution. Therefore it is essential that solutions be prepared thoroughly before use. Sometimes it is necessary to degas buffers to remove dissolved air that may otherwise come out of solution following rapid decompression of the reaction solutions. In practice, it is

important to ensure that there are no air bubbles observed in the drive syringes before triggering, as these bubbles lead to optical artefacts. If the air bubbles produce meaningless data, it is wasteful for small or expensive samples.

3.14.3 Selecting the Wavelength

If one is to use the stopped-flow apparatus in the absorbance mode it is important to know the spectra of the starting reactants and of the final products in order to select the best wavelength at which to collect kinetic data. This wavelength is generally the one where the absorbance change is greatest on going from reactants to products. This may not always be the case, and one must sometimes be prepared to work at wavelengths away from the peak in the difference spectrum in order to work in regions of the spectrum where the apparatus is more sensitive.

3.14.4 Anaerobic Experiments

For oxygen-sensitive systems, anaerobic stopped-flow techniques are required. The anaerobic kit is available from some stopped-flow companies. Two principal strategies are commonly used: either solutions and instruments are cleansed of oxygen and manipulated in a way that excludes oxygen from the experiment, or the instrument and all solutions are kept in an anaerobic chamber.

3.15 Conclusions

In summary, the simple but versatile stopped-flow technique, coupled with optical detection (typically absorbance, fluorescence, or CD), has long been the primary source of kinetic insight into fast reactions. A major strength of stopped-flow methods is that they can be readily combined with a wide range of detection methods. As the need to understand molecular mechanisms increases, stopped-flow methods will continue to play an important role.

4 ABBREVIATIONS AND ACRONYMS

CD = circular dichroism; DCPIP = 2, 6-dichlorophenolindophenol; EPR = electron paramagnetic resonance; ESI-MS = electrospray ionization mass spectrometry; FTIR = Fourier transform infrared; FRET = fluorescence resonant energy transfer; 5′-GMP = guanosine-5′-monophosphate; L-Met = L-methionine; NAAD = nicotinic acid adenine dinucleotide; MS = mass spectrometry; NMR = nuclear magnetic resonance; PEEK = polyetheretherketone; SF = stopped-flow; SVD = singular value decomposition; tu = thiourea.

METHOD SUMMARY

Acronyms, synonyms

- Resonance Raman (RR)
- Resonance Raman effect (RRE)
- Resonance Raman scattering (RRS)

Measured physical quantities

- Intensity of inelastically (Raman) scattered photons (i) as a function of the wavenumber separation (Raman shift) from the elastically (Rayleigh) scattered photons and (ii) as a function of the exciting radiation wavelengths (three-dimensional spectrum).

Information available

- Vibrational frequencies of the chromophore in resonance with incident frequency.
- Metal coordination geometry and ligand environment via analysis of vibrational frequencies.
- Metal−ligand bond strengths via analysis of vibrational frequencies.
- Electronic assignments via resonance excitation profiles (REPs).

Information NOT available, limitations

- Not useful for nonchromophoric metal sites.
- Insensitive to magnetic properties for metal centers, e.g., Zn^{2+}.
- Cannot be used for absolute quantitation of metal centers.

Examples of questions that can be answered

- What are the spin state, oxidation state, and axial ligation of this heme?
- What is the effect of this substrate/inhibitor/mutation on this metal coordination sphere?
- What type of Fe–S cluster is this?
- What is the Fe–O–Fe bond angle in this diiron center?

Major advantages

- Extremely sensitive to minor structural and electronic changes at the active site.
- Selective determination of the vibrational properties of individual chromophores possible in proteins with multiple chromophoric prosthetic groups.
- Can monitor kinetics of changes at the metal site down to the femtosecond timescale using time-resolved techniques.
- Requires minuscule amount of material for low-temperature studies ($\sim$10 µl).
- Can be used at room temperature or low temperature with (frozen) solutions, solids, or single crystals.

Major disadvantages

- Fluorescence or traces of fluorescent impurities can prevent acquisition of RR spectra.
- Meaningful vibrational analysis requires extensive isotope substitution data.
- The factors controlling the extent of resonance enhancement of discrete vibrational modes are generally not well understood.

Sample constraints

- Requires at least 10 µl of pure protein ($\sim$1 mM).

1 INTRODUCTION

Resonance Raman (RR) spectroscopy is a powerful and versatile technique for the study of both vibrational and electronic structures of chromophoric molecular systems. RR spectra are obtained by irradiation of the sample with a monochromatic light source whose energy is close to that of an electric-dipole-allowed electronic absorption band. Most of the Raman bands are attenuated by the absorption, but some bands may be greatly enhanced. This effect arises from a coupling of the electronic and vibrational transitions, and the vibrational modes that do show enhancement are localized on the chromophore, that is, on the group of atoms that give rise to the electronic transition.

Early RR spectra[1,2] indicated that only one allowed electronic transition (the resonant one) was responsible for the strongly enhanced intensity of the Raman scattering with excitation lines in the visible or near-ultraviolet region. Classical examples of these are the RR spectra of such inorganic species as MnO_4^-, CrO_4^{2-}, TiI_4, SnI_4, $Mo_2Cl_8^{4-}$, etc.[1] All of the above are characterized by an enormous enhancement of the intensity of one or more totally symmetric vibrational modes, together with an appearance of a long series of overtone bands (usually only one of the totally symmetric modes). The RR spectroscopic studies of the $Mo_2Cl_8^{4-}$ ion[3,4] had verified the close relationship between the electronic transition and the vibrational mode to be resonance enhanced.

This ion exhibits an intense absorption band at ~525 nm, which arises from the allowed $\delta \rightarrow \delta^*$ charge-transfer (CT) transition involving excitation of a δ-electron of the quadruple Mo–Mo bond.[5] Thus, it is not surprising that of the three totally symmetric fundamentals, ν(MoMo), ν(MoCl), and δ(ClMoCl), it was only the ν(MoMo) stretch that showed strong RR activity in the spectrum taken with excitation corresponding to the $\delta \rightarrow \delta^*$ CT transition. Similar RR spectra obtained from other metal–metal bonded $M_2X_8{}^{n-}$ ions[6] have led to the correction of their electronic spectra assignments in the visible region.

The advantage of selective enhancement has quickly made RR spectroscopy a favorite method for the study of relatively large molecules such as heme proteins,[7–14] whose chromophoric center is an iron porphyrin complex (*see* ***Iron Porphyrin Chemistry***). Excitations in the visible and near-ultraviolet region have produced relatively simple Raman spectra, because only the vibrations associated with the heme chromophore are resonance enhanced, but the vibrations of the surrounding polypeptide chains are not. Among those enhanced, the in-plane stretching vibrations of the porphyrin ring (1000–1700 cm^{-1}) showed the largest increase in intensity due to interactions with the $\pi \rightarrow \pi^*$ allowed electronic transitions (400–600 nm), which are also polarized in the porphyrin plane. There was further differentiation of this set, with bands enhanced depending upon whether the excitation wavelength was tuned to the near-UV (Soret) or visible bands (α and β). The RR spectra obtained by using excitation lines with $\lambda_{ex} < 500$ nm, i.e., with lines approaching the energy of the Soret band, were dominated by bands attributable to totally symmetric vibrations. On the other hand, such vibrations were not observed when $\lambda_{ex} > 500$ nm were used (α–β region). Instead, bands attributable to nontotally symmetric vibrations were strongly enhanced. This differential enhancement of the Raman bands in different scattering regimes of heme proteins is the first reported example of more complex resonance behavior under multiple resonant state conditions.[7–10] It attracted the attention of theorists and inspired the development of the vibronic theory of RR scattering (*vide infra*).

Progress in the field of Raman and RR spectroscopy has been heavily dependent on laser technology. The advent of accessible and relatively inexpensive laser sources in the early 1960s has caused a revolution in Raman techniques, by largely displacing the traditional mercury discharge lamp as a Raman excitation source. Before lasers were available, the process of obtaining a good quality Raman spectrum of anything but the most straightforward molecular systems involved as much art as science, required about 10–20 ml of sample, and was often a very time-consuming operation. While important early investigations of resonance enhancement were carried out,[15] highly colored materials could not be studied. The laser has changed this situation dramatically by providing an intense directional line source. In fact, the laser is almost ideal as a Raman excitation source; it gives a very narrow, highly monochromatic beam of intense radiation, which can be focused very precisely into a small sample under a variety of flexible sampling geometries.[16–18] The sample can be moved rapidly through the laser beam to minimize complications due to local heating or photochemistry. In addition to the development of laser technology, the introduction of extremely sensitive phototubes and later diode array transducers enabled Raman and RR spectra to be recorded photoelectrically rather than photographically, with consequent enormous saving in recording time. Further, high-quality double and triple monochromators, spectrographs, cutoff filters, and Fourier-transform Raman interferometers of high efficiency have been developed,[19] so that it is now possible to scan to within a few wavenumbers of the exciting laser line and acquire excellent quality Raman and RR spectra of any material in any physical state.

Technical advances continue to grow, and applications will certainly multiply. The purpose of this article is to lay out the principles behind RR spectroscopy and to illustrate them with examples from recent research, especially in the context of bioinorganic chemistry.

2 TECHNICAL BACKGROUND

2.1 IR and Raman Basics

Molecular vibrational frequencies (10^{-13}–10^{-14} Hz) lie in the infrared (IR) region of the electromagnetic spectrum. Transitions to vibrationally excited states can therefore be probed by direct absorption of IR photons (IR spectroscopy) (*see* ***Vibrational Spectroscopy***).[20–22] All molecules except homonuclear diatomic molecules (e.g., H_2, O_2, N_2, and the halogens) absorb IR light. In IR spectroscopy the vibrational frequency is observed as a peak in the absorption spectrum at the absolute frequency of the absorbed IR radiation. Alternatively, inelastic collisions of the sample molecules with the quanta of light in the ultraviolet, visible, or near-infrared regions can induce the same vibrational transition via an inelastic light scattering process. This Raman process is shown diagrammatically in relation to IR absorption in Figure 1. All molecules including the homonuclear diatomics are Raman scatterers. In Raman spectroscopy, the exciting photon has much higher frequency and energy than the molecular vibration. As a result of the inelastic collision, part of the incident photon energy $h\nu_0$, equal to the vibrational quantum, $\upsilon \rightarrow \upsilon'$, is retained by the vibrating molecule, while the scattered photon emerges with lower frequency, $\nu_0 - \nu_{\upsilon,\upsilon'}$, and energy $h(\nu_0 - \nu_{\upsilon,\upsilon'})$ (Stokes scattered radiation). The molecular vibration is therefore encoded in the Raman spectrum as the frequency separation between the incident photon (or the elastic scattering Rayleigh peak) and the scattered photon (Figure 2). A Raman experiment requires illuminating the sample with *monochromatic* radiation and

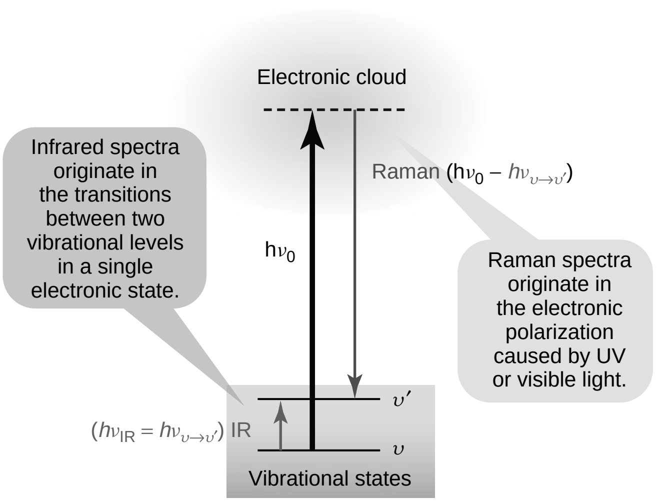

Figure 1 Origin of infrared (IR) absorption and Raman scattering spectra

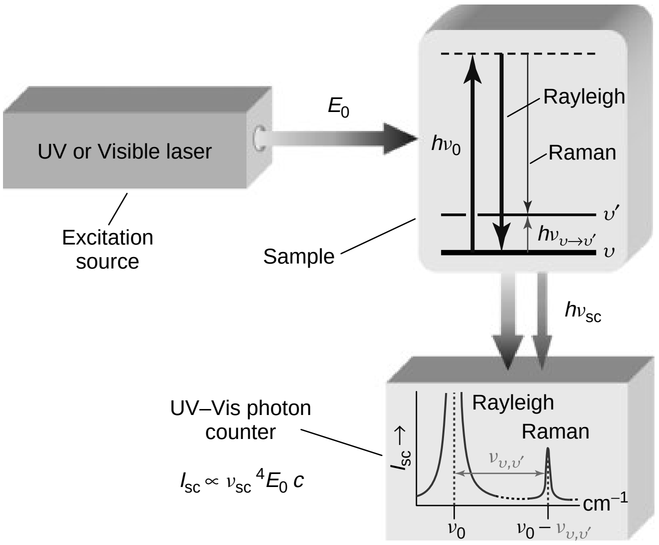

Figure 2 Measurement of scattered light at 90°: The excitation radiation for the Raman experiment must be monochromatic. Scattering of UV or visible photons produces an intense Rayleigh peak and weaker Raman peaks, displaced from the Rayleigh by $\nu_{\upsilon,\upsilon'}$. These arise because of energy transfer from the incident photon $h\nu_0$ to the molecule, which is raised to an excited vibrational level. The readout signal is proportional to the flux of the scattered light (I_{sc}), which is directly related to the fourth power of the scattered frequency (ν_{sc}), irradiance of the source (E_0), and the concentration of scattering molecules

analyzing the polychromatic radiation scattered by the sample. In practice, a monochromatic radiation of any convenient frequency from the laser is shone on to the sample and the absolute radiant power of scattering can be measured at any convenient angle with respect to the excitation beam; 90° collection geometry is shown in Figure 2.

If the incident frequency is offset to zero, then Raman peaks occur at the same frequencies as peaks in the IR spectrum. Different selection rules, however, govern the intensity of the IR- and Raman-active vibrational modes. Absorption of IR photons requires a change in the dipole moment during molecular vibration, and IR band intensity $I_{IR} \propto (\partial\mu/\partial Q_k)^2$, where μ is the dipole moment and Q_k is the vibrational coordinate. Raman scattering, on the other hand, depends on the variation of the polarizability (or induced dipole moment) of the molecule, α, during vibration, and Raman band intensity $I_R \propto (\partial\alpha/\partial Q_k)^2$. Hence, the vibrations of polar bonds such as O–H, N–H, S–H, and C=O are more readily observed in the IR spectrum, while vibrations of less polar bonds are better seen in the Raman spectrum (C≡C, C=C, P=S, S–S, and C–S). Moreover, totally symmetric bond stretching vibrations, which preserve the symmetry of the molecule and produce large polarizability changes, usually dominate the Raman spectra, whereas antisymmetric stretching and deformation modes, which distort the molecule and involve large dipole moment changes, tend to be more intense in IR spectra. This makes Raman spectroscopy more favorable for the study of biological materials, because there is considerably less spectral interference from the deformation modes associated with the H-bond network of water molecules; these are often dominant features in the IR spectra of aqueous samples.[20] The IR spectra of liquid H_2O and D_2O are shown in Figure 3. The Raman spectra of liquid and frozen water (H_2O, D_2O) are shown in Figure 4.

For highly symmetrical molecules and ions such as $TiCl_4$ (T_d), C_6H_6 (D_{6h}), and $PtCl_4{}^{2-}$ (D_{4h}), both IR and Raman spectroscopies are required to obtain the full set of vibrational frequencies. If a molecule or an ion possesses a center of inversion, there is a *rule of mutual exclusion*; no fundamental vibration that is active in the IR absorption can be active in the Raman scattering, and no fundamental vibration that is active

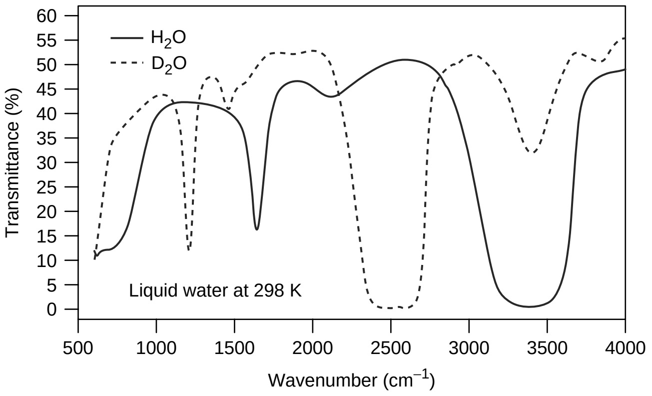

Figure 3 Infrared spectra of neat liquid H_2O (solid line) and D_2O (dashed line)

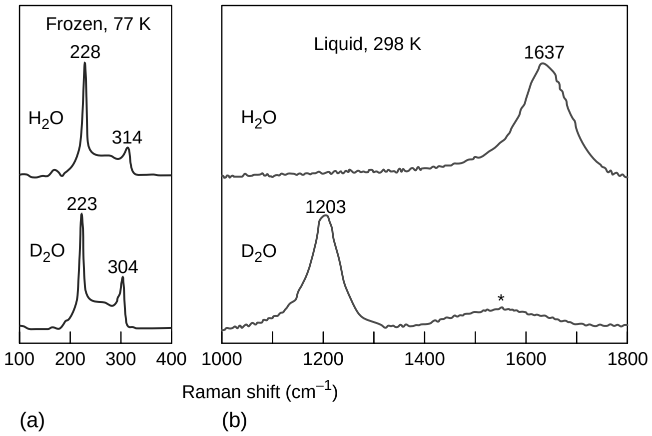

Figure 4 Raman spectra of H_2O and D_2O: (a) as ice at 77 K and (b) as neat liquid at 298 K

in the Raman scattering can be active in the IR absorption. Thus, IR absorption and Raman scattering are complementary and overlapping methods for investigating the vibrations of molecules. Table 1 summarizes the basic aspects of IR and Raman spectroscopy.

2.2 The Raman Effect

The Raman effect – first predicted from theoretical considerations by A. Smekal (1923) and H. A. Kramers and W. Heisenberg (1924) – is a *light scattering* phenomenon with a change of frequency.[23,24] When monochromatic light of frequency ν_0 passes through molecular matter, much of the light continues in its original direction, but a small fraction ($\sim10^{-3}$) is scattered in other directions (Figure 5). Most of the scattered light emerges at the same frequency as the incident light; this is *elastic* or *Rayleigh scattering*; except for being deflected, the photons neither lose nor gain energy in their collisions with molecules. Rayleigh scattering carries no information about molecular vibrational transitions. A few collisions, however, are *inelastic*. A net transfer of quantized energy ($\Delta E = h\nu_k$) occurs and some scattered light ($\sim10^{-6}$) obtains new modified frequencies ($\nu_0 \pm \nu_k$). The frequency changes are equal to the frequencies associated with transitions between vibrational (υ_k) or, less frequently, rotational or electronic levels of the system. These two forms of light scattering with change of frequency were first observed by C. V. Raman and K. S. Krishnan in liquids,[25,26] and independently by G. Landsberg and L. Mandelstam in

Table 1 Basic characteristics of infrared (IR) and Raman spectroscopy[a]

Parameter	Infrared spectroscopy	Raman spectroscopy
Spectroscopic phenomenon	Absorption of light: $h\nu_{IR} = \Delta E_{vibr}$	Inelastic scattering of light: $h\nu_{ex} - h\nu_{sc} = \Delta E_{vibr}$
Allowed transition	$\Delta\upsilon = +1, +2, +3, \ldots$	$\Delta\upsilon = \pm1, \pm2, \pm3, \ldots$ (transitions for $\Delta\upsilon = +2, +3, \ldots$, i.e., overtones are considerably less conspicuous than in IR)
Excitation	Polychromatic IR radiation	Monochromatic radiation (ν_{ex}) in the UV, visible, or near IR
Molecular origin	Dipole moment: $\mu = q\boldsymbol{r}$	Induced dipole moment: $\boldsymbol{P} = \alpha\boldsymbol{E}$
Requirement for vibrational activity	Change in dipole moment during vibration: $(\partial\mu/\partial Q_k)0 \neq 0$	Change in polarizability during vibration: $(\partial\alpha/\partial Q_k)0 \neq 0$
Band intensity	$I_{IR}{}^{1/2} \propto (\partial\mu/\partial Q_k)0$	$I_R{}^{1/2} \propto (\partial\alpha/\partial Q_k)_0$
Frequency measurement	Absolute: $\nu_{vibr} = \nu_{IR}$	Relative to the excitation frequency: $\nu_{vibr} = \nu_{ex} - \nu_{sc}$
Readout signal	Comparative: transmittance: ($T = \Phi_s/\Phi_r$) or absorbance ($A = -\log T$)	Absolute: radiant power or intensity of scattered radiation
Spectral plot	Linear in $\%T$ or logarithmic in A versus wavenumber (cm^{-1})	Linear: Raman intensity versus wavenumber shift (cm^{-1})
Dominant spectral feature	Vibrations destroying molecular symmetry: antisymmetric stretching and deformation modes	Vibrations preserving molecular symmetry: symmetric stretching modes
Inactive molecule	Homonuclear diatomics	None
Centrosymmetric molecule	Only ‘‘u’’-symmetry modes active	Only ‘‘g’’-symmetry modes active
Medium	Water is a strong absorber and is a poor solvent for IR studies	Water is a weak scatterer and is a good solvent for Raman studies

[a] h, Planck’s constant; ΔE_{vibr}, energy difference of vibrational levels; ν, photon frequency; $\Delta\upsilon$, change in vibrational quantum number; q, charge; $\boldsymbol{r}$, charge spacing; α, molecular polarizability; $\boldsymbol{E}$, electric field; Φ_s and Φ_s, radiant powers transmitted by the sample and reference cells, respectively; Q_k, vibrational normal coordinate ($k \leqslant 3N - 6$); ‘‘g’’ and ‘‘u’’, normal modes of vibration symmetric (*gerade*) and antisymmetric (*ungerade*) with respect to the molecular center of inversion.

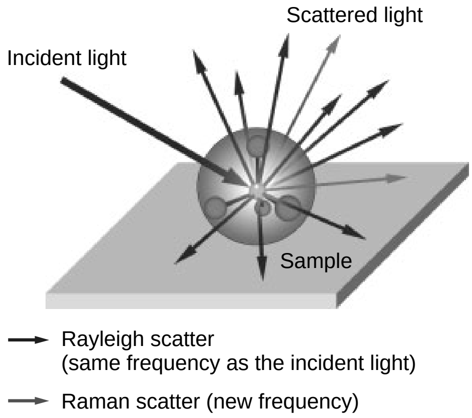

Figure 5 Principle of Rayleigh (elastic) and Raman (inelastic) scattering

quartz[27] in 1928, and are now called *Raman scattering*. C. V. Raman received the Nobel Prize in 1930 for his work on the scattering of light. In 1998, the Raman effect was designated an ACS National Historical Chemical Landmark in recognition of its significance as a tool for analyzing the composition of liquids, gases, and solids. Radiation scattered with a frequency lower than that of the incident light (i.e., $\nu_0 - \nu_k$) is referred to as *Stokes Raman scattering*, while that at the higher frequency (i.e., $\nu_0 + \nu_k$) is called *anti-Stokes Raman scattering*. The magnitude of the frequency shift from the incident radiation provides a measure of the vibrational energy level spacing. In practice, the former spectral region is used for this purpose because the Stokes Raman scattering is *always* more intense than the anti-Stokes Raman at normal temperatures.

The transfer of energy results from the perturbation of the electronic wavefunction of the molecule by the rapidly changing electric field of the photon. The wavefunction of the perturbed system can be expressed as a linear combination of all possible wavefunctions of the unperturbed molecule, with time-dependent coefficients. For a very short time interval ($<10^{-14}$ s), the photon loses identity and becomes indistinguishable from the kinetic and potential energy of the perturbed electrons. Formally, the molecule is regarded as having attained a higher nonstationary energy level (*virtual state*); it returns to a stationary (typically vibrational) state by reemitting (scattering) a photon (Figure 6). If the molecule returns to its original stationary state, the reemitted photon has the same frequency as the incident photon (Rayleigh scattering, $\nu_{sc} = \nu_0$). However, if the final state differs from the initial state by a vibrational quantum ($h\nu_k$), the photon is reemitted with shifted frequencies (Raman scattering, $\nu_{sc} = \nu_0 \pm \nu_k$). At temperatures normally used, a decrease

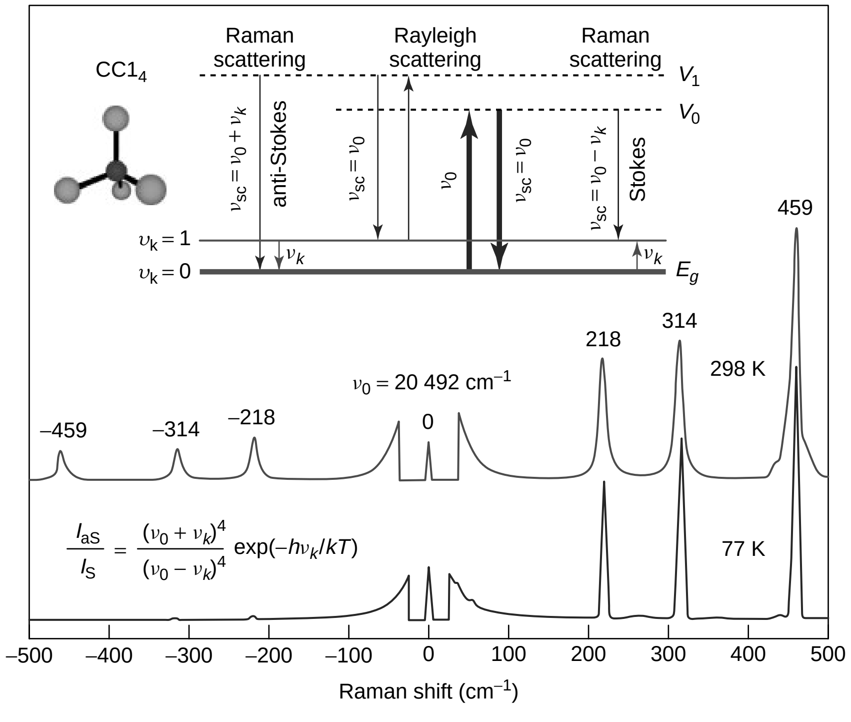

Figure 6 Energy transfer diagram illustrating Rayleigh and Raman scattering (*top*), and Raman spectra for CCl_4 excited at room (298 K) and liquid-N_2 (77 K) temperatures by Ar^+ ion laser radiation of $\lambda_0 = 488.0$ nm or $\nu_0 = 20\,492$ cm^{-1} (*bottom*). The number above the peaks is the Raman shift, $\Delta\tilde{\nu} = \tilde{\nu}_0 - \tilde{\nu}_{sc}$ cm^{-1}. Since the fraction of molecules occupying excited states depends on the Boltzmann factor ($kT = 207$ cm^{-1} at 298 K), the intensities of anti-Stokes bands fall off rapidly with decreasing temperature ($kT = 54$ cm^{-1} at 77 K) and increasing vibrational frequency ν_k

in frequency (Stokes emission) is more probable because there are few thermally excited molecules. Although we can speak of a sequence of events in which the emission of a photon from the virtual state follows an absorption process, it is important to appreciate that these processes are actually simultaneous and cannot be separated in time. This means that the Rayleigh and Raman scattering are two-photon processes in which one photon is destroyed and one created at the same time (*induced secondary emission processes*).

The scattered radiation has a spectrum characteristic of the given substance, with an intense band at the incident frequency, ν_0, resulting from Rayleigh scattering, and fainter Raman bands on both sides of ν_0 at distances corresponding to the molecular vibrational frequencies, ν_k. Typical examples of such bands are seen in Figure 6, which displays the Raman spectra obtained on pure carbon tetrachloride, CCl_4, at 298 K (liquid) and 77 K (frozen liquid) upon excitation with an Ar^+ ion laser line at 488.0 nm (20 492 cm^{-1}).[28,29] The measured spectral frequencies are expressed in wavenumber shifts $\Delta\tilde{\nu}$, or *Raman shifts*, which are defined as the *difference in wavenumbers* (cm^{-1}) between the incident and scattered rays, $\Delta\tilde{\nu} = \tilde{\nu}_0 - \tilde{\nu}_{sc}$. Hence, $\Delta\tilde{\nu} = \tilde{\nu}_0 - \tilde{\nu}_0 = 0\,cm^{-1}$ for the Rayleigh peak and $\Delta\tilde{\nu} = \tilde{\nu}_0 - (\tilde{\nu}_0 \pm \tilde{\nu}_k) = \pm\tilde{\nu}_k\,cm^{-1}$ for the Raman peaks. Since Stokes transitions occur at wavenumbers $\tilde{\nu}_0 - \tilde{\nu}_k$, they exhibit *positive* Raman shifts (an *increase* of energy by the scattering system); anti-Stokes transitions occur at $\tilde{\nu}_0 + \tilde{\nu}_k$, and exhibit *negative* Raman shifts (a *decrease* of energy by the scattering system). That is, Stokes bands of CCl_4 are found at 218, 314, and 459 cm^{-1} while their anti-Stokes counterparts occur at −218, −314, and −459 cm^{-1}, regardless of the wavelength of excitation. In general, only the *fundamental* vibrational modes show up in the Raman spectrum because of the much greater probability of transitions involving the two lowest energy vibrational states ($\upsilon_k = 0$, $\upsilon'_k = 1$) of a molecule.

2.3 Requirements for Raman Scattering

In Rayleigh scattering, the sample particles, like molecules, scatter radiation *elastically* by removing radiant energy from the incident beam of (usually) UV–visible photons and instantly reemitting that energy in all directions as the molecules return to their unperturbed forms.[21] Except for undergoing a brief polarization, i.e., momentary distortions on irradiation, the scattering molecules neither gain nor lose energy in their collisions with photons. The Rayleigh light intensity increases with the size of scattering particles; it has a symmetrical and uniform angular distribution, and varies directly with the fourth power of the frequency. For a substance to Rayleigh scatter radiation, it must possess polarizable molecules or aggregates of polarizable molecules with dimensions significantly smaller ($d_m < 0.05\lambda_0$) than the wavelength of the incident radiation (λ_0). (Scattering of radiation by larger particles ($0.05\lambda_0 < d_m < \lambda_0$) is often called *Debye scattering*, while that by still larger particles ($d_m > \lambda_0$) is often termed *Mie scattering*.) Since typical molecular dimensions are on the order of nanometers, the UV–visible photons (∼200–680 nm) readily satisfy this criterion and Rayleigh scattering will always be observed in the Raman spectrum, unless it is suppressed with bandpass filters.

The Raman effect differs from Rayleigh scattering in that the molecules scatter part of the incident radiation energy *inelastically* by increasing (Stokes) or decreasing (anti-Stokes) their own (usually) vibrational energy. For a molecular vibration to Raman scatter radiation, it must (i) have a frequency considerably lower than that of the incident radiation and (ii) change the magnitude and/or direction of the *induced electric dipole moment*, or of the molecular polarizability. Excitation (for a spontaneous Raman effect) must be carried out by radiation having a frequency that is well away from any electronic absorption transitions. These criteria are easy to describe physically when we remember that light can be considered as having oscillating electric and magnetic fields and that a molecule has an electron cloud of negatively charged orbitals. *A molecule scatters electromagnetic radiation because it is polarizable*. When a fluctuating electric field $\boldsymbol{E}$ of frequency ν_0 (laser beam) $\gg \nu_k$ (vibrational frequency) strikes a molecule, it sets the electron cloud around heavy and fixed nuclei of the molecule into oscillatory motion. In its distorted form, the molecule is temporarily *polarized*, that is, it undergoes a momentary charge displacement, forming an *induced electric dipole moment* $\boldsymbol{P}$, which oscillates at the frequency, ν_0, of the incoming laser beam. However, if the oscillating dipole induced by light activates (excites) or deactivates (relaxes) a molecular vibration of frequency ν_k, the frequency of the electron cloud oscillation will change correspondingly to $\nu_0 - \nu_k$ or $\nu_0 + \nu_k$. Thus, the polarized molecule becomes an instant source of its own radiation (vibrating electrons emit radiation in all directions) by reemitting excitation energy as light of frequency $\nu_{sc} = \nu_0$ on immediately relaxing to its original stationary energy state (Rayleigh scattering) or at frequencies $\nu_{sc} = \nu_0 \pm \nu_k$ on returning to its stationary states other than the original one (Raman scattering).

The scattered intensity varies directly with the square of the induced dipole moment $\boldsymbol{P} = \alpha\boldsymbol{E}$, where α is the polarizability of the molecule, a volumetric measure of its electron cloud distortion in the path of an incident light, relative to the nuclear framework. The polarizability α is closely related to the structure and bonding properties of the molecule and is *always* nonzero; it increases with decreasing electron density, decreasing bond strength, and increasing bond length. The probability of transition for fundamentals in the Raman spectrum is proportional to the square of the polarizability gradient along the normal coordinate of the vibration, $(\partial\alpha/\partial Q_k)_0$. Accordingly, if there is no net change in polarizability when the vibration occurs, i.e., $(\partial\alpha/\partial Q_k)_0 = 0$, the intensity of a band in the Raman spectrum equals zero and the vibration is said to be Raman inactive. In contrast, the probability of transition of fundamentals in IR absorption

is proportional to the square of the dipole moment gradient along the normal coordinate of the vibration, $(\partial\mu/\partial Q_k)_0$. Accordingly, if there is no change in dipole moment when the vibration occurs, i.e., $(\partial\mu/\partial Q_k)_0 = 0$, the intensity of a vibrational band in the IR spectrum equals zero and the vibration is said to be IR inactive.

2.4 Molecular Symmetry and Vibrational Activity

For a molecule that has little or no symmetry, it is usually correct to assume that all its vibrational modes are both IR and Raman active.[20,21] However, when the molecule has considerable symmetry, it is not always easy to picture whether the molecular dipole moment and polarizability will change during the vibration, especially for large and complex molecules. Fortunately, we can easily solve this problem by resorting to simple symmetry selection rules. The molecular vibration is active in IR absorption if it belongs to the same representation as at least one of the dipole moment components (μ_x, μ_y, μ_z) or, since the dipole moment is a vector, as one of the Cartesian coordinates (x, y, z). In contrast, the molecular vibration is active in Raman scattering if it belongs to the same representation as at least one of the polarizability components (α_{xx}, α_{xy}, etc.) or, since the polarizability is a tensor, as one of the binary products of Cartesian coordinates (x^2, xy, etc.) or their linear combinations ($x^2 + y^2$, $x^2 - y^2$, etc.). The symmetry species of the Cartesian coordinates and their binary products are customarily given in the point group *character tables*. IR and Raman activities for vibrational modes of any symmetry species can therefore be simply read off from these tables. Figure 7 is an example of a character table for the point group $C_{4\upsilon}$. It follows from that table that the symmetry species (irreducible representations) $\Gamma(z) = A_1$ and $\Gamma(x, y) = E$, and hence fundamental vibrations of type A_1 and E are *allowed* and of type A_2, B_1, and B_2 are *forbidden* in the IR spectrum for any molecule that belongs to the $C_{4\upsilon}$ point group. The vibrations of type A_2 are also *forbidden* in the Raman spectrum of $C_{4\upsilon}$ molecules but those of type A_1, B_1, B_2, and E are all Raman *allowed* because $\Gamma(x^2 + y^2, x^2) = A_1$, $\Gamma(x^2 - y^2) = B_1$, $\Gamma(xy) = B_2$, and $\Gamma(xz, yz) = E$ in $C_{4\upsilon}$ point group.

2.5 Depolarization Ratios and Symmetry of Vibrations

Useful information on the scattering process and on the symmetry of the vibration involved can be obtained by measuring the depolarization ratio, ρ, of a Raman band.[1,21,24,30] The incident and scattered photons in Raman scattering both involve a polarization (plane in which the radiation vibrates), and the polarization of the scattered light is related to but not necessarily the same as that of the incident light, even if the sample molecules are randomly oriented. If the incident radiation is linearly (or plane) polarized, as it is with a laser source, the Raman scattered light can be polarized to various degrees that depend on the nature of the active vibration. The depolarization ratio is given by $\rho = I_\perp/I_\parallel$, where $I_\perp$ and $I_\parallel$ are the intensities of Raman light that is linearly polarized perpendicular and parallel, respectively, to the polarization of the excitation radiation. Experimentally, it is obtained by inserting a polarization analyzer between the sample and the monochromator, which upon rotation by 90° passes $I_\perp$ or $I_\parallel$ (Figure 8). For totally symmetric vibrations, which by nature do preserve molecular symmetry during the motion of the nuclei, the incident beam polarization is largely maintained in the scattered light leading to small ρ values ($0 \leqslant \rho < 3/4$,

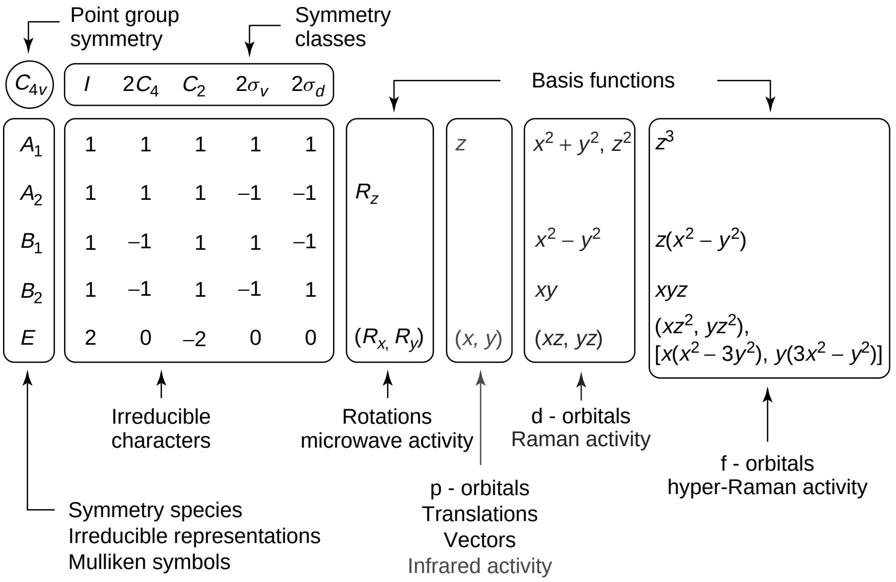

Figure 7 The structure of the character table for the symmetry point group $C_{4\upsilon}$

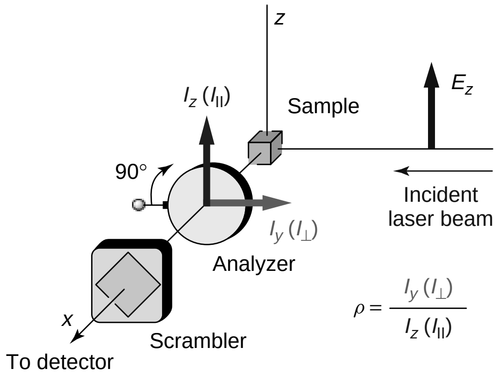

Figure 8 Schematic layout of a typical 90° Raman depolarization experiment showing the positions of the polarization analyzer and the scrambler. The analyzer may simply be a polaroid sheet, which can be rotated by 90° to allow the parallel (||) and perpendicular (⊥) components of the scattered light to pass through to the detector. The function of a scrambler is to change linear into circular polarization of the light entering the Raman spectrometer slit in order to avoid measurement errors due to the variable spectrometer transmittance of the light polarized in different directions

polarized Raman bands). The higher the symmetry of a molecule, the closer to zero is the value of ρ. It should also be pointed out that the polarized bands are (usually) the strongest features in the Raman spectrum. On the other hand, if the vibrational motion distorts the symmetry (nontotally symmetric vibrations), a significant depolarization can occur producing depolarized Raman bands. From scattering theory, it is predicted that for such vibrations $\rho = 3/4$. In the Raman spectrum of CCl_4, shown in Figure 9, the dominant band at 459 cm^{-1} loses nearly all intensity in the perpendicular scattering ($\rho = 0.006$) and a number of weaker bands at 217, 314, 759, and 788 cm^{-1} are only slightly weakened ($\rho = 0.75$). The band at 459 cm^{-1} is therefore immediately assignable to a totally symmetric vibration of the molecule and the ones at 217, 314, 759, and 788 cm^{-1} cannot arise from totally symmetric modes.

Under resonance or near-resonance excitation conditions, however, certain nontotally symmetric modes can also give rise to anomalously ($\rho > 3/4$) or even inversely ($\rho = \infty$) polarized Raman bands.[9] Figure 10 depicts RR spectra of nickel(II) porphine (NiP) and indeed the strongest bands show exactly the opposite of what is observed for CCl_4 (Figure 9), i.e., the perpendicular scattered radiation (⊥) is dramatically more intense than that with parallel radiation (||). NiP has a D_{4h} symmetry and these bands arise from the A_{2g} vibrational modes that have rotational symmetry themselves ($\Gamma(R_z) = A_{2g}$ in D_{4h} point group). Modes of this type are normally Raman forbidden, but can be activated under certain resonant excitations in the RR spectrum by vibronic mixing of excited electronic states (*vide infra*). Table 2 summarizes the ranges of values expected for the depolarization ratio for bands arising from modes of various symmetries in the off-resonance and RR spectra.[1,30]

The depolarization ratio in Raman scattering has no true counterpart in IR absorption. However, the dipole moment is

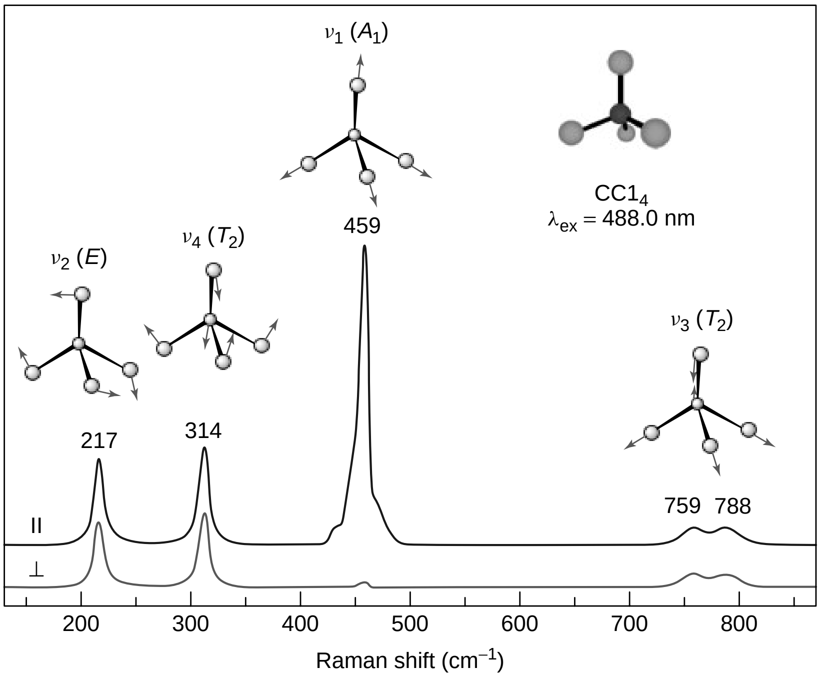

Figure 9 Parallel (||) and perpendicular (⊥) scattered Raman spectra from liquid CCl_4 showing the polarized (ν_1) and depolarized (ν_2, ν_3, and ν_4) bands associated with totally symmetric (A_1) and nontotally symmetric (E, T_2) vibrations, respectively

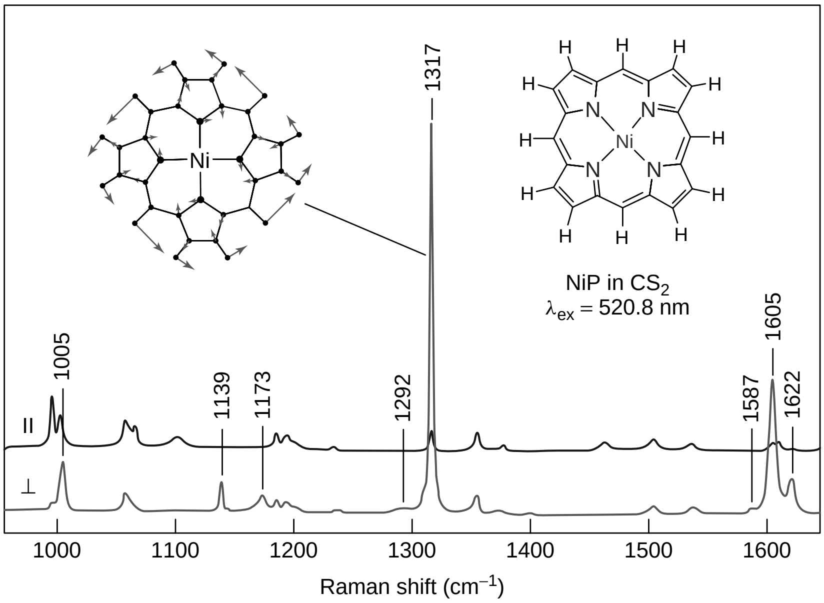

Figure 10 Parallel (||) and perpendicular (⊥) scattered resonance Raman spectra from NiP in CS_2 showing the anomalously polarized bands (labeled) associated with the ring A_{2g} vibrations

Table 2 Values of depolarization ratio for vibrational Raman bands observed in normal Raman and resonance Raman spectra

Type of Raman scattering	Vibrational band character	Polarizability tensor symmetry	Depolarization ratio
Off-resonance (all cases) and resonance (most cases)	Polarized (totally symmetric modes)	Symmetric, $\alpha_{\rho\sigma} = \alpha_{\sigma\rho}$	$0 < \rho < 3/4$
	Depolarized (nontotally symmetric modes)	Symmetric, $\alpha_{\rho\sigma} = \alpha_{\sigma\rho}$	$\rho = 3/4$
Resonance (special cases)	Anomalously polarized (nontotally symmetric modes, normally Raman forbidden)	Nonsymmetric, $\alpha_{\rho\sigma} \neq \alpha_{\sigma\rho}$	$\rho > 3/4$
	Inversely polarized (nontotally symmetric modes, normally Raman forbidden)	Antisymmetric, $\alpha_{\rho\sigma} = -\alpha_{\sigma\rho}$	$\rho = \infty$

a vector quantity, and the absorption of IR light depends on the relative orientation of the molecule and the photon electric vector. If all the molecules are aligned, as in a crystal or a stretched film, and the photon vector points along a molecular axis, e.g., z, then absorption occurs for those vibrations that displace the dipole along z. Vibrations that are purely x or y polarized would be absent. Thus, extra information about the character of the vibration is available from IR absorption spectra for oriented samples.

2.6 Enhancement of Raman Scattering

The intensity of Raman scattering depends strongly on the excitation frequency.[21,22] Figure 11 illustrates what happens if, for a given molecular system, we change excitation frequency so that it moves from the transparent region (a) to the vicinity of an allowed electronic absorption band (b)–(e). As discussed before, excitation in the transparent region of a scattering system leads to a normal (or off-resonance) Raman effect. Under this circumstance, the intensity of Raman bands is described by a ν^4 law (Figure 2), and some advantage can be taken of this dependence by using the higher frequency irradiation (e.g., the blue and green lines of the argon laser, rather than the red line of the helium–neon laser). However, when the frequency of the exciting laser line is close to (preresonance) or equal to (resonance) the frequency of an allowed electronic absorption of a molecule, as in (b) and (c), the intensities of certain Raman bands are greatly increased (up to 10^6-fold) above their off-resonance values. This happens because the polarizability, and its dependence on the molecular motions, is enhanced via the electronic transition. Not all Raman bands intensify,

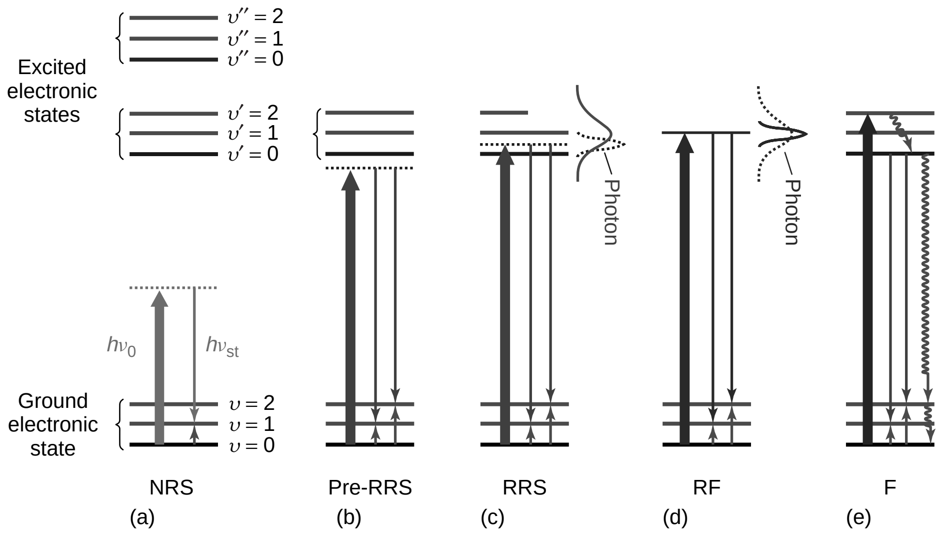

Figure 11 Diagram of Stokes transitions ($h\nu_{St}$) of Raman scattering (a)–(c) and fluorescent emission (d), (e) as a function of excitation energy ($h\nu_0$). (a) Normal Raman scattering occurs upon excitation in the transparent region of the molecule. The molecular polarizability creates a nonstationary (virtual) state to interact with $h\nu_0$, which does not resemble any particular molecular state. Many excited electronic states contribute to this state and the scattering process is nonselective in that all vibrations (usually fundamental) that can change the polarizability may be observed. (b) Preresonance Raman scattering in which $h\nu_0$ approaches the energy of an electronic transition. The interacting state is then dominated by this electronic state, which produces some enhancement of Raman scattering (10–100-fold) and possible appearance of overtones. (c) Resonance Raman scattering, in which the interacting state is dominated by a few vibronic levels in the interior of the excited electronic state. Many Raman bands are then attenuated by the absorption, but those associated with normal coordinates that can carry the molecule into its excited-state geometry may be greatly enhanced (10^3–10^6 times). (d) Resonance fluorescence occurs when $h\nu_0$ coincides with a single sharp level of the electronic manifold (small molecules in gas phase). The distinction between RRS and RF is that the RF involves actual population of the upper state (its width is smaller than that of the $h\nu_0$ pulse), the emission decaying with the excited-state lifetime, whereas RRS process is simultaneous (actually $<10^{-14}$ s) with the excitation pulse. If not in exact resonance with the upper state, only RR scattering occurs. (e) Relaxed fluorescence, in which radiational relaxation to the ground state is preceded by prior radiationless relaxation to the lowest vibrational level of the excited electronic state. This produces a red-shifted broad envelope of emission on the 10^{-6}–10^{-8} timescale

however, but only those due to vibrational transitions that couple with the electronic transition. This is illustrated in Figure 12 which shows a dramatic increase in intensity of the Cu–S(Cys) vibrational modes near 400 cm^{-1} as the excitation wavelength (647.1 nm) approaches that of the (Cys)S → Cu(II) CT electronic transition (~600 nm) in the blue copper protein, azurin (*see* ***Copper Proteins with Type 1 Sites***).[16] Another example of RR scattering was seen in Figure 10, where stretching modes of the porphyrin π bonds are enhanced because of their coupling with the π–π^* resonant transitions of NiP.[31–33] Thus, the correct identification of the vibrational modes showing RR enhancement will aid in the assignment of the resonant electronic transition and vice versa.

The laser frequency is an important consideration in Raman applications because resonance enhancement greatly increases both the sensitivity and the selectivity of the technique. Nonresonance Raman scattering is weak enough that sample concentrations in the molar range are often required to obtain good quality spectra, but resonance enhancement can lower the required concentration to the millimolar to micromolar ranges. Selectivity is an equally important feature since vibrational spectroscopy frequently suffers from crowding and overlap of bands when complex molecules or mixtures are investigated. Since only Raman modes associated with the excited-state distortion are enhanced, the RR spectrum is simplified and one can be sure that the enhanced bands are associated with the chromophore; interferences from other parts of the molecule or other constituents of the mixture are eliminated. Of course, this selectivity means a loss of information if the nonchromophoric parts of the sample are of interest. Wide tunability of the laser source is desirable so that different chromophores in the sample (or different excited states of the same chromophore, which may enhance different Raman bands) can be accessed. The main differences between Raman and RR scattering are summarized in Table 3.

2.7 Electronic Structure and RR Scattering Mechanisms

The vibronic theory of the RR effect distinguishes two major intensity enhancement mechanisms that play a dominant role in the RR spectra: (i) *Franck–Condon* (*FC*) *principle* and (ii) *Herzberg–Teller* (*HT*) *vibronic coupling*, which have quite different properties.[21,33–35] The FC scattering mechanism involves displacement of the potential minima of the ground and excited electronic states along a vibrational normal

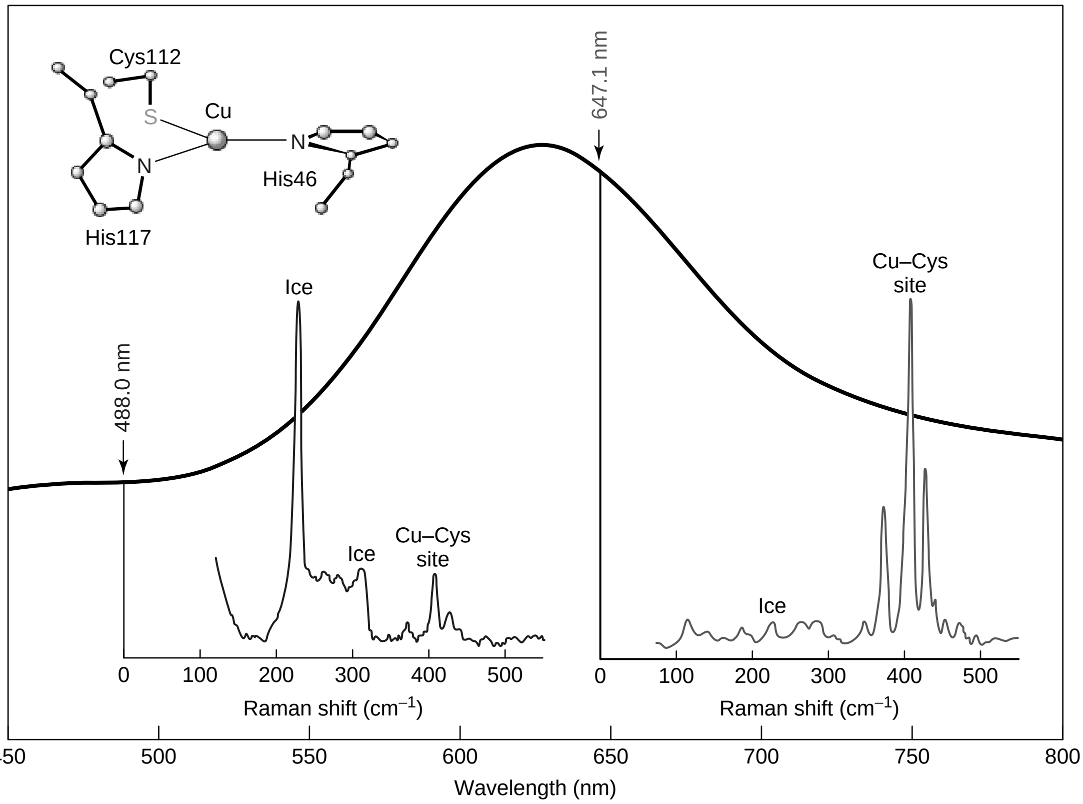

Figure 12 Vibrational enhancement selectivity available from resonance Raman spectroscopy. The UV–visible spectrum of a *P. aeruginosa* azurin is shown together with two different Raman spectra (frozen solution at 77 K) that derive from laser excitation within the S(Cys) → Cu(II) charge-transfer absorption band at 625 nm (647.1 nm) and away from the absorption (488.0 nm). Excitation within resonance leads to dramatically increased Raman scattering from the Cu active site, whereas off-resonance excitation produces a spectrum dominated by bands of nonchromophoric ice

Table 3 Main differences between Raman and resonance Raman scattering

Raman scattering	Resonance Raman scattering
B-term effective (any Raman allowed mode)	A-term (totally symmetric modes), B-term (nontotally symmetric modes), and C-term (first overtones and binary combinations of vibronically active modes) effective
Polarized (p) and depolarized (dp) bands only	Anomalously polarized (ap) and inversely polarized (ip) bands attainable as well
Overtones and combination bands very weak and seldom observable	Overtones and combination bands common
More vibrations observed in the spectrum	Some vibrations selectively enhanced
No electronic information	Electronic information present
Inherently weak scattering (10^6–10^9 times weaker than Rayleigh scattering)	Much stronger scattering (10^3–10^6 times greater than normal Raman scattering)
Intensity arises from the dependence of the ground-state polarizability on molecular vibrations only	Ground-state polarizability and its dependence on molecular vibrations is enhanced via electronic transition(s)

coordinate, whereas the HT scattering mechanism involves a transfer of the transition moment between different excited electronic states induced by a vibrational excitation. This means that by moving into the resonance region, the vibrational modes that reflect the change in geometry when converting the molecule from its ground to excited state (FC allowed) or those that are able to vibronically couple the resonant excited state to some other electronic state with different transition moments (HT allowed) will be strongly enhanced. In general, the former effect is most pronounced for *totally symmetric modes* and *allowed resonant electronic transitions*, whereas the latter is pronounced for *nontotally symmetric modes* and

weakly allowed or forbidden resonant electronic transitions. This selective enhancement is one of the most important and valuable aspects of RR spectroscopy, since it leads to a considerable simplification of the observed spectra; the RR spectra consist primarily of bands arising from either totally or nontotally symmetric vibrations depending upon the nature of the resonant electronic transitions.

To determine the scattered radiation spectrum of an oscillating molecule under conditions of resonance excitation, we must consider how the polarizability α varies not only with normal modes of vibration but also with frequency of the incident radiation that excites them. For a molecule in a molecular state $|g\rangle$ (initial) perturbed by the electromagnetic wave of frequency ν_0 so that it passes into a molecular state $|f\rangle$ (final) while scattering light of frequency $\nu_0 \pm \nu_k$ ($\nu_k = \nu_f - \nu_g$), the matrix elements of α for the vibrational transition k, $[\alpha_{\rho\sigma}]_k$, are given by the Kramers–Heisenberg–Dirac (KHD) dispersion equation[36,37]:

$$[\alpha_{\rho\sigma}]_k = \frac{1}{h}\sum_e \left(\frac{\langle f|M_\rho|e\rangle\langle e|M_\sigma|g\rangle}{\nu_{eg} - \nu_0 + i\Gamma_e} + \frac{\langle f|M_\sigma|e\rangle\langle e|M_\rho|g\rangle}{\nu_{eg} + \nu_0 + i\Gamma_e} \right) \quad (1)$$

where ρ, $\sigma = x, y, z$, which independently refer to the molecule-fixed nonrotating Cartesian coordinate system and represent the polarizations of the incident (σ) and scattered light (ρ), $|g\rangle$ and $|f\rangle$ are the initial and final states of the molecule, and the summation is over all the excited electronic states $|e\rangle$. The integrals $\langle f|M_\sigma|e\rangle$ and $\langle e|M_\rho|g\rangle$ are the electric dipole transition moments along the ρ and σ directions; M is the electron position operator; $h\nu_0$ is the energy of the incident radiation; and Γ_e is a damping factor (which prevents the denominator at resonance from reaching zero), reflecting the finite natural lifetime and sharpness of the excited state, $|e\rangle$.

Far from resonance ($\nu_0 \ll \nu_{eg}$), the magnitude of $[\alpha_{\rho\sigma}]_k$ is independent of ν_0; the number of excited electronic states contributing to the polarizability is large. In this case, all the energy denominators in the KHD equation become large and the scattering tensor $[\alpha_{\rho\sigma}]_k$ correspondingly small, leading to very weak scattering (normal Raman or Raman scattering). As the excitation frequency, ν_0, is tuned to the frequency of an electronic transition, ν_{eg}, the first (resonance) term of the KHD equation will become dominant and large because $\nu_{eg} - \nu_0 \approx 0$ in its denominator, and the second (nonresonance) term will become negligible. As a result, the scattered intensity is expected to increase drastically (but not to infinity owing to the Γ_e term) when ν_0 is in resonance region, provided the resonant state $|e\rangle$ has a large enough transition dipole moment from the ground state. The summation over all the electronic states can be relaxed except for the electronic state in resonance, and by applying (following Albrecht[36]) the adiabatic Born–Oppenheimer approximation of separability of electronic and vibrational wavefunctions for $|g\rangle$, $|e\rangle$, and $|f\rangle$ states, the KHD equation can be rewritten as

$$[\alpha_{\rho\sigma}]_k = \frac{1}{h}\sum_\upsilon \frac{\langle j|(\mu_\rho)_e|\upsilon\rangle\langle\upsilon|(\mu_\sigma)_e|i\rangle}{\nu_{\upsilon i} - \nu_0 + i\Gamma_\upsilon} \quad (2)$$

where $(\mu_\rho)_e = \langle g|(\mu_\rho)_e|e\rangle$ and $(\mu_\sigma)_e = \langle e|(\mu_\sigma)_e|g\rangle$ are the pure electronic transition moments, along ρ and σ directions, for the resonant excited state e; of which υ is a particular vibrational level of bandwidth Γ_υ; $\nu_{\upsilon i}$ is the transition frequency from the ground vibrational level i to the level υ; $|i\rangle$, $|j\rangle$, and $|\upsilon\rangle$ represent vibrational states of a given normal coordinate, Q_k; and the summation is over all excited-state vibrational levels, υ. The dependence of $(\mu_{\rho,\sigma})_e$ on Q_k is small if the Born–Oppenheimer approximation is valid and therefore it can be expanded as a Taylor series:

$$\mu_e = \mu_e^0 + \sum_k \mu_e' Q_k + \ldots \quad (3)$$

where $\mu_e' = (\partial\mu_e/\partial Q_k)_0$. (In writing equation (3), we have dropped the polarization subscripts.) When the electronic resonant transition is weakly allowed, μ_e' can be of the same magnitude as μ_e^0, or even exceed it, if the excited-state $|e\rangle$ can gain absorption strength from other excited states by vibronic mixing via the coordinate Q_k (called *vibronic coupling*). In the HT formalism for the vibronic coupling,[36–38]

$$\mu_e' = \mu_s^0 \frac{\langle s|(\partial H_e/\partial Q_k)_0|e\rangle}{\nu_s - \nu_e} \quad (4)$$

where $|s\rangle$ is another excited state that can be mixed in to $|e\rangle$ by Q_k; ν_s and μ_s are the frequency and transition dipole moment of the mixing electronic state, $|s\rangle$; and $(\partial H_e/\partial Q_k)_0$ is the vibronic coupling operator that connects two excited states $|e\rangle$ and $|s\rangle$, with H_e being the Hamiltonian for the total electronic energy of the molecule. Thus, the stronger the transition to the state $|s\rangle$, and the closer it is in energy to $|e\rangle$, the larger the μ_e' will be.

Substitution of equations (4) and (3) into equation (2) yields an expression with many terms, of which the first three terms, called *A*-, *B*-, *and C-terms*, are the dominant mechanisms in RR scattering.

$$[\alpha]_k = \mathbf{A} + \mathbf{B} + \mathbf{C} + \cdots \quad (5)$$

where

$$\mathbf{A} = (\mu_e^0)^2 h^{-1} \sum_\upsilon \frac{\langle j|\upsilon\rangle\langle\upsilon|i\rangle}{\nu_{\upsilon i} - \nu_0 + i\Gamma_\upsilon} \quad (6)$$

$$\mathbf{B} = \mu_e^0 \mu_e' h^{-1} \sum_\upsilon \frac{\langle j|Q_k|\upsilon\rangle\langle\upsilon|i\rangle + \langle j|\upsilon\rangle\langle\upsilon|Q_k|i\rangle}{\nu_{\upsilon i} - \nu_0 + i\Gamma_\upsilon} \quad (7)$$

$$\mathbf{C} = (\mu_e')^2 h^{-1} \sum_\upsilon \frac{\langle j|Q_k|\upsilon\rangle\langle\upsilon|Q_k|i\rangle}{\nu_{\upsilon i} - \nu_0 + i\Gamma_\upsilon} \quad (8)$$

Each term of equations (6)–(8) is factorized into parts that can be related to the electronic and vibrational wavefunctions and excitation frequency. The electronic contribution (matrix elements of μ_e^0 and μ_e'), weighted with the differential energy denominators ($\nu_{\upsilon i} - \nu_0 + i\Gamma_\upsilon$), determines the *total* enhancement of all the normal vibrations for a given

electronic transition and a given ν_0. Since μ_e^0 and μ_e' in $[\alpha]_k$ also determine the optical absorption spectrum, structural information often emerges from the interpretation of both the RR and UV–visible spectra. The vibrational part described by FC factors and $(\partial H_e/\partial Q_k)_0$ (vibronic coupling operator) governs the intensity distribution among the enhanced modes, and is therefore responsible for the selectivity of the vibrational mode enhancement, the enhanced modes containing information about the vibronic nature of the electronic transitions as well as the molecular distortion and dynamics at the electronic excited state(s).

2.7.1 A-term RR Scattering

The A-term is the leading RR scattering mechanism encountered in practice and involves vibrational interactions with a single excited electronic state, $|e\rangle$, by way of FC overlap integrals, $\langle j|\upsilon\rangle$ and $\langle\upsilon|i\rangle$ (FC scattering), as illustrated in Figure 13. This term is nonzero only if $\mu_e^0 > 0$ and $\langle\upsilon|i\rangle\langle j|\upsilon\rangle \neq 0$. Consequently, the A-term is most pronounced for strongly allowed electronic transitions, with large values of $(\mu_e)^2$ and substantial nonorthogonalities of the FC factors $\langle\upsilon|i\rangle$ and $\langle j|\upsilon\rangle$ upon electronic excitation, such as electric-dipole-allowed $\sigma-\sigma^*$, $\pi-\pi^*$, and CT transitions. Excitations into weak electronic transitions, such as forbidden $\pi-\pi^*$, ligand field d–d, and spin forbidden transitions, will not produce significant FC scattering.[16,21,22] The relative enhancements for different vibrational modes are determined by the values of the FC factors, which are nonzero, and may become large if there is a substantial shift of the excited-state potential, Δ_k^e, along the vibrational coordinate Q_k. Only totally symmetric modes are subject to A-term enhancement, because they can satisfy the latter condition ($\Delta_k^e \neq 0$) by symmetry. Frequently, Δ_k^e in the excited electronic state is large enough to give appreciable magnitudes of $\langle\upsilon|i\rangle\langle j|\upsilon\rangle$ products for up to several quanta of vibrational energy. Intense overtone progression $n_k\nu_k$ of totally symmetric modes ν_k can then be observed in the RR spectrum, making it possible to determine their harmonic frequencies and anharmonicity constants. Clark and coworkers have carried out extensive work in this area on coordination compounds.[1,39] The longest progressions observed thus far

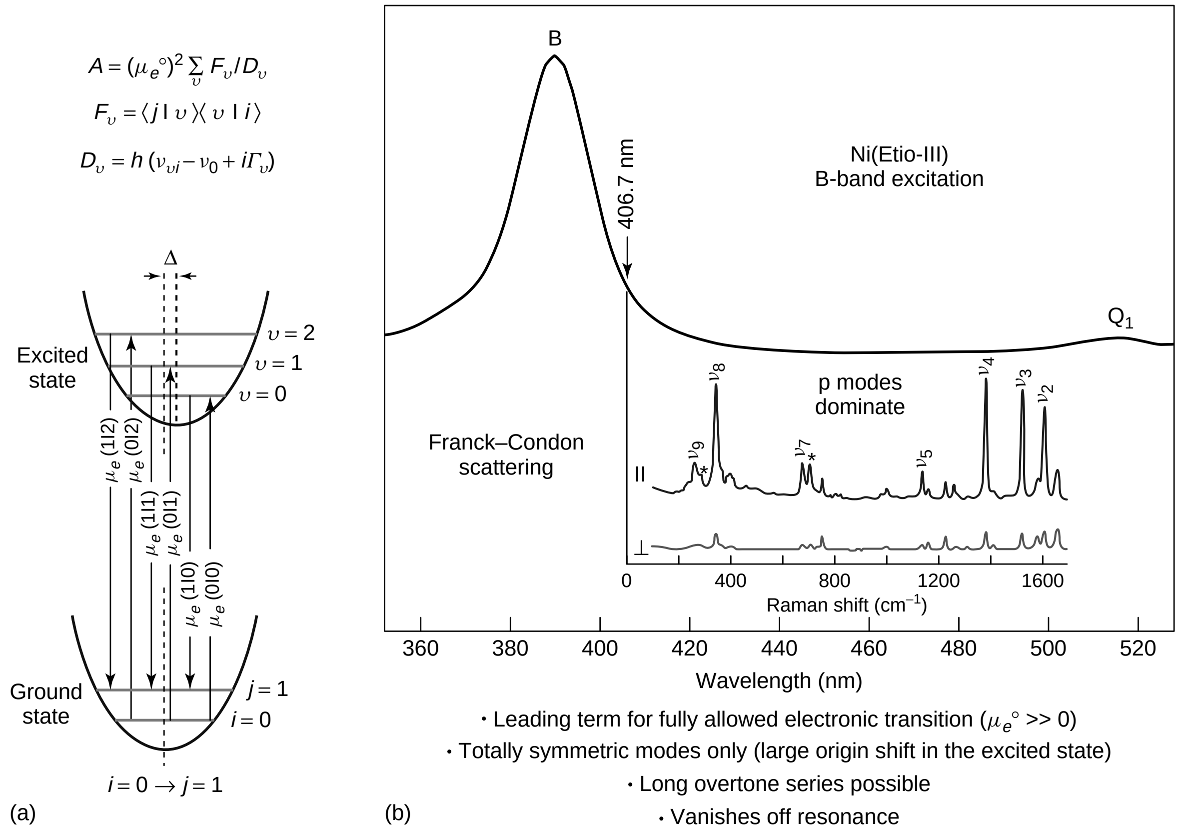

Figure 13 (a) Diagrammatic representation of Raman process responsible for A-term resonance scattering. The applicable electronic transition moment and vibrational overlap integral is indicated for each contributing transitions for $\upsilon = 0$, 1, and 2 intermediate levels of the resonant excited state. (b) Soret electronic transition excitation and Franck–Condon (A-term) scattering in metalloporphyrins. Soret absorption band (B) is shown for Ni(Etio-III) together with the RR spectra in parallel (‖) and perpendicular (⊥) scattering excited at 406.7 nm. Resonance with the Soret absorption band enhances mainly polarized bands (p), arising from totally symmetric modes, A_{1g}. The asterisks indicate solvent bands (CH_2Cl_2)

are for the diatomic I_2 (up to $n_1 = 25$), the linear-chain ($[Pt(tn)_2][Pt(tn)_2Br_2])^{4-}$ (up to $n_1 = 18$), tetrahedral SnI_4 (up to $n_1 = 15$), and μ-oxo-bridged $[Ru_2OCl_{10}]^{4-}$ (up to $n_2 = 12$) for which the respective $\nu_2 < 400\,cm^{-1}$.[1,39]

2.7.2 *B-term RR Scattering*

The B-term scattering arises from the vibronic coupling of the resonant state, $|e\rangle$, to another excited state, $|s\rangle$ (HT scattering). Since the magnitude of μ_e' increases with the oscillator strength of μ_s and decreasing frequency separation between the $|e\rangle$ and $|s\rangle$ states, the B-term scattering is most pronounced when the exciting frequency is tuned to a weakly allowed electronic transition that is mixed vibronically with a nearby strong one ($\mu'e > \mu_e^0$ under this circumstance). The B-term denominator is the same as for the A-term, but its numerator contains the Q_k-dependent vibrational overlap integrals $\langle \upsilon|Q_k|i\rangle$ and $\langle j|Q_k|\upsilon\rangle$. These integrals connect ground- and excited-state vibrational levels that differ by one quantum (Figure 14). When they are multiplied by FC factors $\langle j|\upsilon\rangle$ or $\langle \upsilon|i\rangle$, having the same quantum numbers in the ground and excited states (e.g., $\langle 1|1\rangle$ and $\langle 0|0\rangle$) , the numerator does not vanish even if there is no excited-state shift of the potential upon electronic excitation. Thus, B-term scattering is exhibited only by fundamental vibrational modes and the vibrations enhanced may have any symmetry that is contained in the direct product of the two electronic transition representations, $(\Gamma|e\rangle \times \Gamma|s\rangle)$. The relative enhancement factors for different mode symmetries depend on the effectiveness of the vibration in coupling the excited states $|e\rangle$ and $|s\rangle$. Consequently, B-term scattering provides a primary mechanism for RR activity of nontotally symmetric modes, which can be, and usually are, enhanced. The more efficient the vibronic coupling of the two excited electronic states, the more effective B-term enhancement can be observed. Moreover, under nonresonance

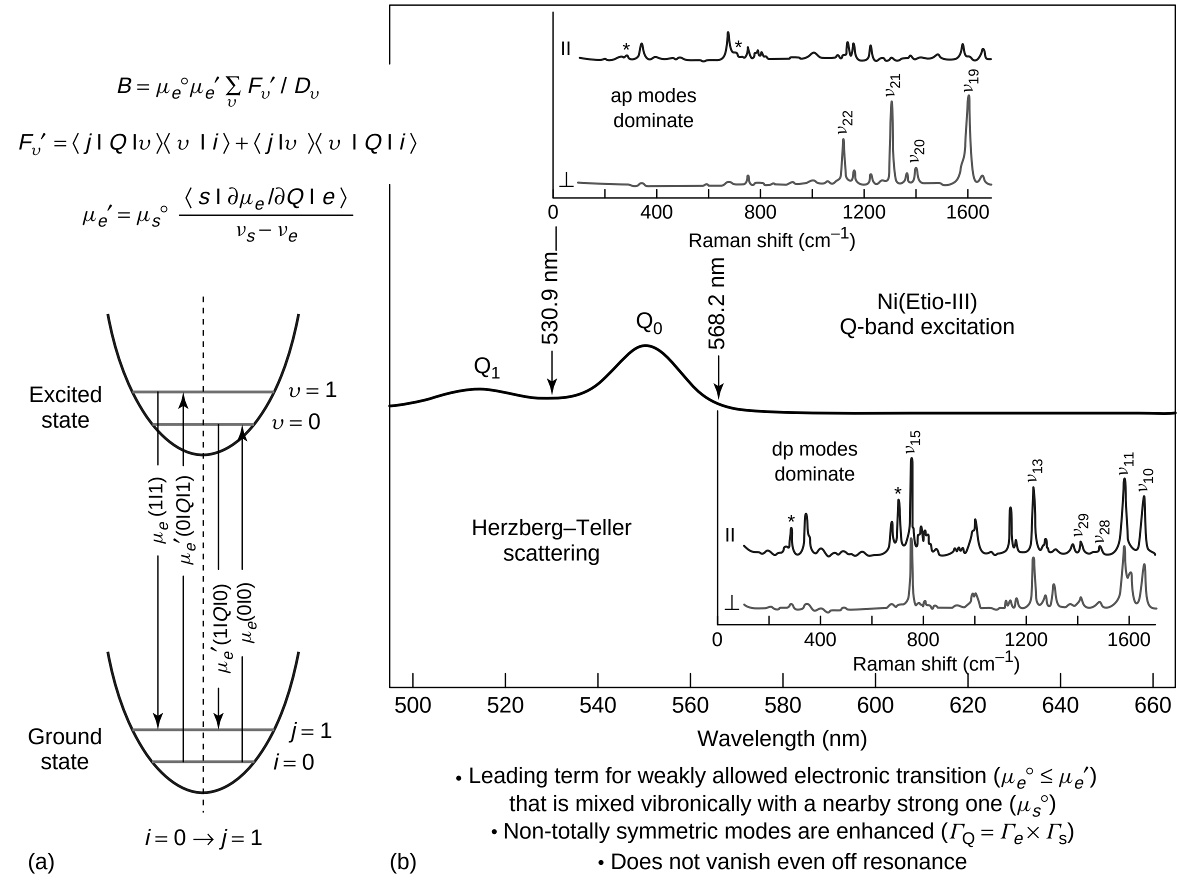

Figure 14 (Left) Diagrammatic representation of Raman process responsible for B-term resonance scattering. The applicable electronic transition moment and vibrational overlap integral is indicated for each contributing transition for $\upsilon = 0$, 1, and 2 intermediate levels of the resonant excited state. (Right) Q-electronic transition excitation and Herzberg–Teller (B-term) scattering in metalloporphyrins. Q absorption band (Q_0 and Q_1) are shown for NiEtio-III together with the RR spectra in parallel (‖) and perpendicular (⊥) scattering excited at 530.9 (top) and 568.2 nm (bottom). Resonance in the Q-band region enhances depolarized (B_{1g}, B_{2g}) and anomalously polarized (A_{2g}) modes that are effective in vibronic mixing of the Q and Soret electronic transitions. Owing to interference effects, the A_{2g} modes are brought out most strongly via excitation between Q_0 and Q_1 (530.9 nm), while the B_{1g} and B_{2g} modes are brought out more strongly with excitation outside the Q bands (568.2 nm). The asterisks indicate solvent bands (CH_2Cl_2)

conditions, when the energy denominator $(v_{\upsilon i} - v_0 + \mathrm{i}\Gamma_\upsilon)$ can be factored out, the sum over all excited states in the numerator of equation (7) reduces to $\langle j|Q_k|i\rangle$, which is nonzero for $j = i + 1$, i.e., fundamental modes. Thus, off-resonance Raman scattering is preserved by the B-term (although under these conditions any specific resonance effects are lost in the sum over all excited states of equation (7)).

2.7.3 A- and B-term RR Scattering Illustrated

RR scattering by heme proteins and metalloporphyrins (*see* ***Iron Porphyrin Chemistry***-)[14,31–33] provides a classical example of the differential A- and B-term vibrational enhancement pattern, as shown in Figures 13 and 14 for nickel(II) etioporphyrin-III, Ni(Etio-III),[40] which occurs naturally in crude oils and marine sediments. The electronic absorption spectrum of Ni(Etio-III) is due to two allowed in-plane π–π^* transitions, $a_{1u} \rightarrow e_g{}^*$ and $a_{2u} \rightarrow e_g{}^*$, which have the same $a_{1u} \times e_g = a_{2u} \times e_g = E_u$ symmetry in the idealized D_{4h} point group of the porphyrin chromophore.[40,41] The in-phase mixing of these π–π^* transitions gives rise to very intense absorption in the violet region at 391 nm, known as the *B or Soret band* (Figure 13), whereas their out-of-phase combination produces much weaker absorption in the yellow region at 551 nm, known as the Q_0 *or* α *band* (Figure 14). There is also a composite side band in the green region at 515 nm that results from vibronic coupling between the Q_0 and B transitions, referred to as the Q_1 *or* β *band*. As expected, laser irradiation of Ni(Etio-III) near the Soret absorption band (406.7-nm excitation, Figure 13) leads to RR spectra that are dominated by the polarized peaks (p, $\rho = I_\perp/I_\parallel \approx 1/8$) arising from the totally symmetric vibrations of the porphyrin skeleton, A_{1g}.[40] This dominance reflects that only totally symmetric vibrations, that is, those capable of shifting the excited-state potential surface, are subject to the FC (A-term) enhancement mechanism for allowed electronic transitions (equation 6). Porphyrin structure-sensitive modes ν_2, ν_3, ν_4, and ν_8 are especially strong, indicating large geometric displacements in the excited state along these vibrational coordinates.

Laser irradiation of Ni(Etio-III) near the α (568.2-nm excitation) and β bands (530.9-nm excitation) also produces strong resonance enhancement, as shown in Figure 14. In contrast to Soret-band excitation, it is the depolarized (dp, $\rho \approx 3/4$) and anomalously polarized (ap, $\rho \gg 3/4$) Raman peaks from the nontotally symmetric vibrations that are dominant.[40] These vibrations derive their intensity from the B-term (HT scattering) involving a vibronic coupling of the two excited states of the α and Soret electronic transitions (which is also responsible for the β absorption side band). Since both the Soret and α excited states are of E_u symmetry, the allowed symmetries of the mixing vibrations are $E_u \times E_u = A_{1g} + A_{2g} + B_{1g} + B_{2g}$. The A_{1g} modes are, however, not efficient in vibronic coupling. The B_{1g} and B_{2g} modes both give depolarized bands, while the A_{2g} modes give anomalously polarized bands. The Q-band resonance is also subject to an interference effect between 0–0 and 0–1 components, which produces an additional RR selectivity among the mixing nontotally symmetric modes.[31] It selects for A_{2g} modes at excitation wavelengths falling in between α and β bands, while excitation on either side selects for B_{1g} and B_{2g} modes.[35] This is the reason that ap bands are dominant with 530.9-nm excitation, whereas dp bands dominate the 568.2-nm excited spectrum (Figure 14).

2.7.4 C-term RR Scattering

The C-term RR scattering is a dominant mechanism when the exciting frequency is in resonance with a vibronic side band of a forbidden or weakly allowed 0–0 electronic transition, where the side band is allowed ($\mu_s^0 \neq 0$) due to the vibronic coupling between the 0–0 transition and another strongly allowed transition ($|g\rangle \rightarrow |s\rangle$). Under such conditions, the vibronic transition moment μ_e' described by equation (4) is much greater than μ_e^0 and since the electronic factor is $(\mu_e')^2$ in equation (8), the C-term can outweigh the B-term. The special feature of the C-term RR scattering is that it gives rise to first overtones ($k = l$) and binary combination tones ($k \neq l$) of those vibrational modes that are effective in coupling the two electronic states, instead of the fundamentals. This is because the numerator of the C-term equation (8) contains products of two Q-dependent integrals, $\langle j|Q_k|\upsilon\rangle$ and $\langle\upsilon|Q_l|i\rangle$. Since each of these connects vibrational states differing by one quantum, the final state, $|j\rangle$, must differ from $|i\rangle$ by two quanta, i.e., $j = i \pm 2$, as diagrammatically shown in Figure 15. Consequently, only first overtones ($k = l$) and binary combinations ($k \neq l$) are enhanced by the C-term. An example is shown in Figure 15(a), where overtone and combination bands involving the high-frequency ap and dp modes $\nu_{19}(A_{2g})$, $\nu_{10}(B_{1g})$, $\nu_{11}(B_{1g})$, $\nu_{20}(A_{2g})$, and $\nu_{29}(B_{2g})$ in the β-resonant spectrum of vanadyl tetraphenylporphyrin, VO(TPP), are seen to be dramatically stronger than the fundamentals.[32,42] The α absorption band shows no discernible intensity in this case (Figure 15(b)), indicating accidental degeneracy of the a_{1u} and a_{2u} porphyrin π orbitals, while the β band retains ≈10% of the intensity of the Soret band. As a result, $\mu_e^0 \approx 0$ but $\mu_e' \neq 0$ and $B \ll C$.

3 APPLICATIONS

3.1 The Mononuclear Type-1 Cu Site in Cupredoxins

The mononuclear blue (or type 1) copper proteins (cupredoxins) (*see* ***Copper Proteins with Type 1 Sites***), involved in biological electron transport, share a common structural motif, in which the single Cu(II) ion is tightly bound (∼1.9–2.2 Å) to two histidine and one cysteine ligand

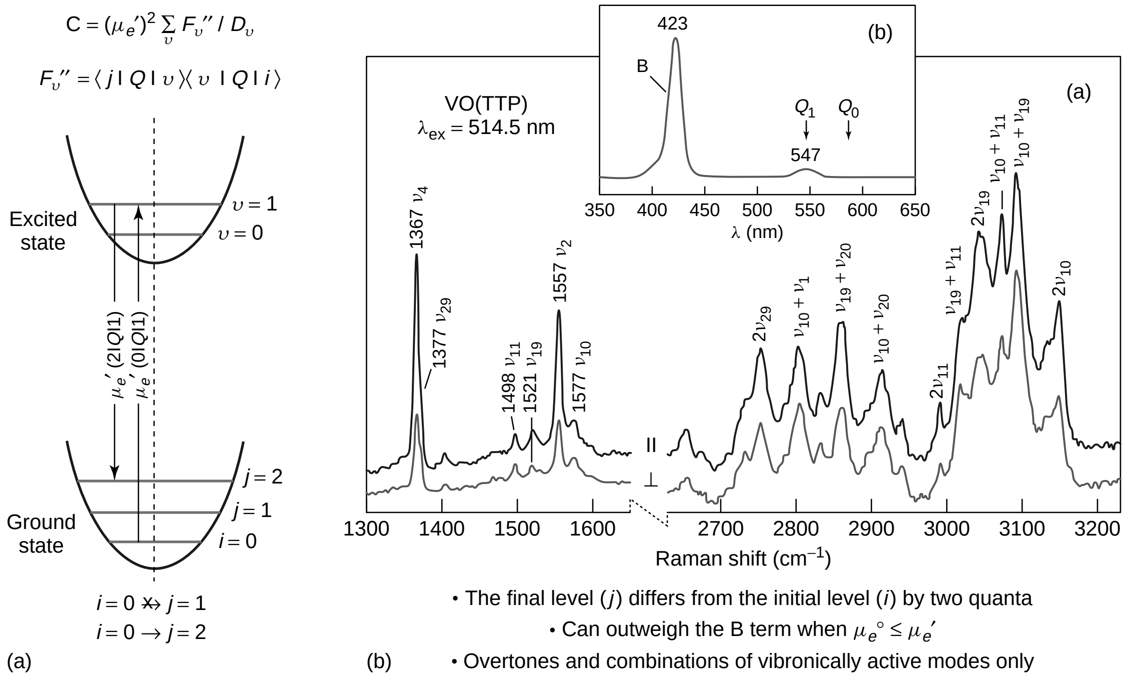

Figure 15 (A) Diagrammatic representation of Raman process responsible for C-term resonance scattering. The applicable electronic transition moment and vibrational overlap integral is indicated for each contributing transition for $\upsilon = 0$ and 1 intermediate levels of the resonant excited state. (B) The RR spectra (a) in parallel (||) and perpendicular (⊥) scattering of solid (VO)TPP (rotating KCl pellet) excited at 514.5 nm showing strong enhancement of overtone and combination modes involving vibronically active ν_{19}, ν_{10}, ν_{11}, and ν_{29}, which themselves are very weak. The Q_0 absorption band (b) is virtually invisible in this case, giving very large overtone/fundamental ratios via the much larger C-term than B-term scattering

in a distorted trigonal CuN_2S planar geometry.[43–47] These three residues are conserved in all cupredoxins. A methionine thioether sulfur atom or, in some cases, a glutamine amide oxygen atom is present above the trigonal plane at a long distance (~2.6–3.1 Å). The azurin structure is different in that it has a fifth distant (~2.8–3.2 Å) ligand to copper, the peptide carbonyl oxygen from glycine (Gly45) across the N_2S plane (His46, His117, Cys112) from the methionine residue (Met121).[48–50] The trigonal bonding arrangement lowers the energy of the half-occupied copper $d_{x^2-y^2}$ orbital, relative to its energy in the usual tetragonal complexes of Cu(II), and in addition orients $d_{x^2-y^2}$ for optimal overlap with the π, instead of the σ filled orbital on the cysteine sulfur atom. Both factors lead to an unusually low energy (Cys)S → Cu(II) CT transition, ~625 nm, which accounts for the intense blue color of these proteins.

The main effect of CT excitation should be to weaken the Cu(II)–S(Cys) bond, and RR enhancement of the Cu(II)–S(Cys) stretching mode, $\nu(CuS)_{Cys}$, is therefore expected. This is a FC overlap argument, based upon equation (6). The Cu(II)–S(Cys) bond is short (~2.1–2.2 Å)[51] and a high stretching frequency is expected, ~400 cm^{-1}. The other Cu(II)–ligand stretches should be at much lower frequencies, because of the very long bonds for the methionine and peptide ligands, and because of the high effective mass of the rigid imidazole rings. Hence, a single dominant RR band might be expected, near 400 cm^{-1}. This is, in fact, what is observed[52] for a set of model compounds, LCu(II)–SR, where L = hydrotris(3,5-diisopropyl-1-pyrazolyl)borate (Figure 16).[53] When R is varied from *t*-butyl to triphenylmethyl to pentafluorophenyl, the frequency of this band decreases from 437 to 422 to 409 cm^{-1}, consistent with the expected weakening of the Cu–S bond due to increasing electron withdrawal. For the blue copper proteins, however, laser excitation within a (Cys)S → Cu(II) CT band results in a group of four or more strong RR fundamental bands near 400 cm^{-1}, as well as a series of weak-to-moderate bands below 300 cm^{-1} and groups of weaker features in the first (~800 cm^{-1}) and second (~1200 cm^{-1}) overtone regions of the ~400 cm^{-1} fundamentals.[43–47] The 647.1-nm excitation spectrum of azurin from *Pseudomonas aeruginosa*,[43] shown in Figure 17, exemplifies the unusual but characteristic richness of the type-1 copper RR scattering. Another property is the species dependence of RR scattering from proteins that have ostensibly the same active site structure. Despite homologous structures, different families of blue copper proteins, as well as individual members of the same family, exhibit considerable dissimilarities regarding the number of RR modes observed, their frequencies, and relative intensities (Figure 18).

The source of this band multiplicity and spectral differences has been a matter of considerable speculation.[45,47]

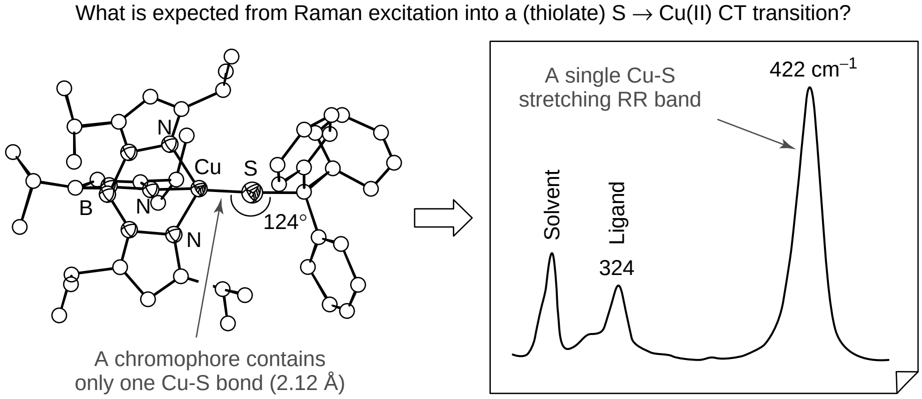

Figure 16 Structural diagram and 647.1-nm excitation RR spectrum of the blue copper site analog complex, LCu(II)–SR (L = hydrotris(3,5-diisopropyl-1-pyrazolyl)borate).[53] A single Cu–S stretching mode is seen in the RR spectrum,[52] as expected from excitation into RS → Cu CT transition of a chromophore containing only one terminal Cu–S bond

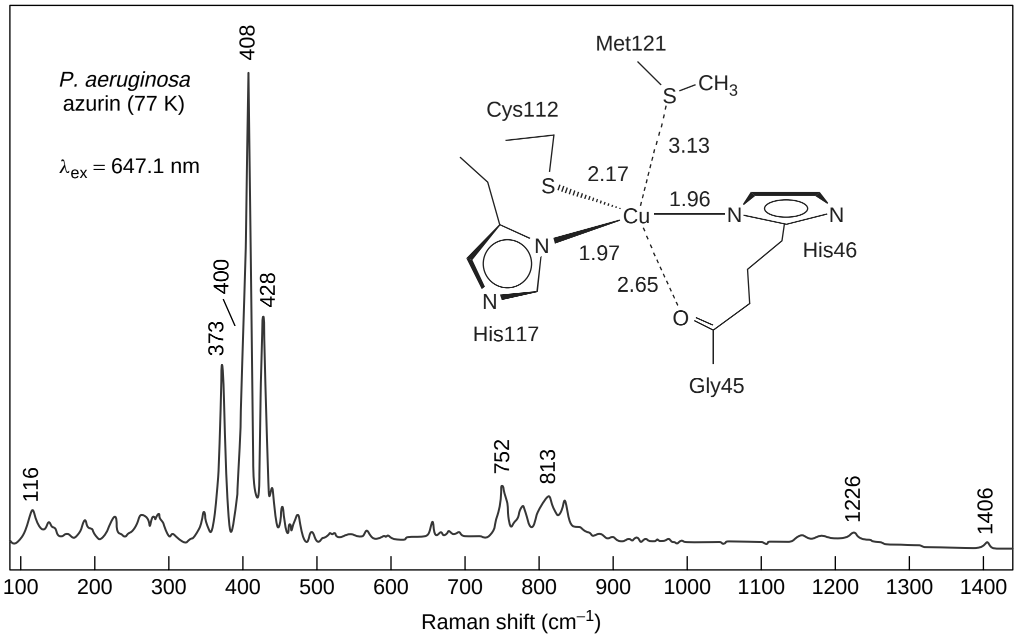

Figure 17 Low-temperature (77 K) RR spectrum of *P. aeruginosa* azurin obtained with 647.1-nm excitation wavelength and structural drawing of the active site showing distances (Å) to the three strong (Cys112, His46, His117) and two weak ligands (Met121, Gly45)

Significantly, the LCu–SR model compound gives three RR bands of nearly equal intensities near 400 cm^{-1} when R = *s*-butyl. Normal coordinate analysis (NCA) calculations indicate that the simple interchange of a methyl group and a hydrogen atom, between R = *t*-butyl and *s*-butyl, is sufficient to induce significant mixing of the C–C–C bending coordinates, δ(CCC), with the Cu–S(thiolate) stretching coordinate, ν(CuS), thereby accounting for the three strong bands.[52] No doubt mixing of ν(CuS) with heavy atom bending coordinates of the cysteine ligand produces some complexity seen in the cupredoxin spectra. Such mixing was anticipated in an early study of stellacyanin,[54] in which the two main RR bands were each found to shift upon $^{65}\rightarrow{}^{63}$Cu substitution, by half the amount expected for an isolated Cu–S oscillator, implying nearly equal contributions from ν(CuS) and another coordinate. Further insight into the coordinate mixing phenomenon has been obtained by $^{34}\rightarrow{}^{32}$S substitution in *P. aeruginosa* azurin and site-specific mutants,[44,55,56] *A. lcaligenes denitrificans* azurin,[57] *Cucumber sativus* stellacyanin,[58] and *Populus nigra* plastocyanin,[59] carried out by bacterial expression of the respective protein gene.

Figure 19 presents the 350–450 cm^{-1} RR spectra for the natural abundance wild-type (WT) *P. aeruginosa* azurin and its M121G (Met121 replaced with glycine) and H46D

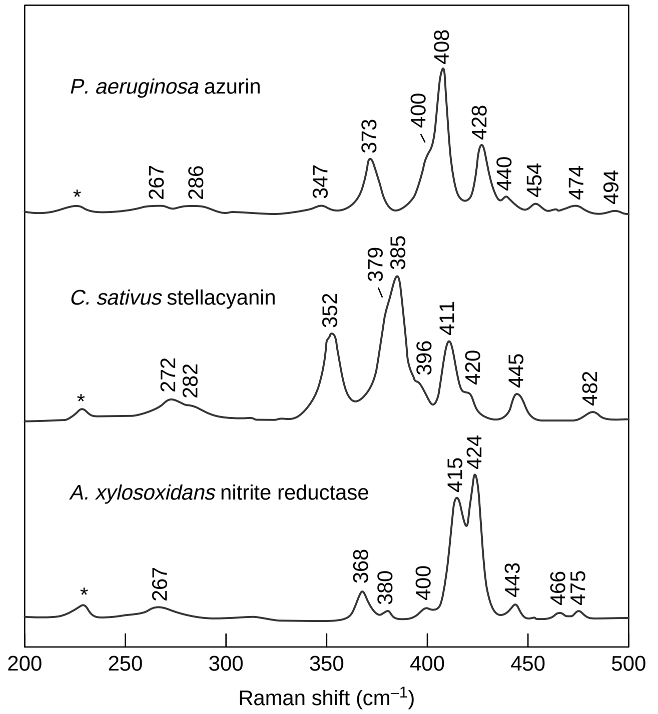

Figure 18 Low-temperature (77 K) RR spectra in the 200–500 cm^{-1} region of indicated blue Cu proteins excited at 568.2 (stellacyanin, NiR) and 647.1 nm (azurin). Asterisks denote ice band

(His46 replaced with aspartate) Cu site mutants, and their corresponding [^{34}S]Cys112-substituted proteins.[55] Each spectrum shows four dominant RR peaks in this region (~370, ~400, 408, and ~427 cm^{-1}) that are characteristic for the type-1 Cu structure of the Cu(II)–Cys chromophores. Among these, the bands showing the greatest intensity and [^{34}S]Cys isotope shift, 408 (WT) and ~400 cm^{-1} (mutants), are identified with the vibrational mode involving primarily stretching of the Cu(II)–S(Cys) bond. This assignment is also corroborated by the $^{63/65}$Cu isotope shifts, as shown in Table 4.[44] A shift of the ν(CuS)$_{Cys}$ character from the 408 cm^{-1} peak of WT to the ~400 cm^{-1} peaks in H46D and M121G indicates a decrease of the Cu(II)–S(Cys) interaction in both mutants as their Cu sites adopt more tetrahedral character relative to the WT site.[44,55,60]

There are far too many strong bands (up to nine) in the cupredoxin RR spectra near 400 cm^{-1} to be entirely due to the metal–ligand stretches, and attention must turn to other vibrational modes of the active site. Toward this end, site-selective isotopomers of azurin[61] and plastocyanin[62] were genetically produced with ^{2}H and ^{15}N labels in the cysteine C$_\beta$ hydrogen and amide nitrogen atom positions, respectively, and their high-resolution RR spectra were recorded and analyzed.[43,61–63] Figure 20 shows the effects on the RR spectrum in the 350–450 (fundamental) and 650–850 cm^{-1} (first overtone) regions of selective deuterium labeling of the Cys112 β-hydrogen atoms in *P. aeruginosa* azurin, carried out by bacterial expression of the azurin gene using a Cys

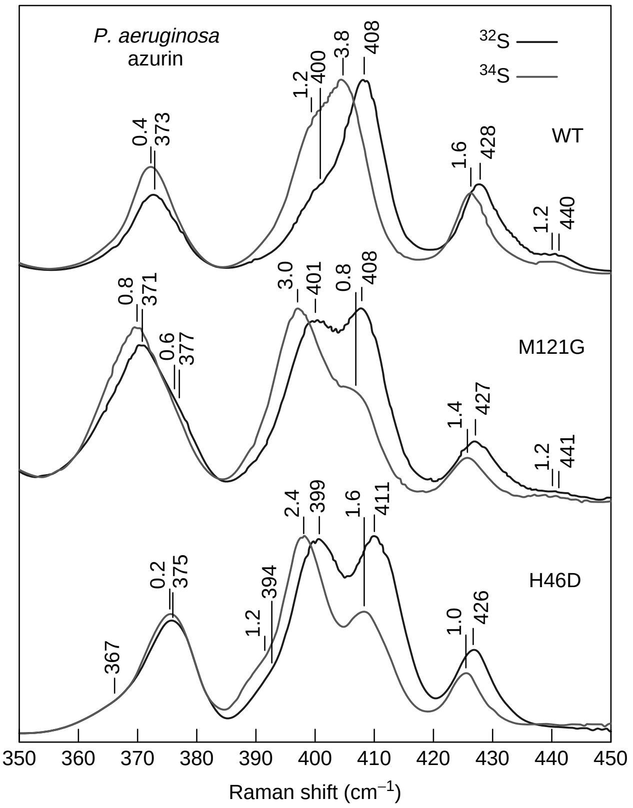

Figure 19 Low-temperature (77 K) RR spectra of *P. aeruginosa* azurins from cells grown on [^{32}S]- or [^{34}S]sulfate, excited at 647.1 (WT) and 568.2 nm (mutants). Italic numbers show the [$\nu(^{32}S) - \nu(^{34}S)$] band shifts

auxotrophic *E. coli* strain and cysteine(3,3-D$_2$).[61] Three of the four RR bands with ν(CuS)$_{Cys}$ character are markedly affected by [C$_\beta$D$_2$]Cys112 incorporation; the 408 and 373 cm^{-1} bands undergo shifts of −6 and −4 cm^{-1}, respectively, while a shoulder near 400 cm^{-1} loses most of its intensity and drops ~3 cm^{-1} in frequency. The fourth S-dependent band at 428 cm^{-1} is much less sensitive to C$_\beta$D$_2$ labeling, shifting approximately −1.5 cm^{-1}. These shifts are further emphasized by the first overtone and combination bands as indicated in the figure. On the other hand, selective labeling of the nitrogen atom in the azurin Cys112 residue causes only small changes in the [^{15}N]Cys112 RR spectrum.[61] Three shoulders at 264, 400, and 377 cm^{-1} all shift downward by ~1 cm^{-1}, while the ^{34}S-sensitive peaks at 408 and 428 cm^{-1} shift less than 0.5 cm^{-1}, indicating only a small contribution from the amide group of the cysteinate ligand. Hence, the [C$_\beta$D$_2$]Cys and [^{15}N]Cys RR data[43,61–63] unambiguously establish that the multiple S-dependent bands of cupredoxins contain contributions mainly from CH$_2$ group-dependent deformations of Cu-bound cysteine,[43,56] as predicted by RR studies on model compounds[52] and ^{34}S- and $^{63/65}$Cu-substituted proteins.[54,55,59]

However, growth of azurins,[45,56,60,61] stellacyanin,[58] and plastocyanin[59] on ^{15}NH$_4$Cl(aq), which completely labels

[a] ^{34}S data not available for M121L azurin.
[b] M121G azurin shows a shoulder at 377 cm^{-1}, which downshifts ~0.6 and ~0.3 cm^{-1} on ^{34}S and ^{65}Cu substitutions, respectively.
[c] H46D azurin shows a shoulder at 394 cm^{-1}, which downshifts ~1.2 cm^{-1} on ^{34}S substitution. All data are from Czernuszewicz *et al.*[44]

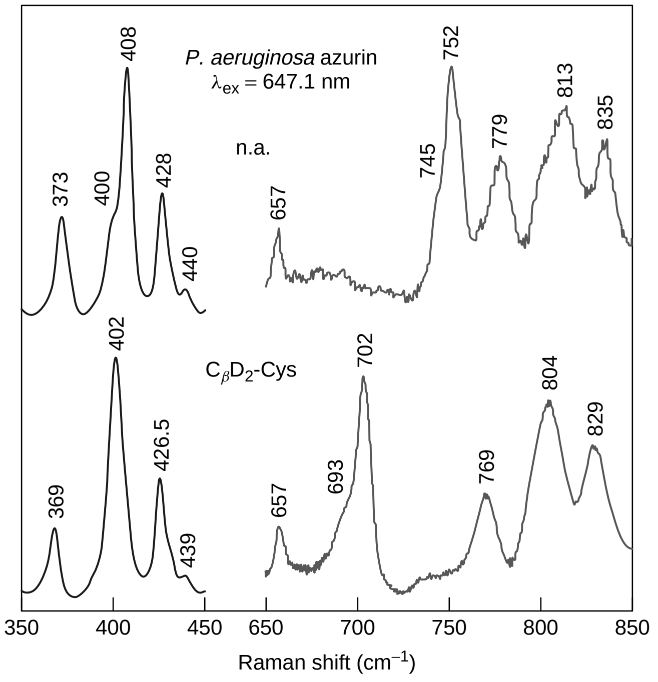

Figure 20 RR spectra of *P. aeruginosa* azurin and its [CβD2] Cys112-labeled protein obtained at 77 K with 647.1-nm excitation

all nitrogen atoms in the protein with ^{15}N, leads to the RR spectra that exhibit relatively large (1.0–4.2 cm^{-1} for *P. aeruginosa* azurin[56]) shifts to lower frequencies for nearly all the fundamental Raman bands in the 100–500 cm^{-1} region. Even the ^{34}S-sensitive strongest Raman bands in the 400 cm^{-1} region showed these downshifts.[56] At first, these results seem to support an earlier suggestion[54,64] that the deformation coordinates of Cu-bound histidine residues could also be good candidates for kinematic mixing with $\nu(CuS)_{Cys}$. Selective isotope labeling of the histidine imidazole ring has become possible through the availability of the azurin ligand mutants (H46G and H117G).[65–67] These mutants bind exogenous imidazole to generate blue copper sites almost indistinguishable from those of the WT proteins. Incorporation of [^{15}N]imidazole into either the H46G or H117G mutant gives no ^{15}N-sensitive RR bands other than a ~285 cm^{-1} band assigned to $\nu(CuN_{Im})$ (~1 cm^{-1} downshift).[68] Clearly, the substantially larger ^{15}N shifts observed for cupredoxins grown in the $^{15}NH_4Cl$ media are due to contributions from vibrations of the backbone amides rather than the histidine ligands. It is also apparent from the [^{15}N]Cys-dependent RR experiments that coupling of ν(CuS) to cysteine amide coordinates alone is not sufficient to explain the observed [^{15}N] protein shifts. That a single ν(CuS) stretch of cupredoxins undergoes extensive kinematic coupling with internal vibrational coordinates of not just one (cysteine) but several side chain residues has been obtained from NCA calculations of azurin[43] and plastocyanin.[63] The multiple vibrational features in the azurin RR spectrum arise from kinematic coupling between ν(CuS) and the internal ligand deformation modes of the coordinated Cys112 and at least three other residues (Thr113, Phe111, and Phe110) linked to Cys112 in the polypeptide chain.

3.2 Effects of Met121 Mutation on the Azurin Active Site

Substitution of amino acid residues at the metal center by site-directed mutagenesis can alter the geometry and properties of the active site, thus allowing elucidation of the minimal requirements for the proper functioning of the metalloprotein.[44,60] As an example, Figure 21 and Table 5 show the results of RR scattering from a series of *P. aeruginosa* azurins in which the active site Met121 has

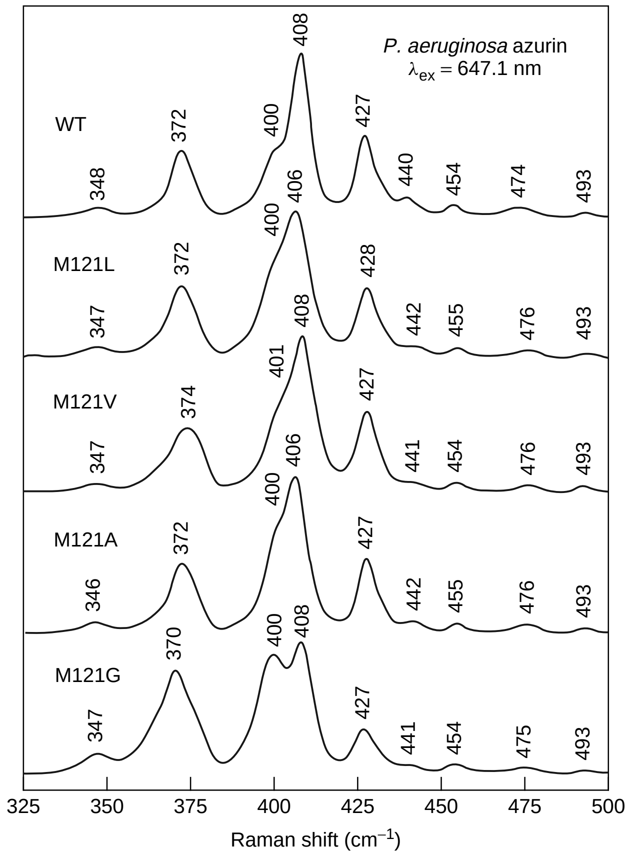

Figure 21 Low-temperature (77 K) RR spectra of *P. aeruginosa* azurin and indicated mutants (M121X, X = glycine, alanine, valine, and leucine) obtained in the 320–500 cm^{-1} region with 647.1- and 568.2-nm (M121G) excitations

been replaced by smaller hydrophobic amino acids: glycine (M121G), alanine (M121A), valine (M121V), and leucine (M121L).[60] The data emphasize that azurin RR spectra contain precise structural information regarding the nature of extremely subtle and minor variations in copper–amino acid interactions caused by Met121 replacements. Among the four most prominent peaks seen at 373, 400(sh), 408, and 427 cm^{-1} for WT azurin (Figure 21, top spectrum), the strongest one at 408 cm^{-1} bears the highest $\nu(CuS)_{Cys}$ character,[55] because it shifts the most to lower frequency (∼4 cm^{-1}) upon ^{34}S substitution (Figure 19); the other three peaks shift appreciably less (∼1.0–2.5 cm^{-1}). Thus, to a first approximation, the position of the most intense azurin fundamental peak reflects the strength of the Cu(II)–S(Cys) interaction. The RR spectral patterns of M121A, M121V, and M121L closely resemble that of the WT azurin; there are only small differences (±0.5 to ±2 cm^{-1}) in the positions of the bands (Table 5) and slight changes in the relative intensities, which indicate that a trigonal N_2S bonding arrangement about Cu(II) of the WT azurin has not been altered much by mutations of Met121 to alanine, valine, and leucine.[60] That M121A, M121V, and M121L retain trigonal character of the Cu is also highlighted

by the axiality of the electron paramagnetic resonance (EPR) signals[69] and small ratios of the molar absorptivities for electronic transitions in the violet (λ_2, ∼460 nm) and red regions (λ_1, ∼620 nm), $R_f = \varepsilon(\lambda_2)/\varepsilon(\lambda_1)$[45,68] (Table 5).

In contrast, the M121G mutant displays the most pronounced changes in the RR spectrum near 400 cm^{-1} (Figure 21, bottom) relative to those of the WT and the other three Met121 mutants under study. It would seem from a comparison of the spectra of all five proteins that the frequencies of the M121G bands are not as changed as their intensities, including the major peaks at 370, 400, 408, and 427 cm^{-1}. However, as we have demonstrated above, through ^{34}S-isotope labeling of the Cys112 ligand,[44,55] the predominantly $\nu(CuS)_{Cys}$ band downshifted from 408 cm^{-1} (WT) to 400 cm^{-1} upon mutation of Met121 to glycine (Figure 19). Since there are still at least four major bands between 360 and 430 cm^{-1}, this implies an increase in frequency for the shoulder at 400 cm^{-1} observed in WT that now has moved to higher energy (408 cm^{-1}) in M121G. Such a frequency crossover indicates differences in kinematic coupling between vibrations of the Cu–Cys moiety because of ground-state alteration. A shift of the $\nu(CuS)_{Cys}$ character from the 408 cm^{-1} band of the WT to the 400 cm^{-1} band in M121G indicates that the Met121 → glycine substitution causes the Cu–S_{Cys} interaction to weaken, as the Cu site adopts more tetrahedral character relative to the WT site. Consistent with the weaker Cu–S_{Cys} interaction is the higher cysteine C_β–S stretching mode frequency (760 cm^{-1} in M121G versus 751 cm^{-1} in WT),[44] whereas the enhanced

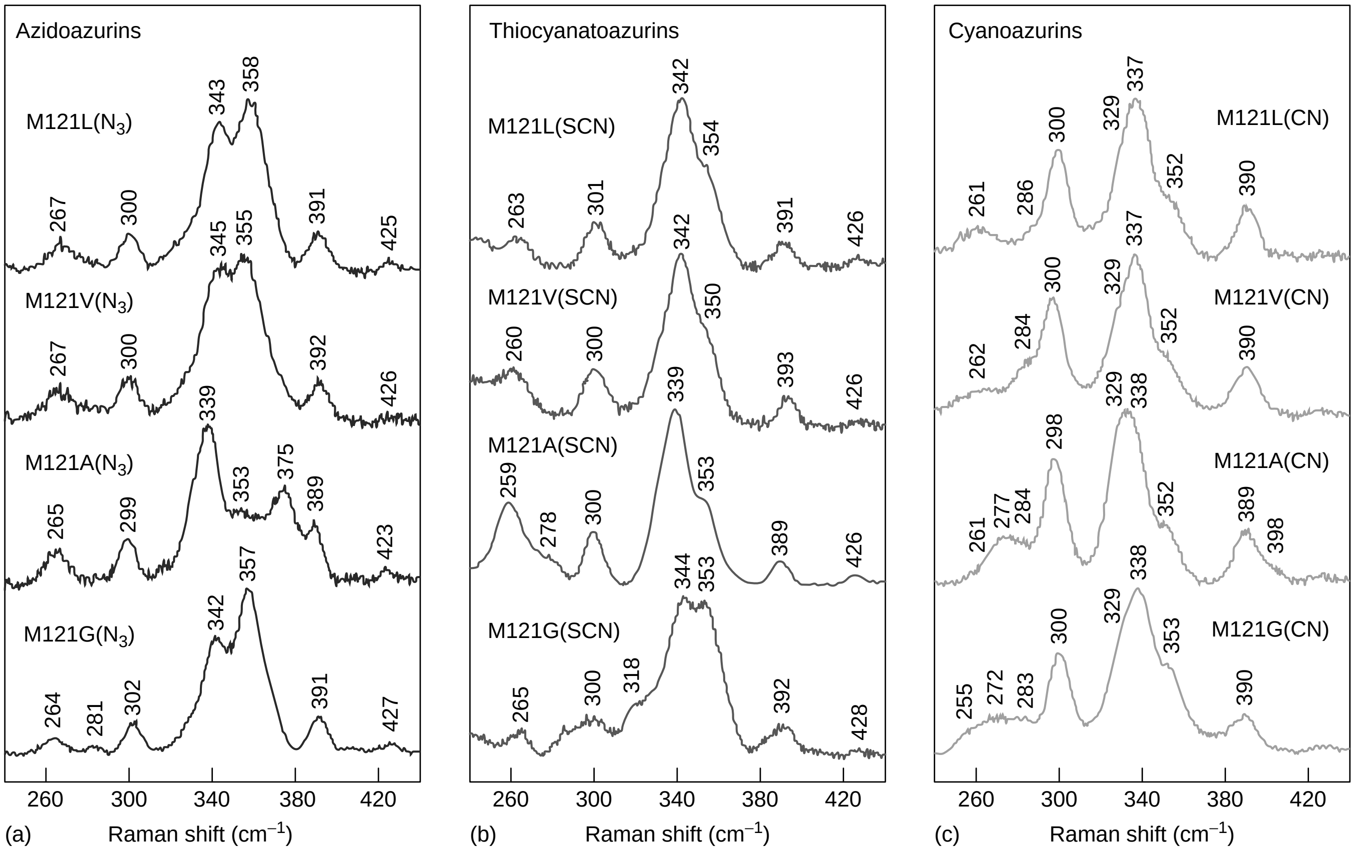

Figure 22 Low-temperature (77 K) RR spectra of indicated (a) azido, (b) thiocyanato, and (c) cyanoazurins obtained in the 240–440 cm^{-1} region with 406.7-nm excitation wavelength

tetrahedral character of the Cu in M121G is emphasized by increased absorption in the violet region (Table 5) and rhombicity of the EPR signal.[69]

3.3 Effects of Exogenous Ligand Coordination on Type-1 Cu Site

Figure 22 compares the RR spectra below 500 cm^{-1} for the azurin Met121X mutants (M121L, M121V, M121A, and M121G) treated with azide, thiocyanate, or cyanide, where most of the copper–ligand vibrations are expected to occur.[44,60] All spectra were obtained on frozen solutions (77 K) using a Kr^+ ion laser excitation at 406.7 nm. This excitation is in close resonance with an intense absorption band of the adducts in the violet region (Table 5), which arises from a hypsochromic shift of the ∼620 nm (Cys)S → Cu(II) CT transition due to a strong apical interaction provided by exogenous ligand binding. The optical parameters and the vibrational frequencies of the dominant RR peaks are summarized in Table 5, and one example of the optical absorption of complexes is given in Figure 23. While the Met121X azurins exhibit the most strongly enhanced vibrational modes in the ∼400 cm^{-1} region, assigned to the

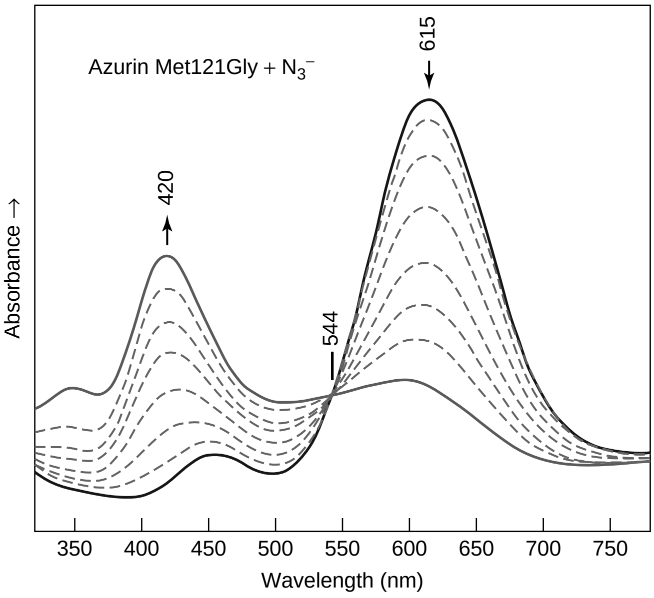

Figure 23 Changes in the UV–visible absorption spectrum of *P. aeruginosa* M121G azurin on sequential addition of aqueous sodium azide

Cu–S(Cys) vibrations, the strongest bands in their azido, thiocyanato, and cyano adducts occur in the ∼350 cm^{-1} region. Such behavior is characteristic of a structural rearrangement of the metal center to a distorted tetrahedron with a markedly weakened Cu(II)–S(Cys) bond caused by strong coordination of an exogenous anion. To investigate the origin of these new sets of bands, the RR spectrum (413.1-nm excitation) was obtained on the ^{34}S-labeled M121G azurin mixed with aqueous NaN_3, focusing on the 280–450 cm^{-1} spectral region.[44,55] The greatest influence of ^{34}S-mass incorporation occurs with the most intense peak at 357 cm^{-1}, which shifts 3.0 cm^{-1} to lower frequency (Figure 24, bottom). This substantial isotope shift identifies the 357 cm^{-1} mode of M121G–azide as predominantly due to stretching of the Cu(II)–S(Cys) bond, analogous to the 401 cm^{-1} mode of M121G that also shifts 3.0 cm^{-1} upon ^{34}S substitution (Figure 24, top). Meanwhile, the frequency of the β-carbon–sulfur(Cys) stretch, $\nu(CS)_{Cys}$, increased from 758 cm^{-1} in M121G to 773 cm^{-1} in the M121G–azide complex (Table 5). These vibrational results indicate a substantially weaker Cu(II)–S(Cys) interaction in the M121G–azide complex and, by extension, in all other adducts.

The most remarkable feature of Figure 24 is that at least four more bands around the dominant 357 cm^{-1} vibration also display isotope sensitivity (^{34}S minus ^{32}S): one strong peak at 342 (−1.6) and three weaker peaks at 302 (−1.2), 391 (−2.6), and 427 (−1.2) cm^{-1}. Thus, these bands must also arise from the vibrational modes that involve some motion of the cysteinyl sulfur atom. This finding is extraordinary in that the extensive kinematic coupling between the $\nu(CuS)_{Cys}$ stretch and internal vibrational modes of the protein matrix exhibited by cupredoxins is evidently independent of their Cu(II)–S(Cys) bond strength.

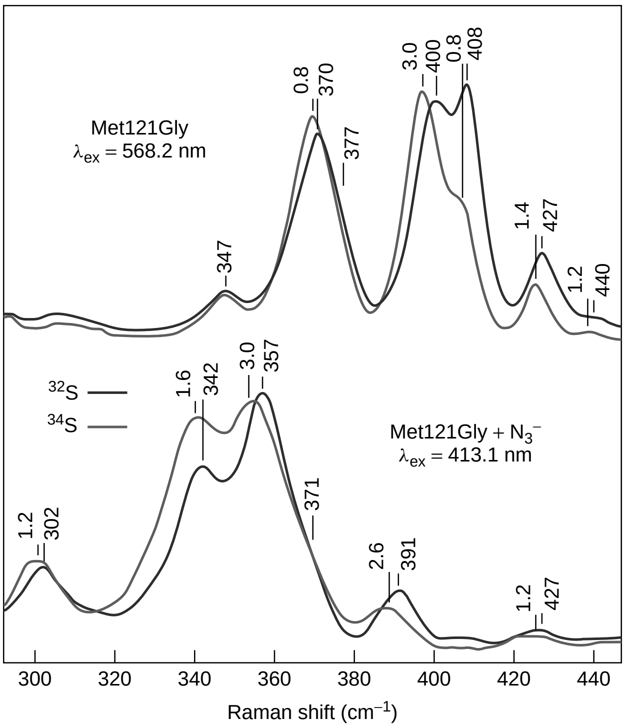

Figure 24 Low-temperature (77 K) RR spectra of *P. aeruginosa* M121G azurin and its azide adduct in the natural abundance and ^{34}S-labeled excited at 568.2 (M121G) and 413.1 nm (M121G–azide) Italic numbers show the [$\nu(^{32}S) - \nu(^{34}S)$] band shifts

Two azide-related vibrational modes in the M121A–N_3^- adduct were found at 375 and 2024 cm^{-1} and assigned as the $\nu(Cu–N_3)$ and $\nu_{as}(N_3)$ stretching modes based on $^{15}N_3/^{14}N_3$ isotopic shifts, −8 and −67 cm^{-1}, respectively, as shown in Figure 25.[60] Their counterparts in the glycine, valine, and leucine variants occur near 371 and 2045 cm^{-1} (Table 6), suggesting a weaker azide interaction with the Cu site than in the alanine variant. A nearly complete set of the thiocyanato-bound vibrational frequencies afforded by RR spectra of M121V–SCN^- has permitted accurate band assignments based on the observed $S^{13}CN^-$ and $SC^{15}N^-$ isotope shifts (Figure 26) and the results of NCA calculations.[60] In particular, the characteristic ν(S–CN) (∼720 cm^{-1}) and ν(C≡N) (∼2100 cm^{-1}) stretching frequencies established that SCN^- binds to the metal via the S atom to give a planar Cu–S–C≡N moiety. The CN^- ligand coordinates to the copper via its carbon atom giving rise to two ^{13}CN-sensitive weak bands at approximately 277 and 398 cm^{-1}, assigned as the ν(Cu–CN) stretch and the δ(Cu–C≡N) bend, respectively (Table 6).

3.4 Metal Substitution in Cupredoxins

Replacement of the Cu(II) ion in native and site-directed mutants of cupredoxins with other divalent metal ions such as Mn(II), Zn(II), Ni(II), Co(II), Ru(II), or Cd(II) proved useful in structural and spectroscopic characterization of type-1 copper sites by a number of different techniques.[70] Single crystal structures of several Zn(II)-, Cd(II)-, Ni(II)-, and Co(II)-substituted azurins showed the metal center that is better described as a distorted tetrahedron, instead of trigonal bipyramidal as in the Cu(II) azurin, because the metal ion is shifted away from the Met121 sulfur toward the carbonyl O-ligand of Gly45.[49,71] Figure 27 shows a comparison of the electronic absorption spectra obtained at room temperature from solutions of WT (Cu-containing) *P. aeruginosa* azurin and its Ni(II)- and Co(II)-substituted metalloderivatives.[70] Addition of Ni(II) or Co(II) to apoazurin causes the major cysteine-to-metal CT electronic transition to blue shift from 627 nm (Cu azurin) to 440 (Ni azurin) and 330 nm (Co azurin). As a result, pronounced changes are also observed in the RR scattering of Ni(II) and Co(II) azurins when the laser excitation is tuned through their absorption bands at 440 and 330 nm, respectively.This is shown in Figure 28, which reports the RR spectra taken in the 100–500 cm^{-1} region from a frozen (77 K) solution of *P. aeruginosa* Ni(II)-substituted azurin upon excitation with laser radiation at 406.7,

frequencies for the fundamental vibrations (100–1750 cm^{-1}) of both native *P. aeruginosa* azurin and its Ni(II) derivative,[70] together with those reported for Cu(II) and Ni(II) derivatives of *Alcaligenes xylosoxidans* azurin II[72] and *R. vernicifera* stellacyanin.[73]

Ni(II)-substituted azurin gives numerous vibrational bands in the 100–500 cm^{-1} range, which are maximally resonance enhanced with exciting radiation at 441.6 nm (as judged by the intensity of the protein Raman peaks relative to the ice band) (Figure 28), and which uniformly correspond to the vibrational modes of native azurin (Figure 29). Essentially, all of the 100–500 cm^{-1} vibrational modes that are observed for the native Cu(II) azurin are also detected in its Ni(II) derivative. The major vibrations that are observed for the Ni(II)-substituted azurin include a group of three intense RR peaks at 346, 360, and 391 cm^{-1} (Figure 29a), which clearly correspond to the strongest RR peaks at 373, 401(sh), 408, and 428 cm^{-1} of the native Cu(II) azurin (Figure 29b). Similarly, Co(II)-substituted azurin also gives three bands at 345, 360, and 390 cm^{-1} upon preresonant excitation at 354.2 nm (spectrum not shown).[70] Although [^{34}S]Cys isotopic shifts are not available for Ni(II)- and Co(II)-substituted derivatives, the apoprotein samples of *P. aeruginosa* azurin were reconstituted with different Ni isotopes (^{58}Ni or ^{62}Ni) and their high-resolution RR spectra were recorded to provide evidence for the Ni(II)–ligand vibrations. Figure 30 shows that upon substitution of ^{62}Ni for ^{58}Ni, the peaks at 424, 390, 360, 346, 285, and 269 cm^{-1} undergo shifts of −0.4, −1.0, −2.0, −0.8, −1.6, and −1.4 cm^{-1}, respectively. Thus, all of these RR bands must arise from vibrational motions that have nickel–ligand oscillatory character. The strongest Ni(II)-azurin band at 360 cm^{-1}, which exhibits the largest isotope shift (−2 cm^{-1}) upon substitution of ^{58}Ni for ^{62}Ni is ascribed to the predominantly Ni(II)–S(Cys) stretching mode, $\nu(NiS)_{Cys}$, analogous to the dominant 408 cm^{-1} $\nu(CuS)_{Cys}$ mode in WT azurin. The $\nu(NiS)_{Cys}$ character is also detected for the bands at 346 and 390 cm^{-1} from their $^{62/58}$Ni isotope shifts (−0.8 and −1.0 cm^{-1}), which is consistent with kinematic coupling of the metal–thiolate stretch with internal vibrations of the cysteine ligand side chain observed in the RR spectra of cupredoxins. Meanwhile, the frequency of the β-carbon–sulfur(Cys) stretching vibration, $\nu(CS)_{Cys}$, increased from 751 cm^{-1} in Cu(II) azurin to 763 cm^{-1} in Ni(II) azurin (Table 7, Figure 29). Taken together, these vibrational results indicate that Ni(II) substitution causes a significant weakening of the metal–S(Cys) bond as the metal coordination changes from trigonal bipyramidal of Cu(II) azurin to tetrahedral in Ni(II)-modified protein. This bond weakening is supported by the trend found in X-ray crystallographic studies of *P. aeruginosa* azurin and its Ni(II) derivative, which showed a much longer Ni–S(Cys) bond distance (2.39 Å) in Ni(II) azurin than in the WT protein (2.25 Å).[49,71]

The excitation wavelength-dependent RR spectra (Figure 28) also provided unambiguous evidence for the nature of the CT electronic transition at 440 nm as due to (Cys)S → Ni(II). Figure 31 compares the Ni(II)-azurin optical absorption spectrum with excitation profiles for the three most intense $^{58/62}$Ni-sensitive RR bands at 346, 360, and 390 cm^{-1}. The profiles are quite similar and closely track the absorption band in the violet region.

3.5 Substrate Binding to Type-2 Cu Site in Blue Nitrite Reductase

Copper-containing nitrite reductases (NiRs) (*see* ***Copper Enzymes in Denitrification***), involved in the anaerobic respiratory pathway as a part of the denitrification process, utilize two types of metal centers, type-1 copper (T1Cu) and type-2 copper (T2Cu), to transfer electrons in the reduction of NO_2^- to NO and further to N_2O and N_2.[74] X-ray crystal structure determinations of several Cu-containing NiRs showed that these enzymes are trimers constituted of three identical monomers, each monomer containing two Cu sites.[75–78] The coordination environment of the T1Cu is consistent with all other blue copper electron-transfer proteins. The T1Cu of *A. xylosoxidans* NiR is coordinated by two histidines, one methionine, and one cysteine in a distorted tetrahedral arrangement, while the T2Cu is ligated by two histidines from one monomer and by one histidine form a

second monomer. The two copper sites of *A. xylosoxidans* NiR are directly connected through adjacent residues Cys130 and His129 that are coordinated to the T1Cu and T2Cu centers, respectively. This linkage provides a 12.5 Å pathway for efficient electron transfer from the T1Cu to T2Cu site.[78] X-ray crystallographic studies on the NO_2^--soaked NiR crystals have revealed that the T2Cu is the substrate-binding site, with an asymmetric coordination of NO_2^- to the Cu.[76–78]

[f]Boldface numbers indicate the RR peaks with the greatest intensity; sh = shoulder. [g]Possibly overlapping bands.

The RR spectroscopic investigation of blue Cu-containing *A. xylosoxidans* NiR (*Ax*NiR) has recently been carried out,[74] and the structural rearrangements at the electron-transfer site of T1Cu caused by substrate binding (NO_2^-) and the depletion of T2Cu, are briefly presented in this section. The electronic absorption spectrum of the *A. xylosoxidans* NiR exhibits the intense absorption band due to T1Cu (Cys)S → Cu(II) CT transition at 597 nm. The T2Cu site does not contribute to the visible spectrum. Trace (a) in Figure 32(A) shows the RR spectrum of the enzyme obtained at room temperature by excitation at 647.1 nm.[74] The *A. xylosoxidans* NiR has its own unique T1Cu spectrum in the $\nu(CuS)_{Cys}$ region, with one strong peak at 412 cm^{-1}, a prominent shoulder at ~420 cm^{-1}, and additional small features at 364 and 376 cm^{-1}.

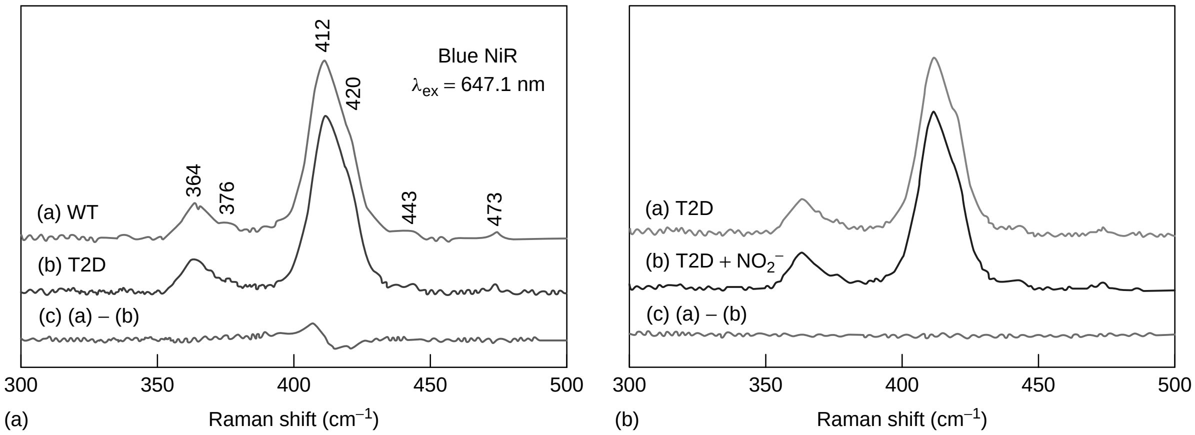

Figure 32 (A) RR spectra of (a) holo-*Ax*NiR (WT) and (b) its T2Cu-depleted protein (T2D) in 20 mM phosphate buffer (pH 7.0), and (c) their difference spectrum. (B) RR spectra of T2D *Ax*NiR in the absence (a) and presence (b) of nitrite and their difference spectrum (c)

To investigate the spectral contribution of the T2Cu, the RR spectra of type-2-copper-depleted (T2D) *A. xylosoxidans* NiR were measured. Trace b in Figure 32(A) shows that the T2D enzyme gave a spectrum almost identical to that of the holoenzyme (trace a in Figure 32A). The difference spectrum (trace c in Figure 32A) between T2D and holoenzyme revealed that the Raman bands associated with stretching the Cu(II)–S(Cys) bond, particularly those at 412 and 420 cm^{-1}, are slightly shifted to higher frequencies upon removal of the T2Cu ion, because of the subtle rearrangement of the T1Cu–Cys130–His129–T2Cu intersite structure.

By the sensitive RR difference spectroscopic technique, *A. xylosoxidans* NiR in the presence of various nitrite concentrations has been probed (Figure 33). The RR spectra of blue NiR recorded in the presence and absence of nitrite do not show significant changes (Figure 33a and b), but their difference spectra (Figure 33i) clearly show that the substrate binding alters the structure of the T1Cu site in NiR. The Raman bands of $\nu(CuS)_{Cys}$ at 412, 420, and 364 cm^{-1} all shift to higher energies in the presence of nitrite, and the intensity of the difference spectra depends on the concentration of nitrite (Figure 33c–i). These spectral changes, upon treatment of the enzyme with aliquots of increasing NO_2^- concentration, imply that nitrite does not enter the coordination sphere of the T1Cu center in NiR but rather binds to its T2Cu ion, as had been previously established by X-ray crystallography.[76–78] The increased frequencies of the Raman bands at 412, 420, and 364 cm^{-1} in nitrite-bound enzyme suggest that there could be a stronger Cu(II)–S(Cys) bonding than that in the absence of substrate, or a weakened hydrogen bonding to the coordinated sulfur ligand of cysteine, as a result of the T1Cu–T2Cu intersite structural rearrangement. That substrate binding occurs at the T2Cu site has been supported by the RR spectra of T2D *A. xylosoxidans* NiR measured in the presence and absence of nitrite. The results are presented in Figure 32(B), where it can be seen that the spectrum of T2D enzyme does not show any changes in the $\nu(CuS)_{Cys}$ bands by the addition of nitrite, as evident from the nitrite-treated T2D minus untreated T2D difference spectrum (trace c in Figure 32B).

3.6 The Mononuclear FeS_4 Site in Rubredoxins

Iron–sulfur clusters (*see* ***Iron–Sulfur Proteins***), involved in a variety of biological redox processes, photosynthesis, nitrogen fixation, and respiration, have a common building block with Fe tetrahedrally coordinated to four S-donor ligands.[16,22,79] In 1-Fe rubredoxins, in which the building block itself constitutes their active site, the sulfur atoms belong to four cysteine amino acids of the protein backbone. In [2Fe–2S] ferredoxins, the iron ions are bridged by inorganic μ_2-sulfides and bound to two sulfur atoms of cysteine residues. In cuboidal [3Fe–4S] clusters, each iron is ligated to three of the four acid-labile sulfur atoms and to one additional cysteinyl sulfur. The most prevalent cluster type is found in [4Fe–4S] proteins, the bacterial ferredoxins, and high-potential iron–sulfur proteins, in which each iron interacts with three inorganic μ_3-sulfides and sulfur atom of cysteine, forming a cubane shape with iron and sulfur atoms in alternation.[79] The Fe–S proteins are brown in color, owing to visible absorption bands that are associated with CT transitions from sulfur (both bridging and terminal) to Fe(III). Consequently, the structurally diverse 1-Fe, 2-Fe, 3-Fe, and 4-Fe centers of Fe–S proteins have been probed extensively with room- and cryogenic-temperature RR spectroscopy, using isotope labeling to identify the Fe–S cluster vibrational modes in the RR spectra.[22,79–85] As expected, the RR spectra show selective enhancement of Fe–S vibrations, due to the extension of the Fe–S bonds in the CT-excited states. The spectral patterns are unique and distinctive for different structural types and several detailed reviews on this subject have been published.[16,22,79]

Rubredoxin was the very first metalloprotein to which RR spectroscopy was applied. In 1970 and 1971, Long and coworkers found four bands in the metal–ligand stretching and bending region in the 488.0-nm excitation RR spectra of rubredoxin from *Clostridium pasteurianum*,[86,87] just the number of normal modes expected for a tetrahedral FeS_4 complex. A strong polarized band at 314 cm^{-1} was assigned to the totally symmetric breathing mode $\nu_1(A_1)$, involving the in-phase stretching of all four Fe(III)–S(Cys) bonds. The other three stretches (there must be four altogether, one for each bond) were assigned to the triply degenerate out-of-phase mode $\nu_3(T_2)$, observed weakly as a depolarized band at 368 cm^{-1}. The remaining two bands at 126 and 150 cm^{-1} were identified with the S–Fe–S bending modes, $\nu_2(E)$ (doubly degenerate) and $\nu_4(T_2)$ (triply degenerate), respectively. These four bands are close in frequency to the modes of the isoelectronic complex $[FeCl_4]^- = 385$ (ν_3), 330 (ν_1), 133 (ν_4), and 108 cm^{-1} (ν_2).[88] Thus, the analysis of the protein RR spectrum was satisfyingly straightforward.

Subsequent RR studies,[89] with better spectral quality and with isotope shift data, have shown the situation to be more complex, however. Figure 34 shows an interesting variation

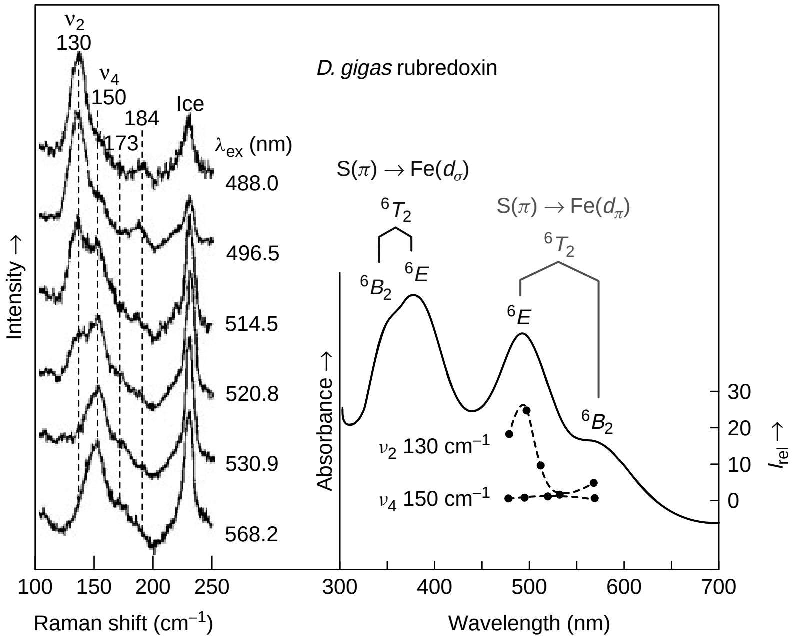

Figure 34 Variable wavelength RR spectra of a frozen *D. gigas* rubredoxin solution in the bending-mode region. The intensities of ν_2 and ν_4 were determined by ratioing them with the 227 cm^{-1} ice band (marked with an asterisk) intensity. The resulting excitation profiles are compared with the absorption spectrum, showing that ν_2 is strongly resonant with the 495-nm absorption band, while ν_4 is weakly resonant with the 565-nm shoulder. These transitions are assigned respectively to the ^6E and $^6B_2$ components of the $S(\pi) \rightarrow Fe(d\pi)$) charge-transfer transition, split by symmetry lowering from T_d to D_{2d}. The former electronic component provides A-term enhancement of the A_1 vibrational component of the E bending mode (ν_2), while the latter provides B-term enhancement to the E component of the T_2 mode (ν_4), via vibronic coupling with the nearby ^6E electronic transition

with laser wavelength of the $\nu_2(E)$ and $\nu_4(T_2)$ bending modes of rubredoxin from *Desulfovibrio gigas*. The excitation profiles, constructed by ratioing the band intensities of the frozen protein sample to the intensity of the nearby ice band at 227 cm^{-1}, showed $\nu_2(E)$ to be strongly resonant with the strong absorption band at 495 nm, while $\nu_4(T_2)$ is weakly resonant with the 565-nm shoulder. These results were interpreted on the basis of a previous electronic assignment by Eaton and Lovenberg,[90] also shown in Figure 34. Two CT transitions are expected in the visible region, from the sulfur π to the Fe d_π and d_σ orbitals, but these are split by a lowering of the effective symmetry of the chromophore, from T_d to at least D_{2d}, because of an elongation of the tetrahedron along the S_4 symmetry axis. The 495-nm band and its 565-nm shoulder were assigned respectively to the ^6E and $^6B_2$ components of the Fe(d_π) ← S(π) transition. These components can be coupled vibronically via a mode of $B_2 \times E = E$ symmetry. The T_2 vibrational modes also have E and B_2 components in D_{2d} symmetry. Therefore, the E component of the T_2 mode can couple the weak 565-nm transition with the strong nearby 495-nm transition, thereby accounting for the ν_4 enhancement via the B-term scattering mechanism. On the other hand, the ν_2 enhancement in resonance with the strong 495-nm transition can be attributed to FC scattering, since the E (T_d) mode has A_1 and B_1 components in D_{2d} symmetry, and the A_1 component is subject to A-term enhancement. The second components of each mode, B_2 of ν_4 and B_1 of ν_2, are not observed because they lack effective enhancement mechanisms.

Further complexity was discovered when the Fe–S stretching region was reexamined at higher resolution in frozen protein solution at 77 K.[89] When the low-temperature spectrum was recorded with 568.2-nm excitation (Figure 35), three bands were now seen at 376, 363, and 348 cm^{-1}, not one, in the $\nu_3(T_2)$ region, implying the degeneracy being completely lifted. In addition, a prominent shoulder at 324 cm^{-1} became apparent on the ν_1 band. The assignment of the bands at 376, 363, and 348 cm^{-1} to ν_3 components was established by examining their isotope shifts in ^{54}Fe-reconstituted protein via RR difference spectroscopy, as shown in Figure 36. All three bands showed clear ^{54}Fe-isotope shifts to higher frequency, as expected for antisymmetric Fe–S stretching vibrations. The dominant RR band at 314 cm^{-1} did not shift on ^{54}Fe substitution, confirming its assignment to the FeS_4 breathing mode, ν_1 (the Fe atom does not move in such a mode). Likewise, a side band at 324 cm^{-1} showed no discernible ^{54}Fe shift; the intensity is canceled in the difference spectrum over the 314–324 cm^{-1} band envelope (Figure 36). This band was therefore assigned to a cysteine SCC bending mode, δ(SCC).[89]

To account for the main features of the rubredoxin RR spectrum, vibrational modes of a series of small molecule analogs, $[Fe^{III}(SMe)_4]^-$, $[Fe^{III}(SEt)_4]^-$, and $[Fe^{III}(S_2\text{-}o\text{-}xyl)_2]^-$ (SMe = methylthiolate, SEt = ethylthiolate, and S_2-*o*-xyl = *o*-xylene-α,α'-dithiolate), have been analyzed using RR and IR spectra of isotopomers (^{54}Fe, ^{34}S, and ^{2}H).[91] The vibrational spectra of analog complexes revealed that the splitting of the triply degenerate ν_3Fe–S stretching mode is mainly due to (i) nontetrahedral S–Fe–S angles, (ii) out-of-plane rotation of the S–C bonds, and (iii) kinematic coupling between Fe–S stretching and S–C–C bending modes, which is greatly dependent on the FeS–CC dihedral angles. Using a consistent force field for all three complexes, NCA calculations provided a good match to the observed values of ν_1, ν_2, ν_{3a-c}, and ν_4, and their respective isotope shifts.

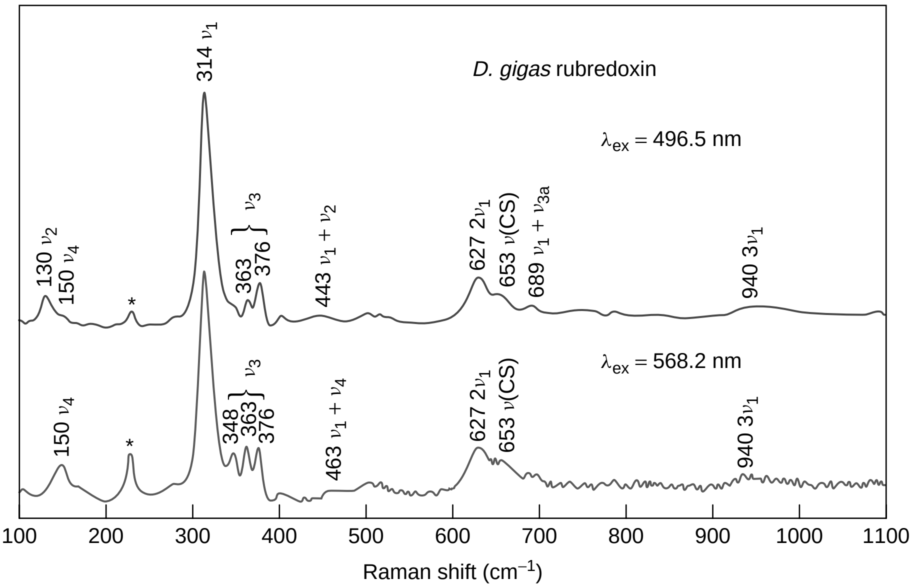

Figure 35 Low-temperature (77 K) RR spectra of *D. gigas* rubredoxin obtained in the 100–1100 cm^{-1} region using 496.5- and 568.2-nm excitations

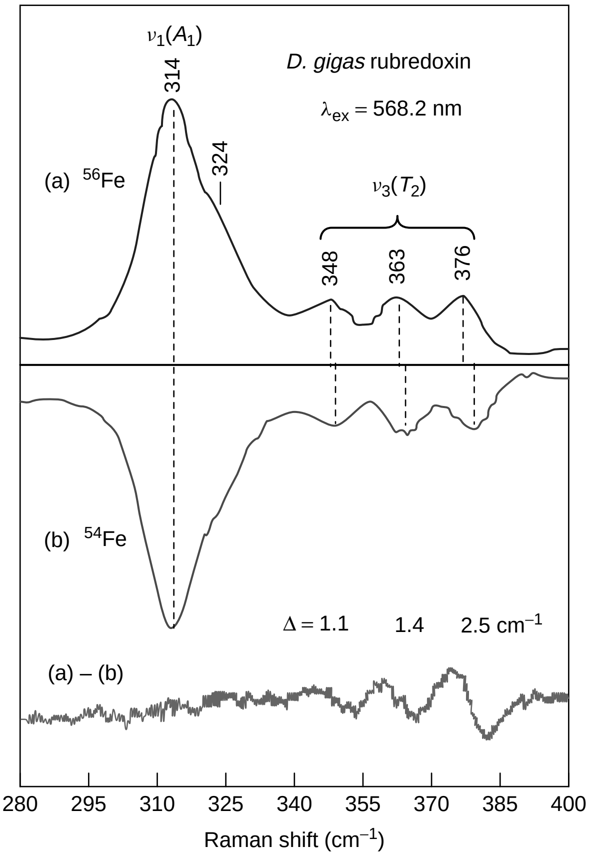

Figure 36 568.2-nm excited RR spectrum in the Fe–S stretching region for (a) natural abundance *D. gigas* rubredoxin and (b) of the protein reconstituted with ^{54}Fe

The rubredoxin RR bands and ^{54}Fe isotope shifts were also modeled with the same force field, which revealed a dominant influence of ν(FeS)/δ(SCC) mixing due to 180° FeS–CC dihedral angles for two of the cysteine ligands at the rubredoxin active site. However, proper calculation of the ν_1 frequency of rubredoxin required a significant reduction of the Fe–S stretching force constant (1.27 mdyn/Å), relative to that of the analog complexes (1.34 mdyn Å^{-1}). The lower force constant implies weaker Fe(III)–S(Cys) bonds. This reduction was proposed to reflect the influence of H bonding to the cysteinate S atom in the protein.[89] The H bonds reduce the negative charge on the S atoms and reduce their donor strength, i.e., weaken the Fe–S(Cys) bonds in the protein.

3.7 The FeS_4 and Fe–O–Fe Sites in Rubrerythrin

This intriguing nonheme homodimeric protein (*see* ***Iron Proteins with Dinuclear Active Sites***), originally isolated from the anaerobic sulfate-reducing bacterium *Desulfovibrio vulgaris*,[92] contains a unique combination of two types of chromophoric iron(III) sites in each subunit: one rubredoxin-like Fe(S-Cys)$_4$ center in the *C*-terminal domain and one nonsulfur, (μ-oxo)*bis*(μ-carboxylato)-triply bridged binuclear Fe(III) cluster in the *N*-terminal domain.[93,94] The initial spectroscopic indications of these sites have been confirmed by protein X-ray crystallography structural studies[95–97] (Figure 37), but the first evidence for the Fe–O–Fe structural unit in rubrerythrin came from RR spectroscopy.[92] Figure 37 shows low-temperature (77 K) RR spectra of as-isolated *D. vulgaris* rubrerythrin in a liquid N_2 cell with excitation at 496.5 and 406.7 nm.[92] These excitation wavelengths are in resonance with the well-separated (Cys)S → Fe(III) (~492 nm) and μ-oxo → Fe(III) (~370 nm) CT electronic absorption bands, respectively, of rubrerythrin. Figure 38 compares RR spectra obtained with 406.7-nm excitation for the protein contained in H_2O and the recrystallized protein dissolved in $H_2{}^{18}O$, D_2O, and $D_2{}^{18}O$. Band frequencies, isotope shifts, and assignments are listed in Table 8. The 496.5-nm excitation spectrum in Figure 37 (upper trace) is overwhelmingly dominated by the vibrational modes characteristic of rubredoxin-like Fe(Cys)$_4$ sites: a strong band at 314 cm^{-1}, assigned to the cluster breathing ν_1 mode; a set of widely spaced weaker bands at 340, 355, and 374 cm^{-1}, assigned to three components of the ν_3 antisymmetric Fe–S(Cys) stretch; weak bands at 128 and 156 cm^{-1}, assigned to ν_2 and ν_4 S–Fe–S bending modes; and numerous overtone and combination bands of the Fe–S(Cys) stretches in the 450–800 cm^{-1} region. Indeed, the number, positions, and intensities of these resonance-enhanced Raman bands closely match those observed for frozen solutions of rubredoxins from *D. gigas* (Figure 35, Table 8)[89] and *Pyrococcus furiosus*.[98]

In contrast, the RR spectrum of *D. vulgaris* rubrerythrin excited at 406.7 nm shows dramatically diminished intensities of the FeS_4 bands with concomitant enhancement of a band at 514 cm^{-1} (Figure 37, bottom trace). This band shifts 18 cm^{-1} to lower frequency (496 cm^{-1}) when the protein is dissolved in $H_2{}^{18}O$ (Figure 38). Therefore, the 514-cm^{-1} band must involve vibrational motion of a water-exchangeable oxygen atom. The frequency of this band and the ^{18}O isotope shift are those expected for the symmetric Fe–O–Fe stretch, ν_s(FeOFe), of a bent μ-oxo-bridged diiron(III) cluster that has one or two additional cobridging carboxylate ligands.[92] From the observed ν_s(FeOFe) frequency (514 cm^{-1}) and its ^{18}O isotope shift (−18 cm^{-1}), an Fe–O–Fe angle of 124° was calculated for the diferric cluster in rubrerythrin by solving a simple X–Y–X three-body vibrational problem.[21] The bridge substitution experiments also revealed a small but reproducible shift (+2 cm^{-1}) to higher frequency for the ν_s(FeOFe) stretch when the rubrerythrin crystals are dissolved in D_2O and $D_2{}^{18}O$ (Figure 38), implying involvement of hydrogen bonding to the oxo group at the Fe–O–Fe site. All these RR inferences have later been confirmed by protein X-ray crystallography performed on single crystals of all-ferric recombinant *D. vulgaris* rubrerythrin.[95,96] As shown in Figure 37, its Fe^{3+} ions are both pseudo-octahedrally coordinated; one Fe^{3+} ion is ligated terminally by one bidentate glutamate and one histidine, the other Fe^{3+} ion

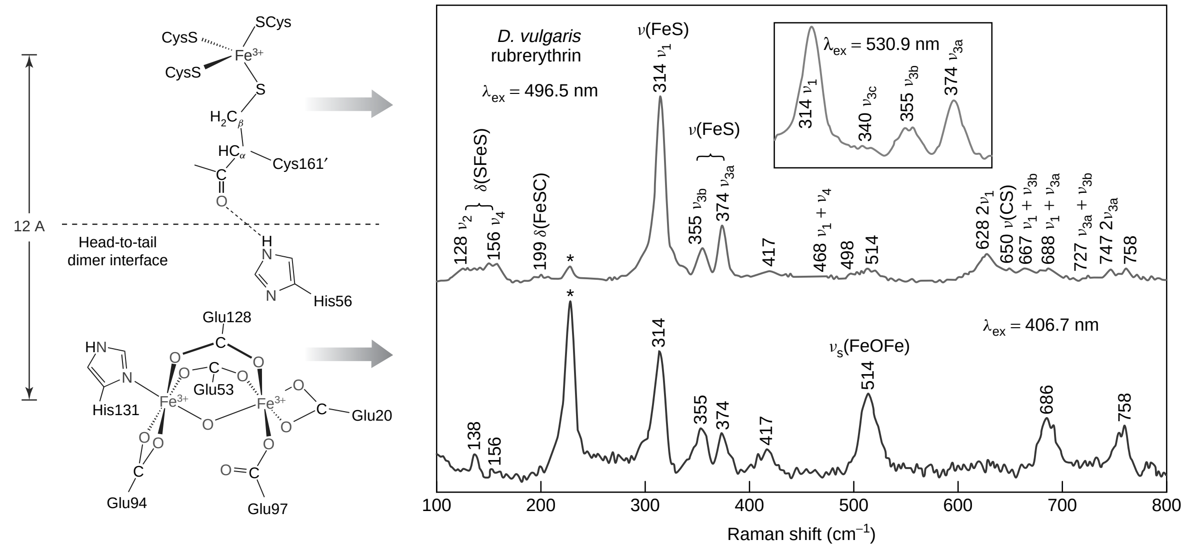

Figure 37 Low-temperature (77 K) RR spectra of *D. vulgaris* rubrerythrin obtained in the 100–800 cm^{-1} region with 496.5- (upper trace) and 406.7-nm (lower trace) excitation wavelengths. The spectrum excited at 496.5 nm is totally dominated by the bands arising from the $Fe(S\text{-}Cys)_4$ cluster, whereas that excited at 406.7 nm shows dramatically diminished intensities of the Fe–S bands with a concomitant enhancement of the band at 514 cm^{-1} assigned to ν_s(FeOFe) mode of a bent Fe–O–Fe cluster. Asterisks indicate the 228 cm^{-1} ice band

Table 8 Observed RR frequencies (cm^{-1}) and assignments for *D. gigas* rubredoxin and *D. vulgaris* rubrerythrin[a]

777		$2\nu_1 + \nu_4$

[a]Rubredoxin data and assignments from Czernuszewicz *et al.*[89] Rubrerythrin data from Dave *et al.*[92]. ? = Indeterminate assignment. [b]δ(XYZ) and ν(XY) are bending and stretching coordinates involving the indicated atoms. [c]ν_{1-4} are normal modes of a XY_4 tetrahedron. [d]Symmetry designation for the $D_{2d}(T_d)$ point groups. [e]The numbers in () and [] indicate the frequency shifts in $H_2{}^{18}O$ and D_2O, respectively. [f]ν_s is the symmetric (in-phase) Fe–O–Fe stretching coordinate.

is ligated terminally by two glutamates, and the two Fe^{3+} ions are bridged by two bidentate glutamate ligands and an oxo (O^{2-}) group derived from the solvent. From the Fe···Fe (3.33 Å) and Fe–O (average 1.93 Å) distances,[96] the Fe–O–Fe angle of ~120° can be calculated for the binuclear Fe(III) structure in rubrerythrin, which compares well with the bridge angle of 124° derived from RR spectroscopy. The Fe–O–Fe site is located close to the protein surface such that the μ-oxo-bridge is accessible to bulk solvent through a crevice formed between two α-helices (A and C).[91] Thus, intramolecular hydrogen bonding between the bridging μ-oxo group and H_2O can be anticipated and is responsible for the deuterium isotope effects on the ν_s(FeOFe) stretch in the RR spectrum of rubrerythrin (Figure 38).[92]

3.8 Cysteine Ligand Substitution in Rubredoxin

Systematic replacement of cysteine ligands at the $Fe(S\text{-}Cys)_4$ active site of rubredoxin[99,100] by site-directed mutagenesis has proven useful in probing many fundamental properties of iron–sulfur proteins.[99–104] For example, mutant forms of rubredoxin from *C. pasteurianum* (Rd*Cp*) in which each of its four cysteine ligands was replaced, in turn, with serine (C6S, C9S, C39S, and C42S)[99,101] constitute a set of four geometric isomers that have differently oriented $Fe(S\text{-}Cys)_3(O\text{-}Ser)$ centers within the same protein chain. Their properties fall into two pairs, depending upon whether a surface (C9, C42) or an interior (C6, C39) ligand is substituted (Figure 39). A comparison of the solution optical spectra of the WT protein and its surface ligand cysteine-to-serine mutants (C9S, C42S, and C9S/C42S) showed blue shifts of the absorption bands arising from (Cys)S → Fe(III)

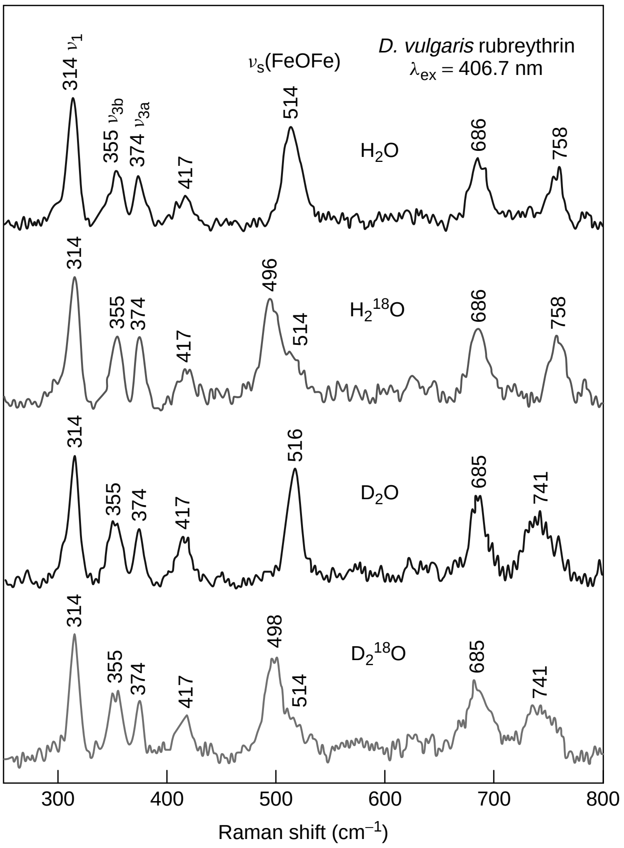

Figure 38 406.7-nm excited RR spectra of *D. vulgaris* rubrerythrin contained in H_2O, $H_2{}^{18}O$, D_2O, and $D_2{}^{18}O$ (frozen protein solutions at 77 K), showing the effects of ${}^{16/18}O$ and H/D exchange on the resonance-enhanced vibrational modes

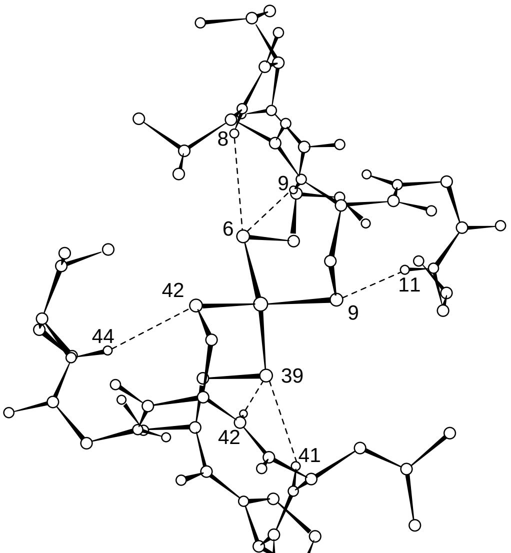

Figure 39 NH···S interactions (- - - -) around the $Fe(S\text{-}Cys)_4$ center in Rd*Cp* (pdb5rxn.ent).[105] A pseudo-2-fold axis is perpendicular to the page, passing through the Fe atom

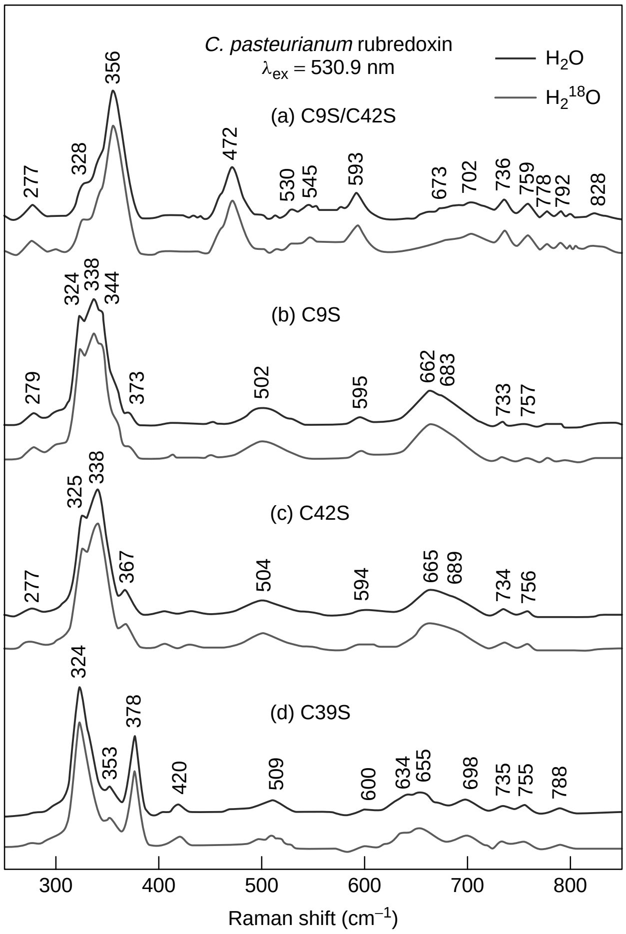

Figure 40 Low-temperature (77 K) RR spectra (530.9-nm excitation) of oxidized Rd*Cp* proteins: (a) C9S/C42S, (b) C9S, (c) C42S, and (d) C39S mutants in H_2O and $H_2{}^{18}O$

CT, consistent with the number of oxygen atoms increasing in the order FeS_4, FeS_3O, FeS_2O_2.[101] Figure 40 compares RR spectra for the C9S/C42S doubly mutated protein in H_2O and $H_2{}^{18}O$ with those of single mutants C9S, C42S, and C39S, using an excitation wavelength of 530.9 nm.[99] Each protein exhibits strong $\nu(FeS_{2,3})$ stretching modes of vibration in the range 325–475 cm^{-1} and a cluster of weaker overtone and combination bands associated with $\nu(FeS_{2,3})$ in the range 650–850 cm^{-1}, as expected for Raman scattering excited in resonance with the rubredoxin (Cys)S → Fe(III) CT transitions.[22,43,89,98] In addition, each gives a band at $597 \pm 4\,cm^{-1}$ that is not present in the WT protein spectrum. These frequencies (i) shift by 1.5–3.0 cm^{-1} to higher frequency in ${}^{54}Fe$-reconstituted protein samples; (ii) do not shift in samples that have been freeze-dried and redissolved in $H_2{}^{18}O$ (compare with the C6S protein discussed later); and (iii) are independent of pH in the range pH 6–10. The new band at $597 \pm 4\,cm^{-1}$, which exhibited a ca. $+3\,cm^{-1}$ ${}^{54}Fe$ isotope upshift, may be assigned to $\nu(FeO_x)$ ($x = 1, 2$) vibrational

modes, consistent with the presence of ferric Fe(S-Cys)$_3$(O-Ser) and Fe(S-Cys)$_2$(O-Ser)$_2$ centers in the single and double mutants, respectively.[99] An enhancement of the Fe–O(Ser) stretching vibration is possible via kinematic coupling with the intense ν(FeS$_{2,3}$) modes.

RR spectra of the interior ligand C6S mutant dissolved in H_2O and in isotopically labeled waters, $H_2{}^{18}O$ and D_2O, are presented in Figure 41.[99,100] Also shown there is the spectrum of C6S reconstituted with ^{54}Fe. The C6S spectra are independent of pH in the range 6–10, but in contrast to those of the other cysteine-to-serine mutants (Figure 40), it is sensitive to $H_2{}^{18}O$. A band at $\sim$617 cm^{-1} in H_2O (Figure 41a), which occurs at $\sim$620 cm^{-1} for the ^{54}Fe-reconstituted C6S protein (Figure 41b), and shifts down by $\sim$25 cm^{-1} on $H_2{}^{18}O$ exchange (Figure 41c). This band must involve vibrational motion of an iron atom and a water-exchangeable oxygen atom and is attributed to a ν(FeOH) vibration of an Fe–OH fragment. Evidence that the 617 cm^{-1} band is associated with a hydroxyl group is provided by its 13 cm^{-1} *increase* in frequency in D_2O (Figure 41d), resulting from differential coupling of the stretching ν(FeOH) coordinate with the bending δ(FeOH) coordinate involving H or D atoms.[106] The frequencies of the δ(FeOH) bending modes are variable but can be close to 700 cm^{-1} for strongly H-bonded hydroxyl groups. The interaction between ν(FeOH) at 617 cm^{-1} and δ(FeOH) near 700 cm^{-1} would be relieved in D_2O because of the large drop in the δ(FeOD) frequency. This would result in the observed *increase* of the ν(FeOD) stretching frequency. The observed upshift of 13 cm^{-1}, upon dissolution of C6S in D_2O, has been reproduced by a simplified NCA calculation with a three-atom Fe–O–H model using reasonable force constants and structure parameters.[99] The RR spectra of the C6S and C39S proteins are very similar, indicating the presence of a similar Fe^{III}S$_3$O center in each protein. Thus, while an [Fe^{III}(S-Cys)$_3$(O-Ser)]$^-$ center is maintained in C39S, the weakness of a longer Fe(III)–O(Ser) bond in C6S has led to its hydrolysis and the presence of an [Fe^{III}(S-Cys)$_3$(OH)]$^-$ center and an unligated HO-Ser-6 residue. The [Fe^{III}(S-Cys)$_3$(OH)]$^-$ center in the C6S protein is a promising model system for a number of M(S-Cys)$_3$ sites, including the mononuclear iron sites in NifU and IscU proteins involved in the iron–sulfur cluster assembly.[103,104] The RR spectrum reported for the monomeric iron-binding site in NifU[103] is very similar to that of the C6S mutant of *C. pasteurianum* rubredoxin.[107]

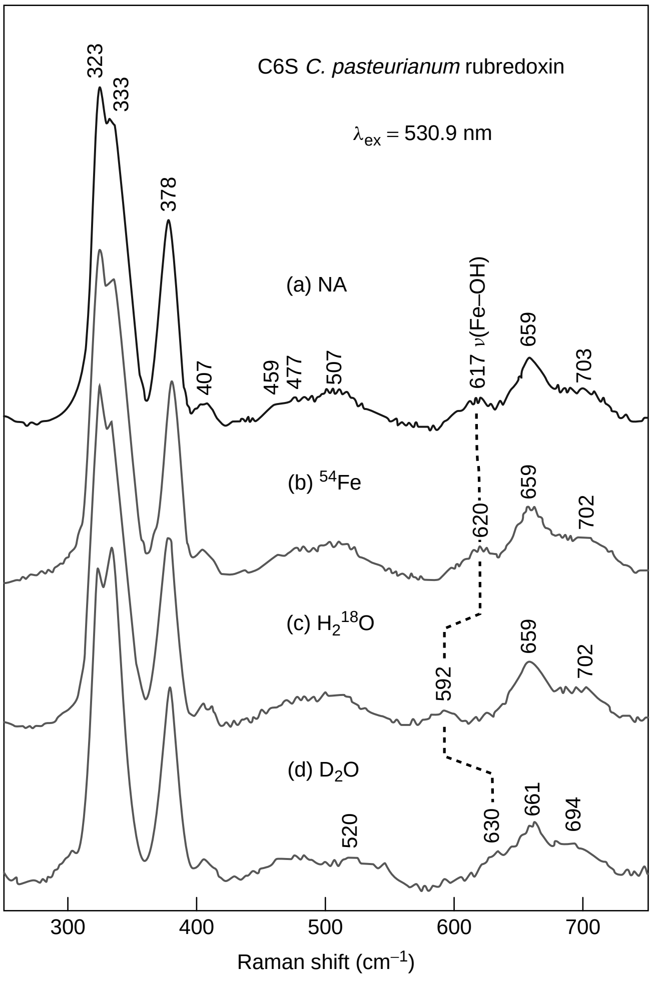

Figure 41 530.9-nm excited (77 K) RR spectra of C6S Rd*Cp* mutant: (a) in natural abundance, (b) ^{54}Fe-reconstituted protein, (c) in $H_2{}^{18}O$, and (d) in D_2O

METHOD SUMMARY

Acronyms, Synonyms

- InfraRed
- Fourier Transform InfraRed
- Resonance Raman
- Time Resolved

Measured physical quantities

- absorption spectrum of IR light
- inelastic scattering spectrum of incident monochromatic (laser) light (Raman)
- intensities, widths, and shapes of IR and Raman peaks
- polarization and anisotropy (IR and Raman)
- in the TR case, kinetics and dynamics (IR and Raman).

Information available

- structure: force constants of bonds; masses and spatial disposition of atoms
- structure: molecular symmetry and symmetries of vibrations
- coupling between vibrational and electronic transitions (RR)
- temporal evolution of structure; excited-state information (TR)

Information not available, limitations

- Specific vibrational assignments often require isotope or (in proteins) mutant studies.

Examples of questions that can be answered

- Is a carboxylic acid or tyrosine sidechain in a protein protonated or not?
- What are the effective oxidation states of metals and organic groups?
- What structural and electronic changes occur in reaction transients and excited states?
- What changes in secondary structure occur due to perturbations of proteins?

Major advantages

- All molecules have vibrational spectra: nearly all vibrations are IR or Raman active.
- Exceptionally small structural changes are observable by difference techniques.

- This method is applicable to all phases of matter and all levels of organization–diatoms to in vivo.
- This method is applicable to all relevant timescales–femtoseconds to months or longer.

Major disadvantages

- Photochemical damage is an issue (Raman, especially RR, TR).
- Structural interpretations are indicative but frequently not unique.
- The more complex the molecule, the more congested the spectrum (e.g. protein IR).

Sample constraints

- Relatively high concentrations (100 µM or higher) may be required (except RR).
- Sample volumes can be very small–typically 1 fl (Raman) to 1 ml (IR).
- Medium (e.g., solvent) interferences are avoided or mitigated by different techniques.

1 INTRODUCTION

Vibrational spectroscopy is defined for the purposes of this article as the measurement of the interaction of electromagnetic radiation with molecular vibrations (this terse definition is expanded in the next section). Modern vibrational spectroscopy comprises a multitude of specialized techniques, in many cases for very sophisticated purposes. However, by far the most common vibrational methods exploit the direct absorption of infrared (IR) light (infrared spectroscopy) or the inelastic scattering of monochromatic light of either near IR, visible, or near ultraviolet wavelengths (spontaneous Raman spectroscopy, or simply Raman). In both IR and Raman the observables include the vibrational frequencies of molecules (see next section), intensities of spectral peaks, peak widths, and polarizations. More sophisticated versions of either technique may measure time-dependent spectral changes, quantum lifetimes, phase relationships, etc. The two most common applications of IR and Raman are (i) to act as analytical ‘‘fingerprint’’ methods to identify specific molecular species or functional groups having known spectral signatures, and (ii) to infer unknown molecular structures or structural changes. A brief historical survey of the development of IR and Raman spectroscopies is in order.

The initial discovery of IR radiation is attributed to William Herschel in 1800.[1] Herschel noticed that, when visible light was dispersed through a prism, invisible radiation beyond the red end of the dispersed visible spectrum caused heating, and could be measured using a thermometer. He called this radiation ‘‘*calorific rays*’’—the term ‘‘*infrared*’’ came into use later in the 19th century. Over more than a century following Herschel's discovery, it came to be recognized that the IR region of the electromagnetic spectrum lies between the shortest-wavelength radio waves (microwave radiation, wavelength longer than one, or a few, millimeters) and visible light (approximately 700 nm). It was also known by the end of the 19th century that spectral features in the IR region were predominately due to the characteristic vibrational motions of molecules.[2]

The first IR *spectra* were reported in 1882 by Abney and Festing who measured the near-IR spectra of some 50 liquids.[3] Because they used a conventional spectrograph and photographic plates, their spectral coverage was limited to wavelengths shorter than approximately 1.2 µm (micrometers, microns), which we would call today the near IR. Further innovations followed quickly in the hands of Ångström,[4] Julius,[5] and others, who used bolometer detectors and rock-salt optics to measure IR spectra to 10 µm and beyond (roughly, the mid-IR region lies at wavelengths between 2.5 and 25 µm). While the collection of IR spectra at this time was an extremely laborious point-by-point exercise, the state of the art by the beginning of the 20th century was such that a major book on IR spectroscopy was authored by William Coblentz.[6] This landmark work (and subsequent books by Coblentz), which among other notable advances established the idea of characteristic vibrational ‘‘group frequencies,’’ is still useful a century later.

The inelastic light scattering effect that we commonly know as *Raman scattering* was discovered concurrently and independently by Raman and Krishnan[7] and by Landsberg and Mandelstam,[8] and reported in papers published in 1928. Raman's observation was highly qualitative, reporting that sunlight extinguished by a set of two complementary colored filters was made visible again when certain liquids were placed between the filters. We now understand this to be due to light shifted some 3000 cm^{-1} (wavenumbers, reciprocal wavelength) to the red by the C–H stretching vibrations of the liquids (see following section). Landsberg and Mandelstam, on the other hand, used a monochromatic light source (a mercury arc lamp), a dispersive spectrograph, and photographic detection to record actual *spectra* of crystals. The experimental setup invented by Landsberg and Mandelstam in the 1920s became essentially the exclusive technique for ‘‘Raman’’ spectroscopy until the advent of scanning multiple monochromators and lasers in the 1960s.

During the first 60 years or so of the 20th century many technical developments occurred that profoundly advanced both IR and Raman spectroscopy. Some of these

developments had immediate effects, and others were integrated in combination, over decades. Examples include the advent of electrical detectors for both IR and visible/ultraviolet light, electronic devices, optical technology, digital computation, and new computer algorithms. The first detectors based on the photoelectric effect[9] were applied to visible spectroscopy early in the century.[10] IR detectors based on thallous sulfide were used to detect aircraft during World War I, followed between the wars by lead chalcogenide and pyroelectric detectors. All of these were used in IR spectroscopy. The development of photomultiplier tubes offered a quantum detector that approached single-photon sensitivity, and one of the first application of the photomultiplier was as a detector for Raman spectroscopy[11]; thus the combination of a scanning monochromator with a photomultiplier detector began to supplant the spectrograph with photographic detection developed by Landsberg and Mandelstam decades earlier.

The vacuum tube was developed between 1904 and 1916 by researchers including Fleming, de Forrest, and Langmuir. The whole field of electronics followed with a multitude of very important applications, many of them essential to modern spectroscopy, culminating in the solid-state revolution that began in the 1950s and continues today. One of the most significant results was the digital computer, a development with a long nonelectronic history transformed by the exigencies of World War II into its modern form, an electronic device with the stored-program architecture pioneered by von Neumann.[12] By the 1960s the digital revolution had advanced to the point where small computers suitable for dedicated laboratory applications appeared. These found immediate application in the chemical laboratory, for automation of data collection and analysis in spectroscopy and many other areas.

The first practical optical interferometer was designed and reported by Michelson in 1881,[13] but the potential applicability of this development to spectroscopy was not realized for some time. The first interferogram (light intensity as a function of the difference in pathlength through the two arms of the interferometer) was reported by Rubens *et al.*[14] beginning in 1910. It was not until 1951 that it was recognized that the interferogram and the spectrum were related by a Fourier transform, and the first numerical Fourier transform spectrum was calculated by Fellgett,[15] who also realized the advantage in sensitivity offered by the interferometer because of its ability to simultaneously detect the entire spectrum as a single, time-varying signal (the multiplex or Fellgett advantage). Jacquinot discovered an additional advantage of the optical interferometer over dispersive systems, namely, its greater optical throughput due to its large aperture (lacking the slits required by a dispersive spectrometer). This throughput advantage is now termed the Jacquinot advantage.[16] Early applications of Fourier transform spectroscopy to IR (Fourier transform infrared (FTIR))—in fact, for technical reasons, to spectroscopy in general—were largely limited to the far IR (wavelengths from roughly 1 mm to 25 μm) where dispersive prism or grating instruments had great difficulties. Advances in detectors, including pyroelectric devices such as deuterated triglycine sulfate (DTGS) and quantum-sensitive semiconductors such as indium antimonide (InSb) and mercury cadmium telluride (MCT) aided both dispersive IR and FTIR during this period. Still, the manual acquisition of an interferogram and computation of a spectrum were very tedious and time-consuming in the absence of appropriate computers. This began to change with the development of the ‘‘minicomputer’’ in the early 1960s, and with the development of the fast Fourier transform algorithm by Cooley and Tukey in 1965.[17] In the early 1960s a number of commercial FTIR instruments were marketed with mixed degrees of success. The first modern FTIR instrument incorporating solid-state electronics, a dedicated minicomputer, and the Cooley–Tukey algorithm were introduced by Block Engineering (Digilab or Bio-Rad) in 1969. A very extensive literature is available on the development and applications of FTIR spectroscopy.[18,19]

Of the many significant developments in spectroscopy during the 20th century, arguably the most revolutionary was the advent of the laser (the word laser is an acronym for light amplification by stimulated emission of radiation). The first laser was a pulsed ruby laser invented by Maiman at Hughes Aircraft in 1960.[20] This was quickly followed by the first continuous-wave (CW) gas laser, the helium–neon (He–Ne) laser reported by Javan *et al.* in 1961.[21] Like the photomultiplier tube, the laser found immediate application to Raman; the extremely bright monochromatic source was a natural for Raman purposes. The first laser Raman spectra were reported by Porto and Wood in 1962,[22] using a Ruby excitation source. However, laser use for Raman created several instrumental problems, a major one being that the laser's great brightness along with increasing demands for high sensitivity and measurement of low vibrational frequencies made stray light levels within a single monochromator an unacceptable interference in the detection of weak spectra. To solve this problem Landon and Porto devised a laser Raman spectrometer based on a double monochromator.[23] This, with various modifications and advances, became the standard type of instrument for Raman spectroscopy for many years, and as lasers became readily available the mercury arc as a Raman excitation source became obsolete in a very short time.

Another advance in detector technology that has been very important in spectroscopy is the development of multichannel detectors, either one-dimensional (e.g., diode arrays) or two-dimensional (e.g., television detectors such as vidicon tubes and, more recently, charge coupled device (CCD) chips). In concept, detectors of this class are similar to the photographic plates that had largely been supplanted by electronic detectors, in that they detect an ‘‘entire’’ spectrum (or a significant part of a spectrum) all at once without the need for scanning dispersed light past the slit of a monochromator to be detected, in essence, point by point. Thus the use of an array or image detector yields a *spectral*

multiplex advantage, meaning that the time to achieve a spectrum of a given signal-to-noise ratio (S/N) is related to the square root of the number of spectral resolution elements that can be detected simultaneously. (In Fourier transform spectroscopy this is known as the *Fellgett advantage*,[15] and this term is sometimes applied to dispersive multichannel spectrography. For FTIR, the Jacquinot advantage and the Fellgett advantage are multiplicative.) Aside from intrinsically better sensitivity (given equivalent detector performance), the multiplex advantage allows spectra to be detected in short times (because no scanning of a monochromator is required), thus enabling time-resolved vibrational spectroscopy (TRVS), especially time-resolved Raman and resonance Raman (RR) (TR^3). This principle was first demonstrated, using image-intensified vidicon detectors, by Delhaye *et al.* at Lille[24] and later for the RR case in our laboratories.[25] This is now routinely done using CCD image detectors for Raman. For IR, InSb image detectors have been available for some time for near-IR imaging and MCT image detectors are now available for the mid-IR. Apart from the multiplex advantage and time resolution, these devices offer the possibility of *hyperspectral imaging*,[26] that is, obtaining Raman or IR images wherein each pixel (the word ''pixel'' is a contraction of ''picture element'') of a two-dimensional spatial image carries a third, spectral dimension. Hyperspectral imaging techniques have very promising potential applications in bioinorganic spectroscopy and materials characterization.

We mentioned earlier that vibrational spectroscopy is a very innovative and rapidly developing field with many very sophisticated and highly specialized applications. In general these are too numerous and specialized to include in this article, but one of the advanced techniques has such profound potential importance as to demand mention. Multidimensional, coherent nuclear magnetic resonance (NMR) spectroscopy (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Metallobiomolecules***) is able to determine molecular structures in solution or other random phases, in short, under realistic chemical conditions without requiring crystals. In principle, all the capabilities of this radio-frequency spectroscopy can be implemented in vibrational spectroscopies, given the right coherent light sources (lasers) and their appropriate manipulation. If this can be accomplished, the possibility will be opened to determine actual time-resolved molecular structures of all sorts (electronically excited molecules, reaction intermediates, transient protein structures, etc.) at very short timescales (picoseconds, or less). The potential of this approach has been demonstrated in the IR.[27]

Inorganic and bioinorganic applications of IR and Raman spectroscopies are covered in some detail in subsequent sections. General types of information that can be obtained include analytical identification, structure and symmetry, ligand and functional group identification, metal–ligand and metal–metal bonding potentials and force constants, structural kinetics and dynamics, excited-state properties, vibronic coupling, etc. Extensive literature on inorganic applications can be found in numerous reference works (Section 4).

2 TECHNICAL BACKGROUND

2.1 General Concepts

Molecular vibrations and vibrational spectroscopies are among the simplest quantum phenomena to understand at an intuitive level via classical concepts. A molecule can be viewed as a system of masses (atoms) held together by springs (chemical bonds). Like a mass-and-spring system in classical physics, each chemical bond is characterized by a *force constant*, k, that reflects the stiffness of the bonding ''spring,'' that is, the force necessary to displace the bonded masses a given distance from equilibrium (k is in units of force per distance, e.g., newtons per meter or millidynes per angström unit). Figure 1 shows this for a diatomic molecule. The equilibrium bond distance is r_{eq}, ''equilibrium'' meaning that at the interatomic distance r_{eq}, no force is exerted on the spring representing the bond. In order to displace the atoms such that the new interatomic distance is $r_{eq} \pm \Delta$r, a force $f = k(\Delta r)$ has to be exerted. The potential energy (force times distance), U, that is stored in the spring system as a result of the Δr displacement is $f(\Delta r)$, thus $U = k(\Delta r)^2$. This leads to the familiar *harmonic potential*, illustrated in Figure 2, where potential energy is quadratic in bond displacement (here it is assumed that there is no anharmonicity, that is that k is independent of Δr, thus that $U = k(\Delta r)^2$ for all Δr. In real molecules the bonding potential is always expected to be anharmonic to some degree, but anharmonic effects are negligible for many purposes and anharmonicity is beyond the scope of this discussion).

If a classical mass-and-spring system is displaced by Δr and then released, it will oscillate around $r = r_{eq}$ (Figure 2). The total energy of the system E will be constant, equal to the potential energy U originally supplied, but divided between potential energy U_r and kinetic energy V_r, both functions of the time-dependent distance r between the centers of mass, such that $E = U_r + V_r$. The maximum

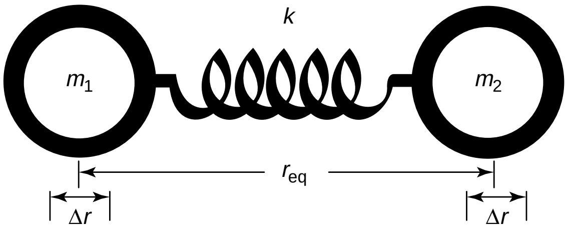

Figure 1 Classical mass-and-spring representation of a vibrating diatomic molecule

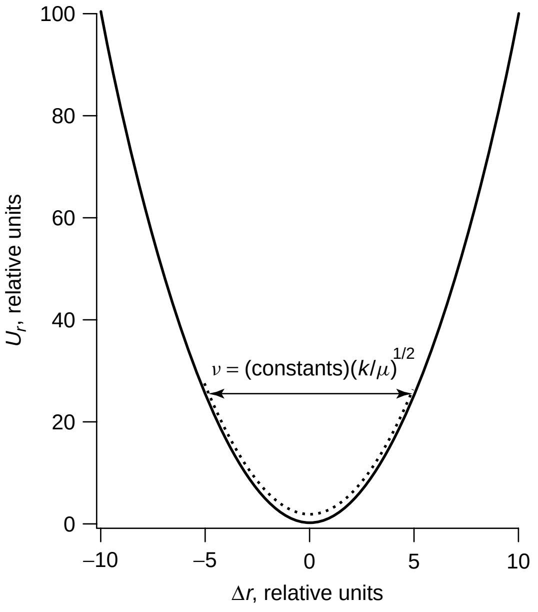

Figure 2 Energy and vibrational frequency of a classical harmonic oscillator. The solid line is the harmonic potential function. The dashed line represents the motion of the mass-and-spring system, displaced by $\Delta r = \pm 5$ units then released

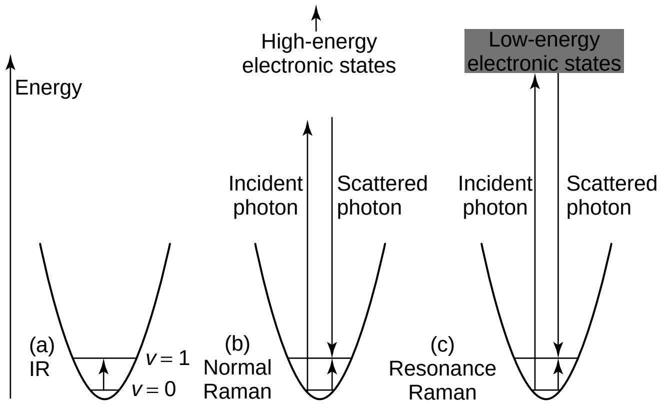

Figure 3 Schematic quantum representation of (a) IR absorption, (b) normal Raman scattering, and (c) RR scattering (see text). The parabolas represent harmonic potentials in the ground electronic states. The two energy levels shown in the harmonic ground-state (GS) potentials are quantum vibrational states; $v = 0$ is the zero-point vibrational energy, and $v = 1$ is the first excited vibrational state

vibrational amplitude is Δr, which is constant with time in a loss-free system. At this extreme, $r = r_{eq} \pm \Delta r$, $V_r = 0$ and $U_r = U$. At $r = r_{eq}$, $U_r = 0$ and $V_r = U$. At intermediate values of r, U_r and V_r will both be nonzero and E will be partitioned between potential and kinetic energy depending on the oscillating masses and their velocity, v. This brings in the concept of *reduced mass*, μ, the effective mass of the oscillating system. For the diatomic system in Figure 1, $\mu = (m_1)(m_2)/(m_1 + m_2)$ and the kinetic energy of the system $V = 1/2\mu v^2$. Without going further with the derivation (see Nakamoto[28] and references therein), the *period* of the oscillations of this system will be proportional to $(\mu/k)^{1/2}$, and the *vibrational frequency*, ν (in Hertz, $1\,\text{Hz} = 1\,\text{s}^{-1}$), is the inverse of the period; $\nu = (\text{constants}) \cdot (k/\mu)^{1/2}$.

2.2 Molecular Vibrations and Quantization

The fact that molecular vibrations are actually quantized alters the foregoing classically based discussion. In the classical case the vibrating system can have any amount of total energy, depending only upon the maximum vibrational amplitude, and the system can be at rest, not vibrating at all. In the quantum case the system can only have energies that are integral multiples of $h\nu$, where h is Planck's constant (e.g., h in erg · s and ν in s^{-1}). Furthermore, in the vibrational *ground state* the system is still in motion, retaining its *zero-point vibrational energy*. This modifies the classical energy diagram in Figure 2 as shown in Figure 3, where only discrete vibrational energy levels are allowed and the energy of the lowest level is nonzero. Thus absorption of IR light occurs when light quanta having $E = h\nu$ are incident on the system; these IR quanta excite the molecule directly from one vibrational *energy level* to another (Figure 3a) and in the process are absorbed. If the molecule is a harmonic oscillator as discussed above, all of the vibrational energy levels are equally spaced. Anharmonicity will cause the higher energy levels to be successively more closely spaced than the lower levels. To summarize the relationships that arise from quantization, $E = h\nu = hc/\lambda$ (c is the velocity of light, $3 \times 10^{10}\,\text{cm}\,\text{s}^{-1}$, and λ is the wavelength of the light; $\nu = c/\lambda$) and, as in the classical case, $\nu = (\text{constants}) \cdot (k/\mu)^{1/2}$.

In contrast to IR absorption, the Raman effect is a fundamentally different way of measuring molecular vibrational frequencies. Light can be scattered by matter in many ways; at the molecular level, scattering occurs because the electric field of light *polarizes*, and induces a dipole in the electron cloud of the molecule. Since the electric field of light is oscillating (at frequency ν), the induced dipole also oscillates and, as an oscillating dipole, radiates light. Most of the incident light is *elastically scattered*, that is, scattered without any change in energy or, equivalently, frequency or wavelength. Elastic scattering is known as *Rayleigh* scattering.[29] The Raman effect is also light scattering by a mechanism similar to Rayleigh scattering, but Raman scattering is inelastic rather that elastic. In the classical sense[30] this occurs because the polarizability of a molecule is not constant, but is modulated by the vibrations of the molecule (the vibrations, in effect, make the molecule larger or smaller at the extremes of displacement, thus making the molecule more or less polarizable). Viewed classically, this in turn results in amplitude modulation of the induced dipole due to the incident light, and in *sidebands* (as in radio technology) in the scattered light, displaced in frequency from the incident by an amount equal to the vibrational

frequencies. In quantum terms, the incident photon exchanges a vibrational quantum with the molecule (Figure 3b). In either case, if the incident light is monochromatic (in the past, an emission line of a mercury arc; at present, a laser line) the vibrational frequencies can be measured by spectroscopically resolving the difference in frequency between the incident and Raman scattered light.

If the frequency of the incident light is remote from any electronic transitions of the illuminated molecules (Figure 3b), the intensity of both Rayleigh and Raman scattering is simply proportional to the fourth power of the scattered frequency, ν^4; that is, blue light is scattered more efficiently than red. This is, in fact, the reason that the sky appears blue. Furthermore, Raman scattering in this case (*normal Raman scattering*) is many orders of magnitude weaker than Rayleigh. Thus a central experimental problem in Raman spectroscopy is the detection of small amounts of inelastically scattered light at frequencies that are close to the Rayleigh (elastic scattering) frequency. Approaches to this challenge have been discussed elsewhere.[31] Despite the ''insensitivity'' of normal Raman scattering, this way of measuring vibrational frequencies has certain advantages over IR (e.g., because the method uses visible light it is easily applied to aqueous solutions, where IR requires special approaches or is simply inapplicable). Moreover, modern techniques give normal Raman adequate sensitivity for reasonably low concentrations (millimolar or lower).

When Raman scattering is excited by light within or near an electronic transition (*see* ***Electronic Spectroscopy***) as illustrated in Figure 3(c), the intensity of Raman scattering may be enhanced by orders of magnitude over the normal Raman case. This is known as the *resonance Raman effect*, which arises from the interactions of molecular vibrations with electronic transitions of the molecule. A detailed discussion of RR is beyond the scope of this article, but in brief, resonance enhancement may arise from two main vibronic mechanisms: a *Franck–Condon effect* where the enhanced vibration distorts the ground electronic state of the molecule to resemble the resonant excited electronic state; and *Herzberg–Teller coupling* wherein the vibration resembles the distortion that couples two different electronically excited states (ES). The RR effect and its consequences are perhaps best understood via the semiclassical wavepacket dynamics approaches pioneered by Heller *et al.*[32]

2.3 Normal Modes, Selection Rules, and Symmetry

The foregoing discussion has used as an example an oversimplified system, a diatomic molecule with just one vibrational *mode*. For more complicated molecules, in fact for arbitrarily complicated ones, the same mass-and-spring model applies — there are just more masses and more springs. Each local vibrational oscillator behaves as we have already discussed, but in a polyatomic molecule local vibrations will interact (couple) with one another — in principle, over the entire molecule. This can occur because local oscillators are not greatly dissimilar in energy and are geometrically arranged so that they interact. This possibility exists for either a classical mass-and-spring system or a real molecule. In molecules there is the additional possibility that displacement of one of the local coordinates (bonds) may actually change the force constant of another, via electronic interactions. Either classical or electronic interactions require us to develop concepts that are applicable to the molecular system as a whole. These are discussed in exhaustive detail elsewhere,[33] leading us to the idea of *normal vibrational modes*. These are a representation of how the local vibrational oscillators couple to produce the ''actual'' molecular vibrations. The normal modes constitute a set of $(3N - 6)$ molecular motions, where N is the number of atoms (this expression becomes $3N - 5$ if the molecule is linear, e.g., the diatom in Figure 1). These motions must be orthogonal to one another, and they must preserve the center of mass of the molecule. The normal modes of the carbon dioxide molecule are shown in Figure 4 (adapted from Tobias[34]).

Not all normal modes of a molecule will necessarily be observed in the IR spectrum, nor in the Raman. The *selection rules* for the two processes are different. The term ''*selection rules*'' refers to the combined properties of light and matter that are required for a quantum transition to occur.

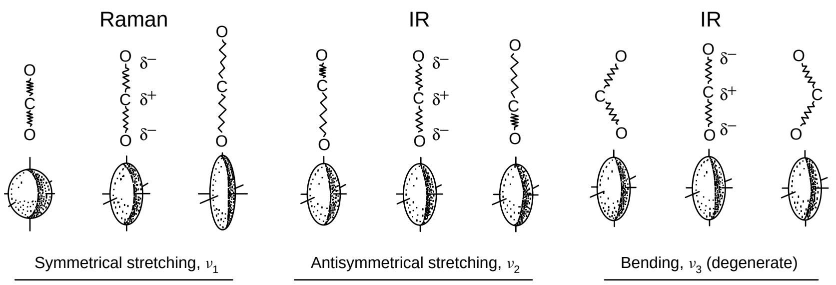

Figure 4 Schematic representation of the normal vibrational modes of the CO_2 molecule (Adapted from Cotton[35]). The molecular schematics show the atomic displacements that occur during each normal mode. The partial charges shown indicate the bond dipoles, and the ellipsoids represent the molecular polarizabilities. Note that only ν_1 results in a change in polarizability but no change in molecular dipole moment (thus is Raman active), while ν_2 and ν_3 result in changes in molecular dipole moment but not polarizability (thus are IR active)

The absorption of IR light by a vibrating molecule follows *dipolar selection rules*. This means that, to interact with the electric field of an incident photon so as to excite a normal mode of a molecule, absorb the photon, and be observed in the IR spectrum, a given normal mode must distort the molecule such that it alters the molecule's *dipole moment*. On the other hand Raman scattering, which is a two-photon process (the two being the incident and scattered photons), follows *quadrupolar selection rules*. This means that, to interact with an incident photon so as to result in the excitation of the normal mode of a molecule and the scattering of a Raman-shifted photon, the mode must distort the molecule such that it alters the molecule's *polarizability*.

The consequences of these differing selection rules can be seen qualitatively in Figure 4, showing the normal modes of the CO_2 molecule: ν_1, the symmetric C–O stretching vibration (''symmetric'' meaning that the vibration preserves the symmetry of the molecule); ν_2, the asymmetric C–O stretching vibration; and ν_3, the degenerate O–C–O angle bending vibrations (''degenerate'' meaning that there are two energetically equivalent but symmetrically distinct bending modes, the in-plane bend shown, and the out-of-plane bend 90° to the plane). Note that CO_2, a linear molecule, has $3N - 5 = 4$ normal modes, three of which are shown in Figure 4. CO_2 has no permanent dipole moment, but the individual C–O bonds are polar in opposite directions as shown in Figure 4. Thus ν_1, which stretches or compresses both C–O bonds equally, results in no transient, oscillating dipole moment and cannot be observed in the IR. However, the symmetric shortening and lengthening of the C–O bonds compresses or expands the electron cloud of the molecule, leading to an oscillatory polarizability change, therefore this mode is observed in Raman scattering. Conversely ν_2, the asymmetric C–O stretching vibration, shortens one of the C–O bonds and lengthens the other during its period, leading to a transient dipole moment that oscillates around zero. This mode is observed in the IR spectrum. However, ν_2 does not alter the size (polarizability) of the molecule's electron cloud, and thus cannot be observed by Raman. Likewise the degenerate ν_3 pair of modes result in an oscillating dipole moment perpendicular to the O–C–O axis but no change in polarizability, and thus are seen in the IR spectrum but not in the Raman.

The preceding paragraph illustrates two points about Raman and IR spectroscopies. First, the two techniques are complementary—information obtained by one or the other alone is generally incomplete. For example, for a molecule that is *centrosymmetric* (possesses an inversion center, like CO_2) IR-active normal modes are forbidden in the Raman, and vice versa. Second, it is implicit that molecular symmetry matters—if CO_2 were a bent molecule instead of linear, the conclusions about IR and Raman activity of the modes (indeed, the number of modes) would not be the same.[30,34] The determination of molecular symmetry groups and how molecular symmetry in turn determines spectroscopic and other properties is the realm of *group theory*.[35] Vibrational spectroscopy is one of the most important applications of group theory, but treatment of this subject is beyond the scope of this article. The reader is referred to any of several excellent texts on the subject (Section 4). For the present purposes it is enough to realize that molecular symmetry, along with number of atoms, determines the number of vibrations of various symmetry types and, in turn, the identity and spectroscopic activity (IR, Raman, both, or neither) of the normal modes.

2.4 Force Constants and Bond Distances

We mentioned earlier that the harmonic potentials depicted in Figures 2 and 3 are only approximations to real chemical bonding potentials. The harmonic approximation is very useful and works well in many cases for the first few quanta of excitation of a strong bond (low in the potential well). The obviously absurd extrapolation of the harmonic potential, however, is that a chemical bond can be stretched or compressed arbitrarily without changing its force constant. In reality a bond will ultimately dissociate (its force constant will go to zero) when stretched to many times its equilibrium length, and its force constant will approach infinity when the bond is compressed to the point that electrostatic repulsion of core electrons becomes very large. This is illustrated by the more realistic potential diagram in Figure 5, where bonding potential energy U is plotted versus internuclear distance r. Here the force constant k is the second derivative of the potential function, d^2U/dr^2, evaluated at the potential minimum (r_{eq}) where the first derivative $dU/dr = 0$ (both dU/dr and d^2U/dr^2 approach zero as r approaches infinity, i.e., at the dissociation limit).

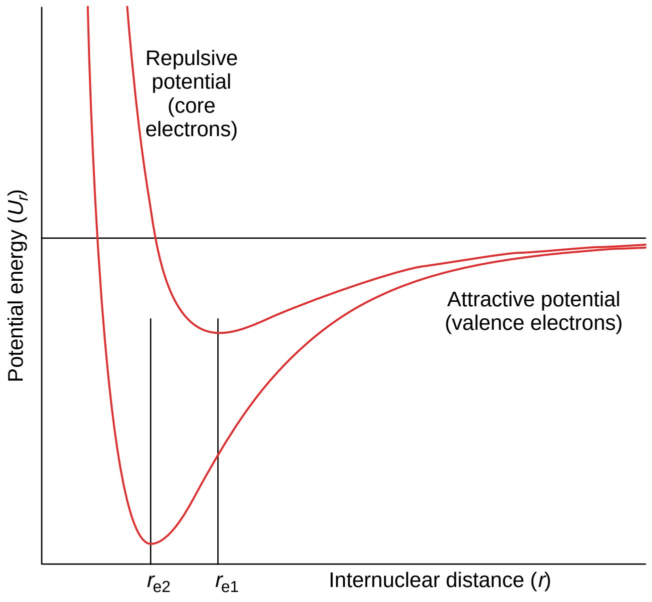

Figure 5 Simulated molecular potential functions

The potential function $U_{(r)}$ has at least two terms, an attractive term U_+ reflecting valence interactions, and a repulsive term U_- due to core electrostatic repulsions (Figure 5). Thus

$$U_r = U_+ + U_-$$

The attractive term dominates at longer distances and the repulsive term at shorter. The point at which $U_{(r)}$ is a minimum and $r = r_{eq}$ requires that

$$\frac{dU_r}{dr} = 0, \text{ thus } \frac{dU_-}{dr} = -\frac{dU_+}{dr}$$

In other words, whatever the functional form of U_+ and U_-, the slope of the repulsive term at r_{eq} must be equal and opposite to the slope of the attractive term. Since the units of dU/dr are force, this means that at $r = r_{eq}$ the forces due to the attractive and repulsive potentials are equal and opposite, that is, there is no net force acting on the bonded atoms, a trivial observation implicit in the definition of ''equilibrium internuclear distance.''

The conclusions regarding the force constant, $k = d^2U/dr^2$, are nontrivial and counter to intuitive expectations. First of all, unlike the harmonic case discussed previously, d^2U/dr^2 is a function of position (value of r) on the potential curve; the force ''constant'' k is evaluated at a specific point, namely, where $r = r_{eq}$. In fact, d^2U/dr^2 is *negative* over a very large range of the attractive part of the potential (negative curvature, see Figure 5). Furthermore, the point at which $d^2U/dr^2 = 0$ is at the *inflection point* of the potential curve, which is at a considerably greater value of r than r_{eq} (Figure 5); at that point $d^2U_-/dr^2 = d^2U_+/dr^2$. At any value of r shorter than that at the inflection point, approaching r_{eq}, the repulsive contribution to the curvature of the potential, d^2U_-/dr^2, is greater than the attractive contribution d^2U_+/dr^2, becoming increasingly greater as r becomes shorter, through r_{eq} and beyond. Thus, at r_{eq}, $d^2U_-/dr^2 \gg d^2U_+/dr^2$, and

$$k = \frac{d^2U_{(req)}}{dr^2} = \frac{d^2U_-}{dr^2} + \frac{d^2U_+}{dr^2} \sim \frac{d^2U_-}{dr^2}$$

Thus, depending upon the validity of the assumptions that we have made about the form of the potential function, *the force constant of a chemical bond is primarily due to the repulsive, not the attractive, part of the potential*! This conclusion will be used quantitatively in a later subsection of this article.

The foregoing gives quantitative insight into the relationship expected between force constants and bond distances. Because k is determined largely by U_-, and because the curvature (second derivative) of U_- is a function of internuclear distance r (positive curvature increasing with decreasing r, at least over normal bonding distances), then a functional relationship between r_{eq} and k is expected, wherein shorter bond distances require larger force constants as the attractive part of U_r forces the potential function against the ''repulsive wall'' determined by U_-. Furthermore, if a valid functional relationship between r_{eq} and k is established, and there have been numerous efforts to do so beginning with Badger and Pauling in the 1930s,[36–42] the repulsive component of a potential function can be approximated by integration of $k \sim d^2U_-/dr^2$. We will undertake this exercise in Section 3.2.

2.5 Group Frequencies in Inorganic Compounds

The concept of vibrational *group frequencies*, frequencies at which particular molecular substructures typically exhibit IR or Raman transitions, dates back to the 19th century.[6] This concept has been of immense value in interpreting vibrational spectra. While group frequencies in organic compounds are relatively well defined, inorganic compounds present significant additional complexities.[28] Many inorganic compounds contain organic functionalities, and these can be expected to obey the basic ''organic'' group frequency behavior, although this may be altered by any number of effects unique to inorganic chemistry, including symmetry-breaking interactions (e.g., monodentate coordination of a carboxylate to a metal ion) or by electronic interactions that change force constants and thus vibrational frequencies from their ''expected'' values (e.g., coordination of CO, NO, or isocyanide to a metal). In general, effects like this depend on the valence electronic configuration of the inorganic species, its position in the periodic table, oxidation state, etc. In addition there are myriad chemical options in inorganic chemistry that do not exist in organic chemistry and that have their own vibrational manifestations, for example, the entire field of coordination chemistry and metal–ligand binding, modes of isomerization unique to inorganic systems, etc. Actual enumeration of group frequencies is beyond the scope of this chapter, but comprehensive works on this topic are available (Section 4) and commercial databases also exist.

2.6 Units

SI units are the proper units for vibrational spectroscopy. In practice, however, chemists have been slow to convert to SI in many areas, vibrational spectroscopy among them. In the following, both the SI units and the common-usage units will be given.

2.6.1 Wavelength

Many optical devices, in particular spectrometers, fundamentally work in wavelength (λ), not frequency. For this reason it is common to see vibration (especially IR) displayed as a function of wavelength, although this has become less common in recent decades as the conversion from wavelength to frequency has become a routine feature of instrumentation. Wavelength is in fact length, and the SI

unit of length is the meter (m). The most common wavelength unit used in vibrational spectroscopy is the micrometer or micron, (μm or simply μ) $1\,\mu m = 10^{-6}$ m. So, vibrational spectroscopy is on firm SI ground with regard to wavelength. The entire wavelength range of vibrational fundamentals is from approximately 1000 μm (1 millimeter, $mm = 10^{-3}$ m; longer wavelengths are more properly radio) to a little shorter than 2.5 μm, the vibrational wavelength of the H_2 molecule. Vibrational overtones and combinations may appear at shorter wavelengths.

2.6.2 Frequency

It is convenient to use frequency units in any spectroscopy because frequency is directly proportional to energy ($E = h\nu$). Frequency units are related to wavelength by the familiar equation $\nu = c/\lambda$ (c is the velocity of light, $3 \times 10^8\,m\,s^{-1}$). The SI unit for frequency is the hertz (Hz, $1\,Hz = 1\,s^{-1}$). This unit is inconvenient for most vibrational spectroscopy because vibrational frequencies in hertz are very large (3×10^9 to greater than 1×10^{14} Hz). Instead it is common to express vibrational frequencies in wavenumber, the number of wavefronts per unit length ($\nu = 1/\lambda$). The most common unit for wavenumber is reciprocal centimeters, (cm^{-1}) ($1\,cm = 10^{-2}$ m). In wavenumber units of cm^{-1} the vibrational spectral range is from approximately $10\,cm^{-1}$ to greater than $4000\,cm^{-1}$.

2.6.3 Bond Length

Chemists are accustomed to expressing bond lengths in angström units, $1\,Å = 10^{-10}$ m. This is not, however, an SI unit. The accepted SI unit for bond length is the picometer (pm) ($1\,pm = 10^{-12}\,m = 0.01\,Å$). Distances in macromolecular assemblies and biomolecules may be expressed in nanometers (nm) ($1\,nm = 10^{-9}\,m = 10\,Å$).

2.6.4 Force Constant

Force is mass times acceleration, in SI units newtons, $1\,N = 1\,kg \cdot m\,s^{-2}$. Thus the proper SI unit for force constant, k, is newtons per meter ($N\,m^{-1}$). The units of force constants typically used by chemical spectroscopists are millidynes per angström, ($mdyn\,Å^{-1}$) ($1\,dyne = 1\,g \cdot cm\,s^{-2} = 10^{-5}$ N, $1\,mdyne = 10^{-3}$ dyn). Thus $1\,N/m = 0.01\,mdyn\,Å^{-1}$.

2.6.5 Vibrational Frequencies from Masses and Force Constants

The relationship between frequency, force constant, and the mass of bound atoms is $\nu = (\text{constants}) \cdot (k/\mu)^{1/2}$ (in this case μ is reduced mass, see earlier). The constant multiplier depends on the units of ν, k, and μ. If ν in cm^{-1} is the desired quantity, k is expressed in millidynes per angstrom, and μ is in atomic mass units (amu), then $\nu = (1302) \cdot (k/\mu)^{1/2}\,cm^{-1}$. The constants that constitute this factor are given elsewhere (Nakamoto[28] p. 10 ff.).

3 APPLICATIONS

Applications of vibrational spectroscopy in inorganic chemistry range from the characterization of inorganic materials and coordination complexes of transition metals to determining bonding and nonbonding interactions in the active sites of metalloproteins. Vibrational methods have proved particularly useful for characterizing the structures and dynamics of bioinorganic systems, which are difficult to handle with conventional structural tools such as NMR (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Metallobiomolecules***) and X-ray crystallography. Many excellent reviews and books have been written on this subject (Section 4). More recently, advances in vibrational spectroscopy techniques have significantly increased the usefulness of these methods by improving both the structural specificity and the time resolution. In this chapter we emphasize applications of these modern vibrational spectroscopy methods to the analysis of the structures and dynamics of inorganic and bioinorganic systems.

3.1 Difference Vibrational Spectroscopy

In principle, vibrational spectroscopy can probe any portion of a large, complex protein, including an embedded metal active site. Information on the local structure and interactions of the metal is obtained through analysis of the frequencies and intensities of the observed spectral lines. However, because every bond or molecular interaction in the protein can contribute to the vibrational spectrum, the spectral features are so highly congested and overlapping in a directly measured vibrational spectrum that their detailed analysis is at best difficult, and often impossible. Thus, the development of experimental methods that reduce spectral congestion has been essential for the application of vibrational spectroscopy methods in bioinorganic systems.

There are two general approaches to reducing spectral congestion in vibrational spectroscopy. The first, which has found wide use in bioinorganic chemistry, takes advantage of the resonance enhancement of Raman scattering cross sections obtained when the excitation wavelength is tuned into an electronic absorption. The large enhancement of Raman scattering for those vibrations coupled to the electronic transition, which is generally spatially localized on the metal chromophore, provides extreme discrimination against all other nonresonant Raman signals. Thereby the study of

the local structure of the metal active site within a much larger and complex protein system is possible. Because the metal center is usually functionally important, RR techniques provide a powerful approach to study the structures and dynamics important to protein function. Selected examples (and related reviews) include the study of photosynthetic proteins,[43] heme proteins[44] blue-copper proteins,[45] and heme-copper oxidases.[46] A more in-depth review of the use of RR spectroscopy in inorganic chemistry is provided in a separate chapter.

The second approach to reducing the spectral complexity of bioinorganic systems is difference vibrational spectroscopy. In this approach, vibrational spectra are recorded before and after some chemical, or physical perturbation is applied. Thus the difference spectrum reflects only the vibrational features that respond to the perturbation and many of the complex, overlapping features of the raw spectra simply cancel. The difference features that remain are observable with much greater sensitivity than in the raw spectra. If the perturbation is specific to the metal active site, then the difference spectrum will reflect the changes to this site and the nearby protein structure. For example, it is often possible to perturb the redox or ligation state of the metal center, both of which lead to changes in the vibrational spectrum. Temperature, pressure and pH are also excellent variables for inducing changes to the spectra, although these changes may be more broadly distributed throughout the protein structure. All of these perturbation methods have been used in conjunction with IR and Raman spectroscopies to probe the active sites of proteins. A few illustrative examples follow.

3.1.1 *Photochemical Difference FTIR Spectroscopy*

Probably the most common approach to generating difference IR spectra of metalloproteins is to use a photochemically induced change of the metal active site to probe its structure and dynamics. This method has been widely used to study ligand binding to the Fe center of heme proteins. An example from our work on heme-copper oxidases illustrates this method.[47] The heme-copper oxidases have a binuclear active site (heme a_3 or o_3 and Cu_B) that is the site of O_2 binding and reduction. Figure 6 shows the raw (unsubtracted) FTIR spectrum of the carbon monoxide complex of the heme-copper terminal oxidase cytochrome *bo*$_3$, the quinol oxidase of *Escherichia coli*. The FTIR spectrum was obtained with 300 µM enzyme in a 50 µm pathlength cell with CaF_2 windows. The observed IR absorbance bands represent the superposition of contributions from three polypeptide subunits comprising more than 1000 amino acid residues and having a molecular weight of approximately 250 kDa. The spectrum is dominated by the amide absorbances of the polypeptide (amide I peak O. D. approximately 0.5) and individual features cannot be discerned except for a very weak peak at 1963 cm^{-1} which is the C≡O stretching mode of heme-bound CO. Figure 6 also shows the difference spectrum

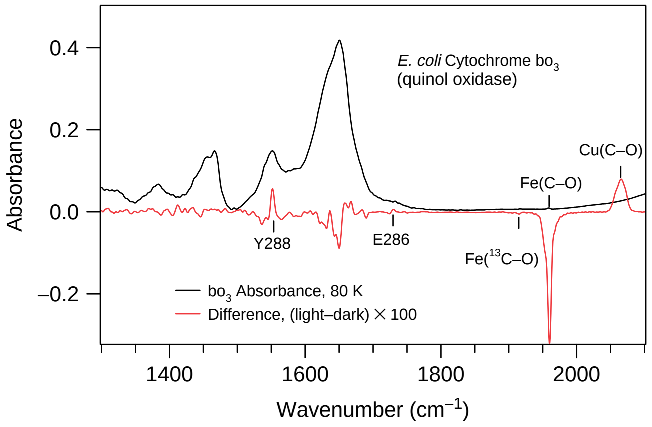

Figure 6 The FTIR absorbance spectrum (black) and the light minus dark difference absorbance spectrum (red) of carbonmonoxy *E. coli* cytochrome *bo*$_3$

(×100 relative to the raw absorbance spectrum) obtained at a temperature of 80 K by subtracting the spectrum taken in the dark from the spectrum taken after the sample is irradiated for a few seconds with a CW Ar ion laser at 514.5 nm. In the dark, the CO is bound to the heme to form a six-coordinate, low-spin Fe^{2+} complex. When CO is photodissociated from the heme at 80 K, the Fe^{2+} becomes high spin five-coordinate and the CO does not immediately recombine, but rather is transferred to the nearby $Cu_B{}^+$. All these changes are reflected in the FTIR difference spectrum. The loss of CO from the heme produces a negative peak at 1963 cm^{-1}, corresponding to the CO stretch when bound to Fe^{2+}. When CO binds to the nearby copper site, a new positive peak at 2063 cm^{-1} is observed. The large increase (100 cm^{-1}) in CO-stretching frequency reflects the different mode of CO binding to the different metals. When bound to the heme, there is significant π-back-bonding from the Fe^{2+} to the CO, resulting in a weakening of the CO bond and concomitant reduction in its stretching frequency (see Section 2.4). The higher frequency of the CO stretch when bound to Cu_B reflects the absence of significant π-back-bonding on this metal.

Obviously, the Fe(C–O) and Cu(C–O) absorbances are detected with excellent signal-to-noise. In fact, the ^{13}CO satellite on the 1963 cm^{-1} peak, due to 1.1% of the total enzyme-CO complexes, is seen at 1941 cm^{-1} with S/N approximately 10. About 10 000 scans were averaged to obtain this quality of data, requiring about 30 min of acquisition time. Other single-residue features in the difference spectrum include the frequency shift (derivative-shaped feature at 1740 cm^{-1}) of the COOH sidechain of glutamic acid 286 and the peak at 1510 cm^{-1} belonging to a ring mode of tyrosine 288, both in subunit 1. In addition, there are difference features due to the heme and the protein amide I backbone vibrations in the 1600–1700 cm^{-1} range. The amide I band (roughly, the collective carbonyl stretch of the peptide bonds) is sensitive to polypeptide secondary and tertiary structures in ways that

are well established by a large body of empirical evidence.[48] Note that most of these features would not be visible in the raw absorbance spectra as they are smaller than the width of the trace as drawn in Figure 6. Clearly, FTIR difference spectroscopy is both structurally and functionally informative and sufficiently sensitive to observe specific features in very complex metalloproteins.

3.1.2 Electrochemical Difference FTIR Spectroscopy

Most metalloproteins are stable in more than one oxidation state, meaning that oxidation or reduction is another perturbation method that can be employed to generate vibrational difference spectra. A change in the oxidation state of a metalloprotein can be achieved chemically, electrochemically or in some cases photochemically. The FTIR spectrum is obtained in each oxidation state, and the difference spectrum contains only those vibrations that respond to the change. Care must be exercised to avoid spectral interference from chemical or photochemical oxidants or reductants. In this sense, the electrochemical approach is the cleanest, although it is still important to obtain an accurate subtraction of the solvent contribution with electrochemical methods. Additional technical difficulties arise from the need to use very thin pathlength cells (required because of the large solvent absorptions) in an electrochemical apparatus that allows controlling the redox potential. In laboratories that have implemented this technique, approaches have included the use of a very small pathlength cell in which the probing beam is reflected off one of the electrodes,[49] or the use of a thin pathlength transmission cell in which the electrode is a partially transmitting grid.[50] In addition, for protein studies, the use of electrochemical mediators is typically required to provide a sufficiently rapid response to changes in applied potential.[51]

The approach developed in our laboratory for electrochemical difference FTIR spectroscopy uses a reflectance cell having a thin film electrode that also serves as an IR reflector. The IR probe beam enters through an IR transparent window (ZnSe or CaF_2), passes through the sample and then is reflected off the electrode back through the sample and out the same window. Such an arrangement is easily adapted to a standard commercial FTIR sample compartment. An example of an electrochemical difference FTIR spectrum is shown in Figure 7 for the heme protein myoglobin. The absorbance spectra of the oxidized (Fe^{3+}) and reduced (Fe^{2+}) forms of the protein are also shown for comparison. Electrochemical mediators have been added to the solution in catalytically small concentrations to accelerate the electrochemical processes in a manner similar to that used by Mantele *et al.*[50] Under these experimental conditions, no spectral changes due to the low-concentration mediators are observed in the difference FTIR spectrum (lower trace). The features in the difference spectrum are primarily due to the changes of the heme and the surrounding protein residues that accompany the oxidation

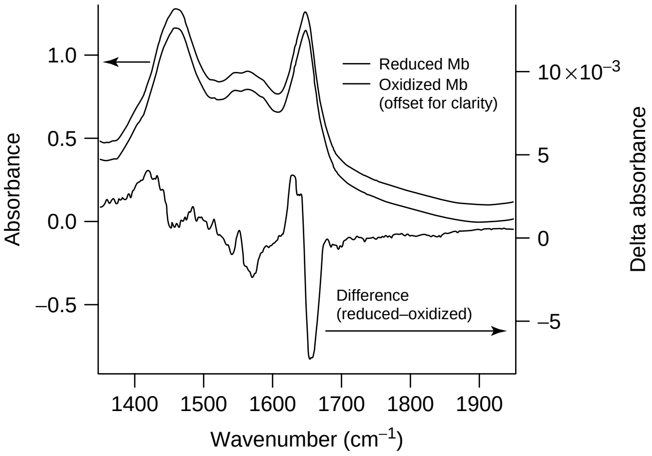

Figure 7 Electrochemical FTIR absorbance spectra (top) and difference spectrum (reduced−oxidized, bottom) of horse heart myoglobin

state change of the iron. The porphyrin ring modes in the 1600−1700 cm^{-1} range are shifted to lower frequency upon reduction, reflecting the change in electron density on the metal and in the π-system of the porphyrin.

Proton transfer reactions often accompany electron transfers to or from the active sites of metalloproteins, termed *proton coupled electron transfer* (PCET). Since movement of electrons through the low dielectric medium of a protein is energetically unfavorable, simultaneous or coupled movement of a proton to balance the charge may reduce the energetic cost. IR spectroscopy is ideally suited to detect changes in the protonation state of ligands bound to a metal, or nearby protein sidechains. The acid dissociation constants of ligands can be modified by several orders of magnitude due to metal binding, or due to the change in the oxidation state of the metal. For example, the carboxylic acid sidechain of Asp or Glu may be deprotonated in the oxidized form of the metal center, but become protonated when the metal center is reduced. This change is readily detected in the IR spectrum from the large shift in the carboxylate mode, the asymmetric COO^- stretch between 1560 and 1590 cm^{-1}, and to the carboxylic acid C=O stretch between 1710 and 1740 cm^{-1}. An example of this behavior is Glu242 in cytochrome *c* oxidase, which serves as a proton gate between the proton channels from the inside of the membrane (the D-channel) to the binuclear active site. Using FTIR spectroscopy we have demonstrated that this residue is protonated in response to the reduction of the binuclear center.

3.1.3 Isotope-Edited Difference Vibrational Spectroscopy

Similar difference measurements can be made using resonance-enhanced or spontaneous Raman spectroscopy.[52] In Raman spectroscopy, in general, the signal from an aqueous solvent is not large (water is a very weak Raman scatterer),

which makes the solvent subtractions much easier or even unnecessary. However, Raman scattering is an experiment with a very low signal rate, so long accumulation times are often required in order to obtain spectra from which good difference data can be generated. In turn, there is a requirement for very high stability in both the laser excitation sources and in the detectors that are used. Obviously, in both techniques, an additional requirement is that the samples being studied must be stable under the experimental conditions for the length of time required for data accumulation.

Figure 8 shows the raw, unsubtracted normal (nonresonant) Raman spectrum of phosphoglucomutase (PGM) which catalyzes the interconversion of glucose 1-phosphate and glucose 6-phosphate. PGM is an approximately 60 kDa protein. Panel (a) shows the Raman spectrum for PGM complexed with [^{16}O]glucose 1-phosphate while panel (b) shows the spectrum for PGM complexed with [^{18}O]glucose 1-phosphate. The differences between these two spectra involve only the phosphate group of bound glucose 1-phosphate, and it is not possible to observe by eye any changes due to the labeling of the phosphate group. The

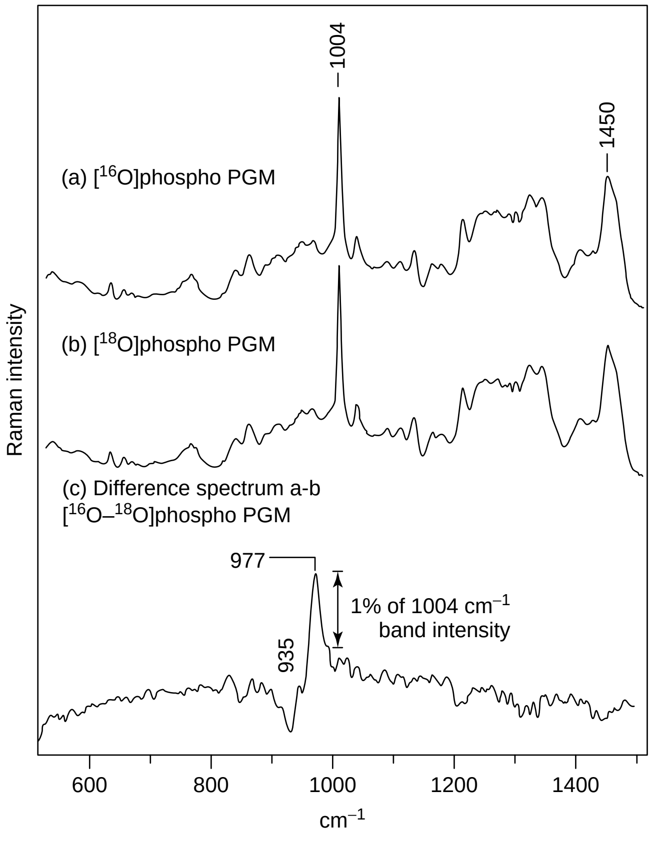

Figure 8 Raman spectra of phosphoglucomutase (PGM) at pH = 7.4 and 4 °C. Approximate data accumulation time was 2 h using 514.5 nm laser excitation. (a) The spectrum of PGM complexed with [^{16}O]glucose 1-phosphate. (b) The spectrum of PGM complexed with [^{18}O]glucose 1-phosphate. (c) The difference spectrum between (a) and (b), ×100

isotopically-edited difference spectrum is shown in panel (c), where the intensity scale is about 100 times that of panels (a) and (b). The spectral changes brought about by isotopic labeling are now evident. The positive peak at 977 cm^{-1} in the difference spectrum is the P$\underline{\cdot\cdot}$^{16}O symmetric stretch of bound glucose 1-phosphate, and the negative peak, shifted down by 42 cm^{-1}, the P$\underline{\cdot\cdot}$^{18}O stretch. The background noise is simple shot noise (at a level of about 0.1% of the main bands of PGM). Hence, the spectrum of a *single* and *specific* phosphate group is determined within a 60 kDa macromolecule.

3.2 Quantitative Relationships between Force Constants and Bond Distances

We observed in Section 2.4 that we expect there to be some relationship between force constants and bond distances, that is, bonds with greater force constants should be shorter. Furthermore, because the force constant (given our previous assumptions) is dominated by the repulsive part of the potential function, and the repulsions are primarily due to nonbonding core electrons which are more numerous row by row down the periodic table, we expect that the ‘‘repulsive wall’’ of the core is further from the nucleus in each successive row (i.e., increasing principal quantum number). So if a functional relationship between force constants and bond distances exists, we expect that the parameters of the relationship, whatever its functional form, will depend on which row(s) of the periodic table the bonded atoms occupy.

The first empirical relationship between force constants and bond distances was ‘‘Badger’s Rule,’’ developed by Richard Badger in the 1930s.[36–38] Badger’s Rule has had impressive staying power and is still used (and useful) today. In the ensuing decades this general idea has been extended (e.g., to solid metals by Pauling[41]) and new functional forms have been proposed, most prominently by Herschbach and Laurie in the 1960s[40] and in the ‘‘complete neglect of practically everything (CNPE)’’ formulation of Burgi and Dunitz.[39] These relationships have been very useful over their applicable ranges of force constants and bond distances, namely, for single and some double bonds, and relatively strong fractional-order bonding (Figure 9a). There are some obviously unrealistic aspects to these empirical functions, however, if they are extrapolated outside their intended bounds. In general they allow arbitrarily long bonding distances when force constants approach zero; the actual expectation is that bonding distances approach a definite value as k approaches zero, and that distance is equal to or less than the van der Waals distance. Furthermore, this kind of function should approach a nonzero asymptote in bond distance as k becomes large, representing the distance at which the repulsive electrostatic forces of core nonbonding electrons overwhelm any possible valence attractions. Some of the earlier empirical functions approach an asymptote at large k, some do not.

Inorganic chemists by definition are interested in bonding of all types, energies, strengths, and formal orders,

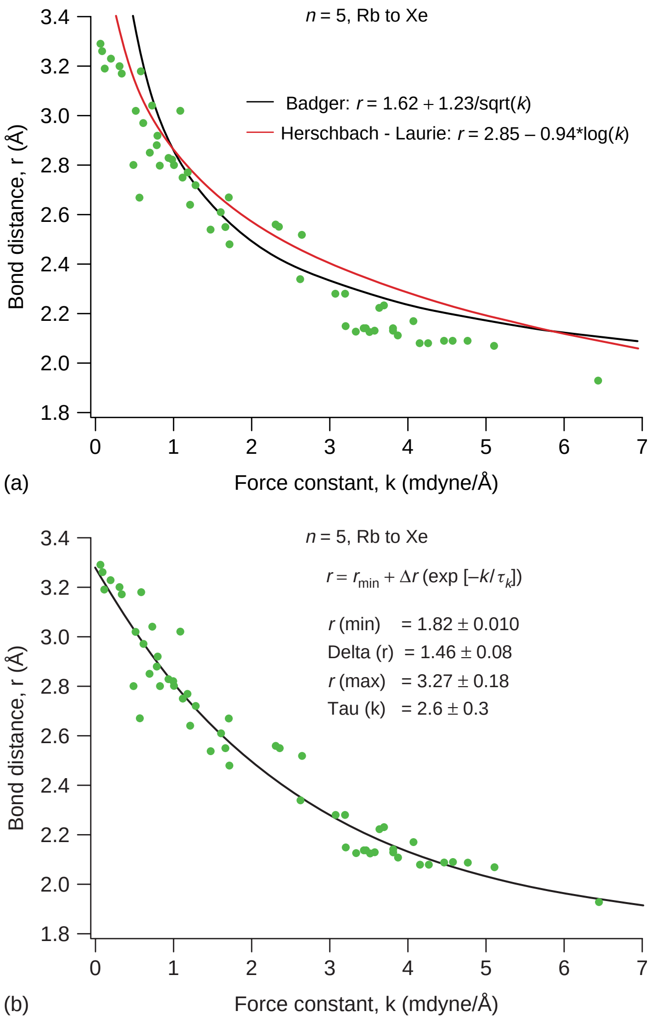

Figure 9 Bond distance versus force constant data for intra-row bonding in the row of the periodic table containing the second transition series ($n = 5$, Rb to Xe): (a) data fit to empirical force constant-bond distance functions (see text); (b) same data fit to the exponential decay function that we have proposed. Identity of the points is given in Ref. 42

in all states of matter. If there are empirical functions that describe bond distances and force constants for all these situations, their significance in inorganic and bioinorganic chemistry could be considerable. First of all, bond distances could be inferred and structural information gained in situations where vibrational frequencies can be measured but direct structure determinations are not possible, for instance, in reaction transients or electronically excited molecules. Secondly, the multitude of inorganic molecular structures that have been determined, plus the large and increasing number of metalloprotein structures, would allow one to infer approximate force constants that could be used to parameterize or verify force fields and theoretical calculations. Thirdly, examination of these relationships over large ranges of force constant and bond distance, and over the periodic table, may lead to general insights into chemical bonding. Finally, a truly valid functional relationship between force constants and bond distances provides a mathematical constraint on the form of the repulsive contribution to bonding potential functions via the relationship between the force constant and the potential function discussed in Section 2.4, $k \sim d^2U_-/dr^2$.

We became involved in force constant-bond distance relationships through our interest in the photochemistry of complexes containing metal–metal bonds at either extreme of the scale; formal zero-order bonds in d^8 dimers,[53] and quadruple bonds in d^4 dimers.[54] We were interested in inferring excited-state structures from vibrational data and we turned to Badger's Rule and other relationships to infer bond distances from vibrational frequencies. We found that, for the weak bonding in d^8 dimers, excited-state displacements calculated from frequency shifts were greatly overestimated (compared to calculations from vibronic data[55]), and that in the quadruple bond regime even ground-state bond distances were overestimated. Figure 9(a) (adapted from Miskowski[42]) shows how both these errors occurred. The data points in Figure 9(a) represent force constants and bond distances of compounds in the row of the periodic table containing the second transition series (Rb to Xe), including Rh and Mo, the subjects of our early studies of metal–metal bonding.[53,54] Both of the empirical relationships plotted in Figure 9(a) (lines) fit the data well in the middle range, but fail badly at small k (predicting unrealistically large r values and having slopes that are much too great) and are systematically above the data at large k. Clearly, a new empirical relationship was needed if we were to fit the whole range of data.

We found that the function that fit the data best (see Figure 9b) is a simple exponential decay ''rule'' having the form:

$$r = r_{\min} + \Delta r \left(\exp \left[\frac{-k}{\tau_k} \right] \right) \qquad (1)$$

where r is internuclear distance, $r_{\min}$ is the minimum r at infinite k, Δr is the total range of r from $k = 0$ to $r_{\min}$, k is the force constant, and τ_k is the exponential 1/e decay constant for k. We found that equations of this form can be fit to force constant and bond distance data within any row of the periodic table, and between one row and another, regardless of the state of matter, formal bonding mode (e.g., ionic or covalent), bond order, spin multiplicity, electronic excitation, symmetry, etc., vide infra. The adjustable parameters in equation (1) (the values of which are dependent on which row(s) of the periodic table is/are involved) are $r_{\min}$, Δr, and τ_k. At first glance this may seem to be an unsatisfactorily large number of parameters, but if data are available over a sufficiently large range of r (and they generally are, see Figure 9b), $r_{\min}$ and Δr are very tightly constrained and only τ_k is really a free-floating adjustable parameter. Moreover, this relationship has satisfying functional properties: r reaches a definite, finite value at $k = 0$ ($r = r_{\max} = r_{\min} + \Delta r$); r approaches an asymptote at large k ($r \rightarrow r_{\min}$); and, the

entire expression can be integrated to establish constraints on acceptable potential functions. All the parameters are expected to depend on which row(s) of the periodic table the bonded atoms occupy (i.e., principle quantum numbers or core electron population). There is a tradition of eponymy in this field that we have attempted to follow,[56] and we gratefully acknowledge the contributions of the late Vinny Miskowski.

Having established the exponential decay function equation (1) as a good descriptor of the force constant-bond distance relationship for bonding between elements both of which are in the row of the periodic table containing the second transition series (Figure 9), we test the generality of this functional form for the other rows of the periodic table, and for bonding between elements in different rows (data primarily from[28,57–60]). Figure 10 shows the relationships, and the exponential fits, for intra-row bonding between elements in rows 1–6. Figure 11 shows the data and fits for row 1 (H–He) bonding to rows 1–6 (Figure 11a) and for row 2 (Li–Ne) bonding to rows 2–6 (Figure 11b). Data for rows 3 and 4 bonding to subsequent rows are not shown, and interrow data involving row 6 are too sparse to be statistically significant. The exponential decay function gives satisfactory fits to the data in all cases, and the fit parameters are given in Table 1.

These relationships have been tested independently of our work and found to be quite accurate in determining bond distances in systems where crystallography is inapplicable (e.g., ES[55]) or estimating force constants where bond distances are known.[61] What other insights may be gained?

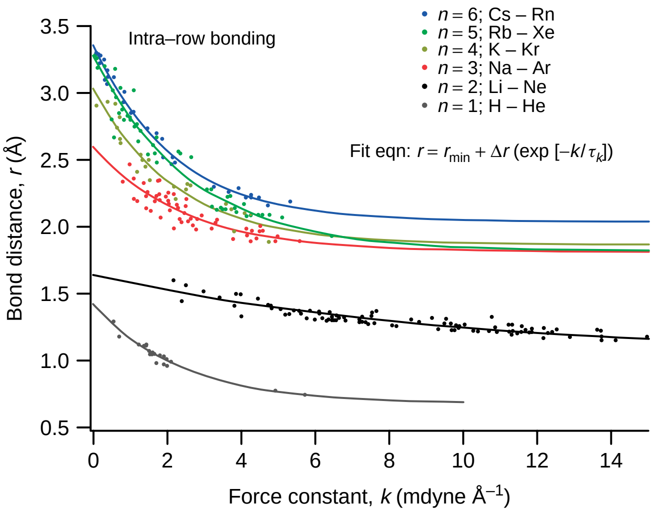

Figure 10 Bond distance versus force constant data for intra-row bonding in all rows ($n = 1$–6) of the periodic table preceding the actinoids. The solid lines show the fits to an exponential decay function (see text)

Table 1 Parameters for homonuclear and heteronuclear bonding of elements in the same (intra-row) and subsequent (interrow) rows of the periodic table (n = principal quantum number; r in angstrom; k in millidyne per angstrom; standard deviations in parentheses)

Parameters fit to equation (1): $r = r_{min} + \Delta r(\exp[-k/\tau_k])$; $r_{max} = r_{min} + \Delta r$
Parameters for intra-row bonding (n = 1,1 to 6,6):

n = 1,1; H–He to H–He	$r_{min} = 0.68(0.04)$	$r_{max} = 1.42(0.05)$	$\tau_k = 2.34(0.29)$
n = 2,2; Li–Ne to Li–Ne;	$r_{min} = 1.05(0.01)$	$r_{max} = 1.65(0.02)$	$\tau_k = 9.20(0.09)$
n = 3,3; Na–Ar to Na–Ar;	$r_{min} = 1.81(0.09)$	$r_{max} = 2.59(0.12)$	$\tau_k = 2.45(0.84)$
n = 4,4; K–Kr to K–Kr;	$r_{min} = 1.87(0.12)$	$r_{max} = 3.03(0.13)$	$\tau_k = 2.23(0.56)$
n = 5,5; Rb–Xe to Rb–Xe;	$r_{min} = 1.82(0.10)$	$r_{max} = 3.28(0.10)$	$\tau_k = 2.61(0.52)$
n = 6,6; Cs–Rn to Cs–Rn;	$r_{min} = 2.04(0.04)$	$r_{max} = 3.36(0.06)$	$\tau_k = 2.17(0.44)$
Parameters for elements in row 1 (n = 1, H–He) to elements in subsequent rows:			
n = 1,2; H–He to Li–Ne	$r_{min} = 0.90(0.03)$	$r_{max} = 1.93(0.07)$	$\tau_k = 2.70(0.29)$
n = 1,3; H–He to Na–Ar	$r_{min} = 1.20(0.05)$	$r_{max} = 2.17(0.07)$	$\tau_k = 2.07(0.32)$
n = 1,4; H–He to K–Kr	$r_{min} = 1.42(0.03)$	$r_{max} = 3.22(0.04)$	$\tau_k = 0.74(0.08)$
n = 1,5; H–He to Rb–Xe	$r_{min} = 1.52(0.09)$	$r_{max} = 3.41(0.11)$	$\tau_k = 0.68(0.17)$
n = 1,6; H–He to Cs–Rn	$r_{min} = 1.54(0.11)$	$r_{max} = 3.33(0.70)$	$\tau_k = 0.68(0.28)$
Parameters for elements in row 2 (n = 2, Li–Ne) to elements in subsequent rows:			
N = 2,3; Li–Ne to Na–Ar;	$r_{min} = 1.44(0.02)$	$r_{max} = 2.32(0.05)$	$\tau_k = 3.13(0.31)$
N = 2,4; Li–Ne to K–Kr;	$r_{min} = 1.57(0.02)$	$r_{max} = 2.56(0.05)$	$\tau_k = 2.52(0.52)$
N = 2,5; Li–Ne to Rb–Xe;	$r_{min} = 1.62(0.05)$	$r_{max} = 2.66(0.08)$	$\tau_k = 2.81(0.56)$
N = 2,6; Li–Ne to Cs–Rn;	$r_{min} = 1.59(0.05)$	$r_{max} = 2.54(0.07)$	$\tau_k = 3.68(0.72)$
Parameters for elements in row 3 (n = 3, Na–Ar) to elements in subsequent rows:			
N = 3,4; Na–Ar to K–Kr;	$r_{min} = 1.94(0.05)$	$r_{max} = 3.04(0.12)$	$\tau_k = 1.67(0.27)$
N = 3,5; Na–Ar to Rb–Xe;	$r_{min} = 2.17(0.10)$	$r_{max} = 3.00(0.14)$	$\tau_k = 1.28(0.42)$
Parameters for elements in row 4 (n = 4, K–Kr) to elements in subsequent rows:			
N = 4,5; K–Kr to Rb–Xe;	$r_{min} = 2.30(0.04)$	$r_{max} = 3.31(0.10)$	$\tau_k = 0.96(0.15)$

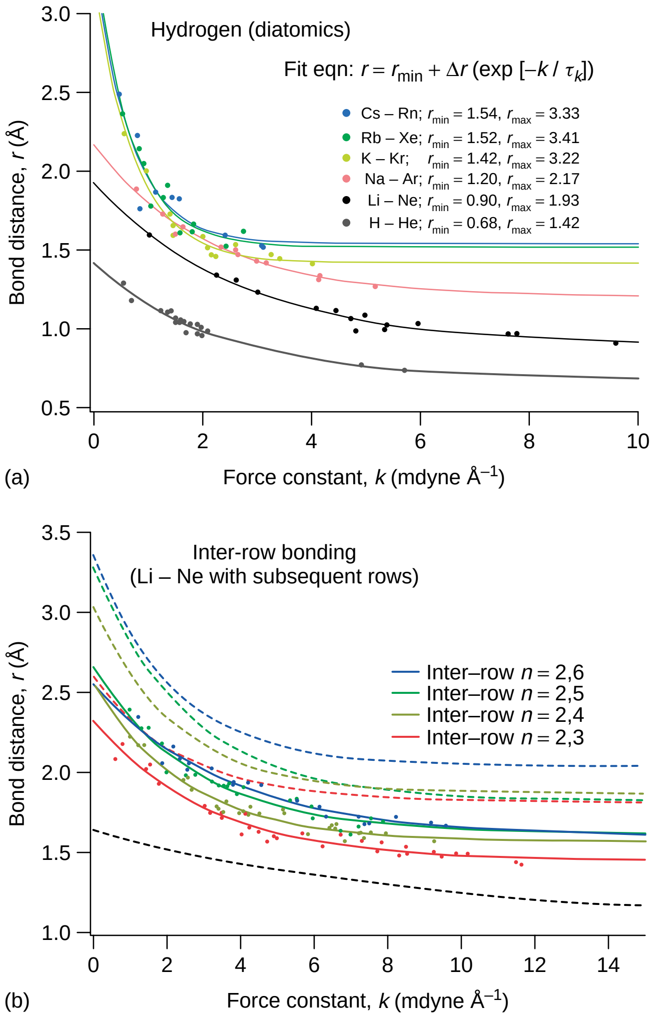

Figure 11 Bond distance versus force constant data for interrow bonding: (a) for hydrogen ($n = 1$) bonding to all rows ($n = 1-6$) of the periodic table preceding the actinoids; and (b) for second-row elements ($n = 2$) bonding to all subsequent rows ($n = 3-6$) of the periodic table preceding the actinoids. The solid lines show the fits to the exponential decay function that we have proposed. The dashed lines in (b) are the fits to the intra-row bonding shown in Figure 10

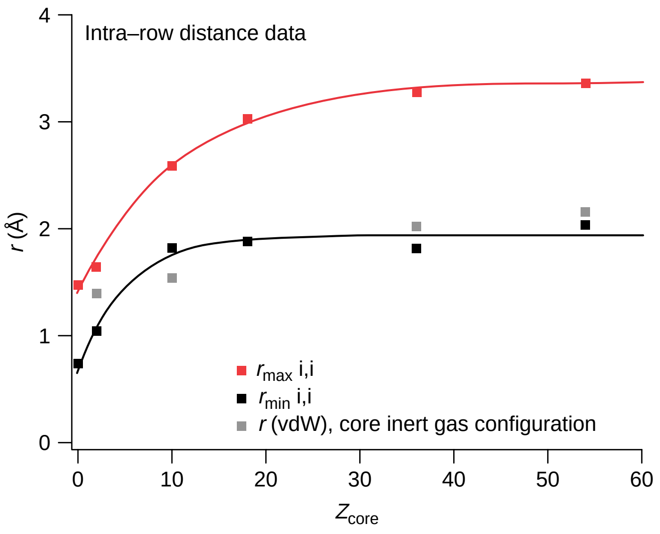

Figure 12 Maximum and minimum bond distances for intra-row bonding within various rows of the periodic table, taken from the intra-row exponential fits shown in Figure 10 and plotted versus the atomic numbers of the core inert gas electronic configurations of the various rows ($n = 1-6$)

3.2.1 *Maximum and Minimum Bond Lengths, Core Repulsions and Inert Gas Configurations*

Figure 12 plots the intra-row r_{max} and r_{min} values, row by row, versus the core inert gas atomic number for each row (i.e., zero for row 1, [He] for row 2, [Ne] for row 3, etc.). Both r_{max} and r_{min} increase as expected with Z_{core}, and both seem to approach constant maxima at large Z_{core} (approximately 3.4 Å for r_{max} and 1.9 Å for r_{min}; the solid lines in Figure 12 are exponentials but their physical significance if any is unclear). All of the interrow data follow the same general behavior; in fact, most of the interrow data can be directly superimposed on the plot in Figure 12, with two exceptions. Both the row 1 (H–He) and row 2 (Li–Ne) interrow r_{min} data are similar, systematically below the r_{min} data for the other rows, approaching a maximum of approximately 1.6 Å. Similarly, the r_{max} values for row 2 (but not row 1) fall below the interrow line, approaching a maximum of only approximately 2.7 Å. Part of this behavior can be ascribed to the unique ability of row 2 elements to form exceptionally strong bonds of all orders at short distances (see Figures 10 and 11) using only their 2s and 2p orbitals, at least in their ground electronic states. Similarly, H is unique in having only its 1s orbital available for GS bonding. Given that we ascribe r_{min} values to core electronic repulsions that overcome attractive bonding forces, we expect there to be some correspondence between minimum bonding distances and the sizes of the corresponding inert gases that are isoelectronic with the respective cores. The van der Waals radii of the inert gases are also plotted in Figure 12, and they qualitatively correspond to the behavior of r_{min}.

3.2.2 *The Lanthanoid Contraction and the Lanthanoid Expansion*

The lanthanoid contraction—the similarity in size of elements in row 5 and row 6 due to the filling of 4f orbitals between Ba and Lu—is an established paradigm that accounts for many chemical similarities between elements in the same groups of these two rows. These similarities are largely properties of the valence electrons, which are incompletely shielded from increasing nuclear charge by the 4f electrons and thus have similar spatial extension in rows 5 and 6 despite increasing atomic number. The lanthanoid contraction is very evident in interrow bonding, for example,

Figure 11, where the entire bond distance and force constant ranges are indistinguishable for rows 5 and 6 bonding to H and to Li–Ne. In a sense this is unexpected, however, because despite the valence similarities between rows 5 and 6, core repulsive forces ultimately must exert their effects at greater distances for row 6 simply because its elements have more core electrons than row 5. One might expect this to manifest itself in a ''lanthanoid expansion'' of r_{min} under certain bonding circumstances. This is actually seen in the intra-row binding within rows 5 and 6 (see Figure 10). While the force constants and bond distances for rows 5 and 6 are virtually indistinguishable for force constants less than approximately 2 mdyne Å^{-1}, at greater values of k the r values begin to diverge, eventually reaching r_{min} values that differ by some 0.2 Å. This novel observation of a lanthanoid expansion is important in understanding very strong bonding regimes and their differences between rows 5 and 6, for example, the chemistry of compounds having intra-row bond orders of 3 or higher.

3.2.3 Bonds, Nonbonds, and Bond Order

The r_{max} values from the exponential decay fits to the bond distance-force constant data set maximum distances for ''real'' bonding (but not, for example, van der Waals interactions, vide infra). Longer distances would generally be considered nonbonding. The converse of this statement is that interatomic distances shorter than r_{max} must be considered to be bonding distances. Nobody would argue, for example, that the internuclear distances between 2.7 and 3.0 Å in the unsupported metal–metal bonds of $Co_2(CN–CH_3)_{10}$ and $Mn_2(CO)_{10}$ in row 4, or those between 3.0 and 3.3 Å in $Tc_2(CO)_{10}$ and $Rh_2(CN–C_6H_5)_8$ in row 5, constitute nonbonding interactions. Yet there are many cases where internuclear distances considerably shorter than $\mathrm{r_{max}}$ are generally thought to be nonbonding. This is particularly prevalent in cluster chemistry, in compounds with bridging groups, and in multimetal sites in proteins, in all of which cases ambiguities may exist and direct measurements may be difficult. It is possible that revised thinking is in order in these cases. For example, we used these arguments along with evidence from model compounds to argue that the dimeric Cu_A site in cytochrome oxidases exhibited a Cu–Cu bond in its Cu(I)–Cu(II) state,[62] and this suggestion has subsequently been verified.[63] Another insight forthcoming from these relationships is that formal bond order is at best only a qualitative indicator of where a particular bond will reside in force constant-bond distance space. There is considerable overlap among all of the formal bond orders of compounds in these correlations.

3.2.4 Exceptions

Pathological potentials, for example, those with double minima, will not adhere to these rules. Very weak interatomic and intermolecular interactions, for example, van der Waals interactions and weak metallic bonding (e.g., Hg and alkali metals) do not fit the relationships given here. Instead they follow their own exponential decay functions at longer distances and smaller force constants. In general the rules given are valid for electronically excited molecules, and are independent of spin state, term symbol, parity, symmetry, and so on. An exception to this, however, is bonding involving heteronuclear compounds of hydrogen in electronically ES. Bonds of this type generally have shorter internuclear distances than the GS H–X distances given in Table 1 and Figure 11. This may be because hydrogen is able to use orbitals other than 1s in these electronically excited species.

3.3 Time-Resolved Vibrational Spectroscopy

TRVS is ideally suited to probe the dynamics of inorganic and bioinorganic systems, including GS reactions (mechanisms of electron transfer, ligand exchange, oxidative addition, etc.) and excited-state photochemistry and photophysics. TRVS methods provide high structural specificity and time resolution. The molecular vibrations are sensitive to changes in charge, symmetry, bond lengths, bond angles, and energy content, any or all of which can be used to follow the molecular dynamics of interest. Furthermore, changes in the vibrational spectrum track molecular dynamics down to ultrashort time scales because vibrational transitions respond to changes in structure or environment on time scales as short as the 10–100 fs periods of molecular vibrations. TRVS can be regarded as a special case of vibrational difference spectroscopy, where the perturbation is generally a laser pump pulse and the time-resolved spectrum is differenced with the equilibrium spectrum. Only the structures that respond to the transient perturbation give rise to features in the difference spectrum. The transient perturbation can be direct excitation of a chromophore of the inorganic complex being probed, or a more indirect perturbation, such as a laser-induced pH-jump. It is now possible to make such measurements on all relevant time scales, from femtoseconds to kiloseconds.

The application of TRVS methods to the study of the dynamics of inorganic and bioinorganic systems has two main challenges. The first is how to initiate the dynamics of interest. Ideally the dynamics are initiated with a pulsed laser, for example, by direct excitation of a metal-to-ligand charge transfer transition. In cases where direct excitation is not possible, other approaches have been developed to rapidly initiate a chemical reaction. Examples of some important new approaches to the initiation problem are given below. The second challenge is the measurement of the vibrational spectrum on the relevant timescale. Despite major advances in methodology in the past decade, TRVS methods remain technologically difficult and require expensive equipment. Ultrafast IR and Raman measurements, for example, require sophisticated lasers and instrumentation that are generally only present in highly specialized laboratories. Even measurements on the nanosecond timescale

and slower, that are possible to make in real-time (direct resolution of the transient signals with fast detectors) are not trivial. A revealing example is time-resolved step-scan Fourier transform infrared (SS-FTIR) spectroscopy. SS-FTIR spectrometers are commercially available from several manufacturers (Bruker, DigiLab, Nicolet). Nevertheless, there are only a handful of groups that have published results using SS-FTIR to study molecular dynamics of inorganic and bioinorganic systems.[64,65] Nevertheless, these studies have demonstrated the power of TRVS methods and their use is becoming more widespread.

3.3.1 Fast Initiation Methods

Direct pulsed-laser excitation is the most commonly employed approach to pump-probe time-resolved IR or Raman measurements. For example, studies of bioinorganic systems have focused on proteins with an absorbing metal active site such as heme or chlorophyll, because the chromophore provides a convenient means to both initiate and probe the dynamics. Generally, these experiments pump an electronic state of the chromophore, leading to photochemistry (ligand photodissociation), conformational changes (cis-trans isomerization) or electron transfer; the response of the chromophore is probed using TRVS. Other rapid initiation methods have been developed that do not rely on direct excitation of a metal center, including laser-induced temperature-jump (T-jump),[66] laser initiated electron transfer,[67] photolytic release of caged reagents such as Ca^{2+},[68] and submillisecond rapid mixing techniques.[69] In contrast to the optical trigger approaches, these techniques are much more generally applicable to the study of the dynamics of inorganic and bioinorganic systems that lack a readily accessible chromophore, or to the study of reactions that cannot be directly initiated with light. The fast mixing techniques, for example, are completely general and have a long history of successful application to the study of inorganic reactions (*see* ***Rapid Scan, Stopped-Flow Kinetics***).[70] The sample is probed downstream of mixing. Since the volume of this continuous flow system is kept small to minimize the sample solution volume required and to improve time resolution, laser-based probes that can be tightly focused are used, especially RR spectroscopy. The best demonstrated dead time to date is ca. 10 µs, an improvement of 2 orders of magnitude over most commercial stopped-flow instruments. Disadvantages are that physical limitations of mixing place a lower limit on the time resolution of the technique (1–10 ms), and that the large shear forces produced by turbulent flow in the mixing volume may affect the dynamics themselves as well as degrade the optical quality needed for some probes. Since all these methods are well developed and described in the literature, we focus here on two new approaches developed in our laboratories: the laser-induced pH-jump and photolysis of caged metals.

Laser-Induced pH-Jump. A macroscopic change in pH can be used to initiate many reactions of inorganic and bioinorganic systems, or at least to shift the equilibrium sufficiently to measure the relaxation dynamics. A persistent laser-induced pH-jump can be produced using a pH-jump reagent such as *o*-nitrobenzaldehyde (*o*-NBA) that acts as an excited-state proton emitter.[71] UV photolysis of *o*-NBA results in an intramolecular redox reaction yielding *o*-nitrosobenzoic acid plus a free proton. The redox reaction occurs with an efficiency of 50% and with a rate constant of $2 \times 10^9\ s^{-1}$. Rapid H_2O addition to the aci-ketene intermediate yields the benzoic acid. Thus, the photochemistry is irreversible and produces a rapid decrease in the pH of the solution. We have demonstrated the efficacy of this approach for initiating protein dynamics by initiating the folding of a helical peptide model, polyglutamic acid. Polyglutamic acid forms a random coil at neutral pH due to the repulsive forces of the ionized carboxylate side chains. However, at low pH ($pK_a \sim 3.4$) the peptide forms an α-helix, as the carboxylate sidechains become protonated. This transition can be induced on a short time scale using a laser-induced pH-jump with *o*-NBA. The steady state difference FTIR spectrum following 266 nm laser excitation (7 ns, 1 mJ) is shown in Figure 13. The short laser pulse generates a 2 pH unit change (from 6.0 to 4.0) within 100 ns. The steady state difference FTIR spectra in Figure 13 were obtained by subtracting the spectrum before excitation from the spectrum after the flash. The *o*-NBA difference spectrum (without polyglutamic acid) is shown for reference. Clearly, the pH-jump initiates two major changes in the polyglutamic acid spectrum: first, the side chains become protonated, as evidenced by the disappearance of the glutamate COO^- bands (1410 cm^{-1}, sym and 1555 cm^{-1}, asym stretches) and appearance of the corresponding COOH band at 1715 cm^{-1}. Second, the polyglutamic acid becomes helical, as evidenced by the shift in the amide I absorbance.

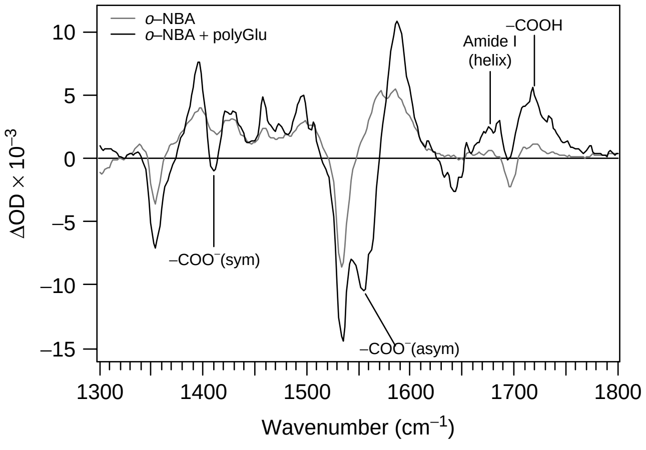

Figure 13 Rapid-scan FTIR difference spectra of an *o*-NBA + polyglutamic acid mixture following a single 266 nm laser pulse, which induces a pH-jump from 6.0 to 4.0, triggering the folding of the polyglutamic acid

Furthermore, a kinetics trace obtained at the helix wavelength indicates that the helix is completely formed within the time resolution of the pH-jump measurement (100 ns).[71] This result not only demonstrates the efficacy of the laser-induced pH-jump but also has important implications for the dynamics of helix formation. The polyglutamic acid refolds from a highly disordered state and hence must cross the helix nucleation barrier, which it does on a very short timescale (<100 ns).

Photolysis of Caged Reagents. Photolysis of caged reagents is a general approach to the study of binding and reaction of substrates and metal ions with proteins. An example of this approach is the photorelease of caged Ca^{2+} to study its binding dynamics to Ca^{2+} binding proteins such as calmodulin. Fundamental unresolved issues related to the dynamics of Ca^{2+} binding to calmodulin include the rates of binding to individual sites, the role of dynamics in cooperativity and the protein dynamics coupled to Ca^{2+} binding. Experimental approaches to these issues must overcome two problems: how to rapidly (impulsively) initiate Ca^{2+} binding and how to probe the binding and coupled protein dynamics on the relevant time scales. Rapid initiation of Ca^{2+} binding has been achieved in our laboratory using a laser-induced release of caged Ca^{2+} thereby allowing the binding dynamics to be observed using time-resolved infrared (TRIR) spectroscopy. Several caged calcium complexes that rapidly release calcium upon photoexcitation have been developed and are commercially available. One of the most promising candidates is nitrophenyl-EGTA (Figure 14 inset), which releases Ca^{2+} when excited at 355 nm through benzylic proton abstraction and subsequent rupture of the cage.[68] The rate of Ca^{2+} release is greater than 100 000 s^{-1}, with 14–20% photolytic yield.

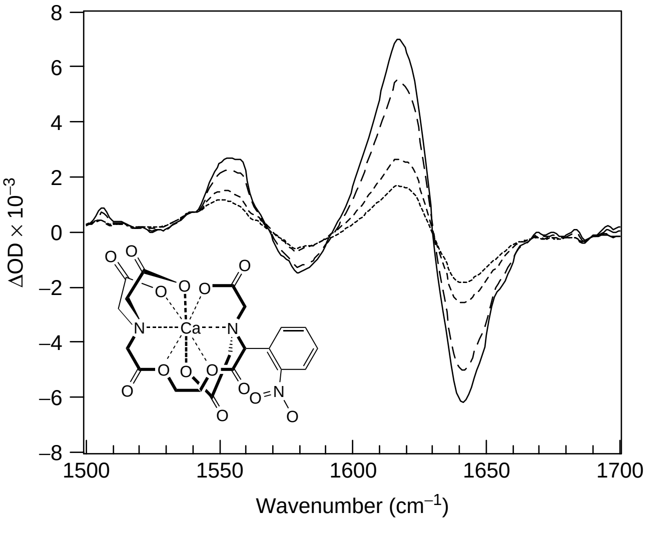

Figure 14 Ca^{2+} titration of calmodulin by photolysis of caged Ca^{2+}. The structure of the cage is shown in the inset. The difference FTIR spectra correspond to the addition of 4, 3, 2, and 1 equivalent(s) of Ca^{2+}, from top to bottom, respectively

Thus a 1 mM solution of nitrophenyl-EGTA: Ca will produce a maximum concentration of 200 µM Ca within a few microseconds of a short (10 ns) laser pulse at 355 nm.

The equilibrium difference FTIR spectra of calmodulin following titration with Ca^{2+} generated by photolysis of nitrophenyl-EGTA are shown in Figure 14. A solution of the apoprotein plus caged Ca^{2+} was irradiated with 355 nm light to photolytically produce 1, 2, 3 and 4 equivalents of free Ca^{2+}, which was then taken up by the protein. The difference spectra are computed as the spectrum after photolysis minus the spectrum before. In addition, the difference spectrum of the cage has been subtracted, to yield the difference spectrum of the protein alone. These spectra are identical to those produced from a chemical titration of Ca^{2+}, thereby demonstrating that the cage does not interfere with the Ca^{2+} binding, nor does it perturb the calmodulin structure. The difference FTIR spectra are dominated by changes in carboxylate modes that act as ligands to the Ca^{2+}. For example the asymmetric stretch of a COO−group is shifted from 1578 to 1550 cm^{-1}, characteristic of bidentate binding to the metal. In order to study the dynamics of Ca^{2+} binding using this approach, the FTIR acquisition must be time-resolved with respect to the cage photolysis. This was accomplished using a flow-flash scheme coupled with rapid-scan acquisition of the FTIR spectra as a function of time after the flash. Since the photolytic release of Ca^{2+} from the cage is irreversible, this scheme also enables repetitive signal averaging by constantly replenishing the sample in the flowing stream. Using this approach the binding kinetics for the individual Ca^{2+} binding events were resolved directly for the first time.[72]

3.3.2 Time-Resolved Resonance Raman (TR^3) Spectroscopy

TR^3 methods were originally developed in our laboratories to study excited-state structures and dynamics of transition metal complexes such as Ru^{3+} $(bpy)_3$ and metalloproteins.[73–75] TR^3 measurements rely on a pump-probe approach in which two separate laser pulses are used, one to excite the system and the other to probe the transient Raman spectrum. The time resolution of the experiment is determined by the width of the laser pulses (typically 7 ns for a Q-switched laser or as short as 1 ps for a mode-locked laser). The pulses are variably delayed with respect to one another to achieve time resolution, either by optically delaying the probe pulse with respect to the pump pulse or by electronically delaying two independently tunable lasers. Thus, two different approaches are required depending on the time scale of interest. The fastest timescale (from 10^{-12} to 10^{-8} s) requires optical delay to achieve sufficiently short separation between the pump and probe pulses. In such a scheme, the probe pulse is sent through a fixed path, but the pump pulse is sent through a variable path that can be scanned. Since light travels about 1 ft per ns, a difference in pathlength of a few feet is sufficient. The second approach typically uses two Q-switched Nd:YAG lasers that are electronically delayed with respect to one another, to access

time scales from 10^{-8} to 10^{-1} s. In both these approaches, the detection of the Raman scattering is accomplished using a spectrograph and multichannel CCD detector. The detector does not need to be gated in this scheme since it relies on the delay of the probe pulse relative to the pump pulse to achieve time resolution.

An important example of the application of TR^3 spectroscopy to the study of metalloproteins has been its use to study the functional dynamics of the terminal oxidase of cellular respiration, cytochrome *c* oxidase (C*c*O).[46,76] TR^3 spectroscopy was first used to identify the reaction intermediates in the reduction of O_2 by C*c*O.[76] More recently, TR^3 spectroscopy has been used to study the dynamics of ligand binding to the binuclear center in greater detail.[46] Figure 15 shows TR^3 spectra for photodissociated carbonmonoxy C*c*O, obtained at pulse-probe time delay of 200 ns; the high- and low-frequency regions are both shown. The upper traces employ relatively high probe laser pulse energy (1 mJ) and the lower traces employ low-energy probe pulses (ca. 10 µJ). In the high-frequency region some diminution in intensity of the high-spin indicator band (1572 cm^{-1}) may occur at low probe pulse energy. At the same time, the oxidation state marker peak appears unchanged in frequency and lineshape at 1356 cm^{-1} in the two traces. This demonstrates that the spectrum in the low-power trace is not due to the CO complex, which would show an oxidation state marker peak at ca. 1372 cm^{-1}. In the low-frequency region the high-power trace clearly shows the Fe–N(Im) stretch of 5-coordinate high-spin cytochrome a_3 at 223 cm^{-1}, as in an earlier TR^3 study. However, this peak is greatly reduced in the low-power trace.

There are two tenable interpretations of the TR^3 results. First, the low-power TR^3 spectrum may be due to a six-coordinate low-spin species with both an unknown ligand L and imidazole as axial ligands. In general, the Fe–N(Im) stretching peak is missing from the RR spectra of six-coordinate low-spin heme complexes. In this interpretation the photolability of the Fe–L bond accounts for the typical 5-coordinate high-spin spectrum observed at high laser pulse energies; L may be imidazole itself or other ligands which are relatively poor π-acids. Alternatively, the low-power TR^3 spectrum may be due to a five-coordinate high-spin cytochrome a_3-L complex wherein L is not imidazole and has properties that induce cleavage of the Fe_{a3}–N(proximal histidine) bond. In this interpretation the disappearance of the 223 cm^{-1} peak occurs simply because the axial ligand L is not imidazole. Photodissociation of L by the probe laser pulse allows photostationary rebinding of the proximal histidine and regeneration of an essentially normal high-spin Raman spectrum. These ligation dynamics may all involve protonation and deprotonation reactions that play a crucial role in the proton pumping mechanism of the protein.

3.3.3 Time-Resolved Infrared (TRIR) Spectroscopy

The application of TRIR spectroscopy to study the dynamics of inorganic and bioinorganic systems has come more slowly than its Raman counterpart. This lag has been due in part to technical difficulties in developing IR sources with sufficient spectral brightness and detectors with sufficient sensitivity required for making fast TRIR measurements. Recent advances in laser technology, including femtosecond lasers and solid-state lasers, have provided the means to generate very bright and tunable sources throughout the midIR. Fast and sensitive IR detectors, optimized for detection of transients in real-time (10^{-9}–10^{-1} s) are now commercially available. In addition, advances in FTIR spectrometers and

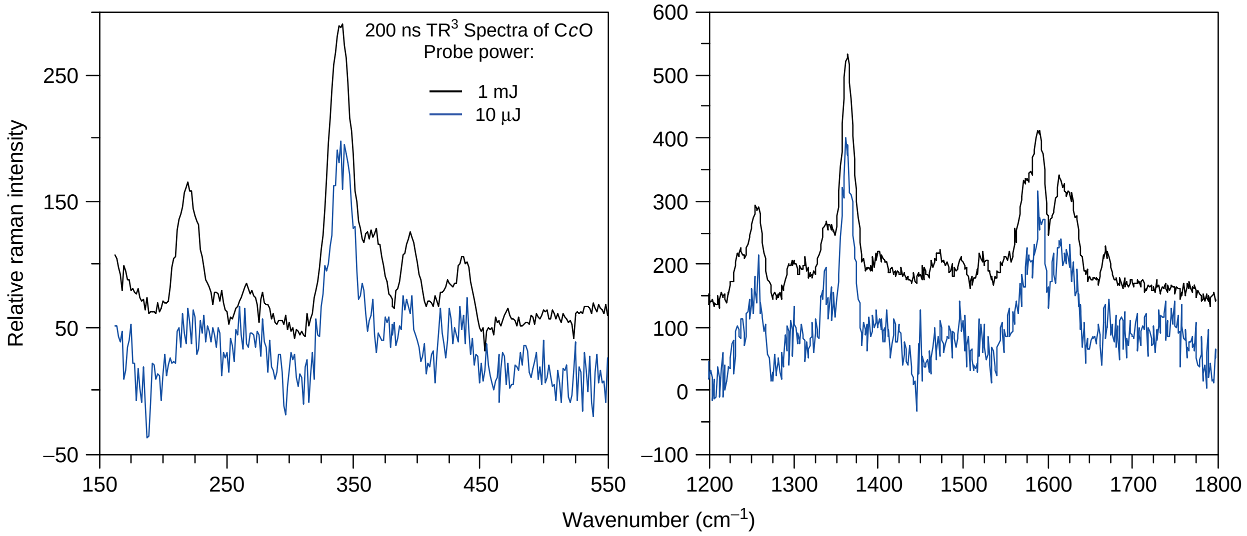

Figure 15 Time-resolved RR spectra obtained 200 ns after photodissociation of CO from fully reduced C*c*O with both high power (1 mJ, upper trace) and low power (10 µJ, lower trace) probe excitation

multichannel IR detectors (focal plane arrays) have improved the ability to measure transient IR spectra. As a consequence of these improvements, the application of TRIR spectroscopy to inorganic and bioinorganic problems has begun to flourish. Here we describe two of the most important examples, time-resolved step-scan FTIR and ultrafast TRIR spectroscopy.

Time-Resolved Step-Scan FTIR Spectroscopy (SS-FTIR). There are two approaches to obtaining time-resolved IR spectra of transient species on the 10^{-9}–10^{-1} s timescale.[77,78] The first employs a monochromatic IR source such as a CW lead–salt diode laser to measure the time course of the transient IR absorbance at a single wavelength. The transient transmission of this probe through the sample in response to a pump laser pulse is measured with a fast IR detector (usually a photovoltaic HgCdTe detector). The IR source is then scanned in a point-by-point manner, until IR transients are obtained throughout the spectral region of interest. Time-resolved spectra can then be generated by plotting the transient absorbance at each wavelength for a specific time following the excitation. While this approach is tedious, it does map the time course of the absorbance changes with high sensitivity. The alternative approach is to use time-resolved FTIR approaches that allow the entire IR spectrum to be obtained with good spectral and temporal resolution. Several specific approaches to time-resolved FTIR have appeared within the last decade, the most useful being time-resolved step-scan FTIR. A step-scan interferometer allows the moving mirror to be held at a fixed position while a transient is repetitively produced in the sample, for example, with a laser excitation. A temporally digitized reaction transient is obtained at each discrete mirror position. The temporal resolution is determined by the detector response and the digitization process. The spectral resolution and free spectral range are determined by the number and interval of interferometer mirror steps. These data are then reorganized by the FTIR control computer to yield a series of interferograms at a sequence of times. These are Fourier transformed into the time-resolved IR spectra. The critical value of this approach is that it allows a rapid survey of where in the IR spectrum the phenomena of interest appear. In this regard the rich detail of IR spectra can be a liability; if one tries to locate the dynamical phenomena of interest using the real-time point-by-point approach described above, the exercise is extremely tedious or else one trusts to luck in finding the right observation wavelength. Once these spectral signatures are identified, however, their temporal evolution can be monitored with greater sensitivity and simplicity using the single wavelength TRIR approach.

Step-scan FTIR systems are available commercially from several vendors. Unfortunately, they are (despite manufacturer's claims) unsuitable for time-resolved measurements without extensive system modifications. Typically, the illumination optics must be modified to permit a tighter focus of the probe beam and overlap of the laser excitation source. Wide-band photovoltaic HgCdTe detectors with high sensitivity are available with response times approaching 10 ns. For optimum time response of the system, the signal processing electronics must be replaced with boxcar integrators and averagers to extend the time resolution down to 10 ns. Finally, appropriate timing circuitry is required to synchronize the laser excitation with the mirror stepping.

Figure 16 shows time-resolved SS-FTIR results for the inorganic complex [*fac*$(CO)_3$(phen)Re(I)-CN-Ru(II)$(bpy)_2$CN]$^+$ (phen = 1,10-phenanthroline, bpy = 2,2′-bipyridine). Photoexcitation of this molecule produces the Ru-based metal-to-ligand charge transfer (MLCT) ES best characterized as [*fac*$(CO)_3$(phen)Re(I)-CN-Ru(III)(bpy$^-$)(bpy)CN]$^+$, which has a lifetime of several microseconds.[79] The frequencies of the C≡O and C≡N stretches are sensitive to the charge redistribution in the ES; the solid trace and the (+) symbols are the 100 ns SS-FTIR and point-by-point TRIR difference spectra, respectively. There are two Re–CO GS bands due to the approximate C_{3v} symmetry at 1920 and 2030 cm^{-1} and two CN bands at 2080 and 2097 cm^{-1} (bridging and terminal, respectively). There are four ES bands and four corresponding ground-state bleaches, the positions of which clearly indicate that the ES is a Ru^{III}-bpy MLCT state. It is important to realize the extreme differences in data acquisition effort required to get the step-scan compared to the point-by-point spectrum. The point-by-point transient difference spectrum represents a heroic effort consisting of separate kinetic measurements at some 70 different wavelengths. Each measurement represents approximately an hour of signal accumulation time, plus setup and alignment, etc. The investment in such a transient spectrum is obvious. The

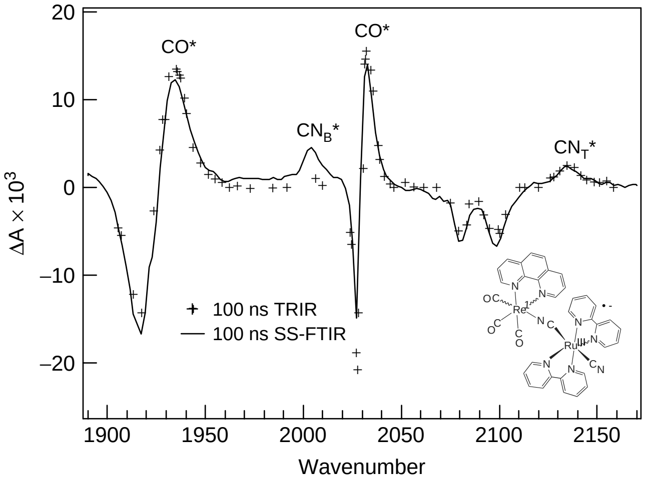

Figure 16 Comparison of the 100 ns TRIR spectrum obtained point-by-point from individual kinetics transients to the 100 ns SS-FTIR spectrum of the MLCT excited state of [*fac*$(CO)_3$(phen) Re(I)–CN–Ru(II)$(bpy)_2$CN]$^+$

step-scan spectrum, on the other hand, requires 60 min of signal acquisition time. Note also the resolution required to get complete information. The sharp C–O stretch at 2030 cm^{-1} shifts only 2 cm^{-1} in the transient spectrum. In the point-by-point spectrum 13 points are necessary over a range of less than 15 cm^{-1} to record this shift. Modest resolution (say, 10 points over the 250 cm^{-1} range instead of 70) might have missed this feature entirely. Furthermore, the ES bridging cyanide band at 2002 cm^{-1} is largely missing in the TRIR spectrum due to incomplete sampling in this spectral region, but is clearly visible in the SS-FTIR spectrum. The advantages of the step-scan approach are obvious. The example also illustrates the utility of the TRIR approach in following the movement of energy and electrons in transition metal complexes. The intense and sharp absorbance bands of the CO and CN ligands act as sensitive reporters of transient changes in the electron density at the metal centers. Similarly, the polypyridyl vibrations in the fingerprint region are sensitive to the localization of charge on the ligand in an MLCT state. Such information is difficult to obtain by any other method. Transient UV-visible absorbance, for example, is ambiguous in such systems because the electronic absorbance bands are broad and overlapping.

Dynamics of Ligation and Electron-Transfer Reactions in Terminal Oxidases. An example of time resolved, step-scan FTIR of a metalloprotein is shown in Figure 17. The spectra in Figure 17 are the time-resolved analog of Figure 6, the FTIR difference spectra observed upon photodissociation of CO from the heme of wild-type cytochrome *bo*$_3$, a terminal oxidase of respiration from *E. coli*. Upon photodissociation from the heme, CO rapidly binds to Cu_B. The spectra show both the bleaching of the Fe(C–O) stretch (1961 cm^{-1}) and the appearance of the Cu(C–O) stretch (2062 cm^{-1}). In addition, changes in the amide and sidechain regions related to protein conformational changes are seen in the region below 1800 cm^{-1}, and these are quite similar among the WT protein

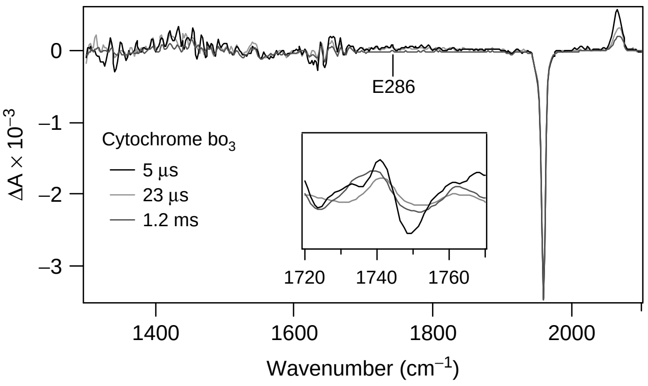

Figure 17 Time-resolved SS-FTIR spectra of photodissociated CO Cytochrome *bo*$_3$ from *E. coli*. The inset shows the evolution of the glutamic acid 286 difference feature. The noise level in the spectrum is indicated by the flat region between 1800 and 1900 cm^{-1}

and various mutants thereof. The mutants involve a particular sidechain, residue 286, which is glutamic acid (E) in WT and is mutated for aspartic acid (D) and cysteine (C), respectively. The identification of the E286 and D286 absorbances near 1750 cm^{-1}, and their absence in the E286C mutant, are apparent in low-temperature static difference FTIR spectra. The high sensitivity of these measurements is also clear. The absorbances of the 286 residue are in the order of 10^{-5} OD units, while the maximum OD's (corresponding to the amide I' absorbance) in the raw spectra from which the difference spectra are extracted are approximately 1. The transient IR absorbance of the 286 residue represents the time-resolved detection and positive identification of *one specific chemical bond*, the C=O of the carboxylic acid sidechain, in a protein having molecular weight of approximately 250 000. Finally, we can clearly follow the dynamics of the specific chemical processes involved. The photodissociated CO, bound to Cu_B, rapidly equilibrates with solution between 5 and 23 µs, and does not return to the Fe_{a3} for several ms. The E286 carboxylic acid peak shifts in concert with CO binding to Cu_B, and the intensity of the difference feature tracks the Cu_B–CO feature in time. These dynamics are important features of the ligand shuttle and coupled proton pumping functions of the binuclear center of oxidases. This work clearly demonstrates the capability of time resolved, SS-FTIR for following metalloprotein dynamics with high structural specificity and time resolution.

Ultrafast TRIR. The most fundamental processes of bond making, bond breaking and electron transfer have ultrafast dynamics. Access to these ultrafast time scales by TRIR requires a different approach from real-time measurements. Instead, pulsed-laser techniques based upon optical delay for measurement of time must be used. There are several approaches to measuring TRIR on the $10^{-13} - 10^{-8}$ s time scale.[80] These include upconversion of a CW IR laser into the visible by sum frequency generation with picosecond (or shorter) visible pulses, use of an amplified optical parametric oscillator (OPO), and production of femtoseconds or picoseconds IR pulses by difference frequency generation. Probably the most versatile approach is the use of an OPO to generate a spectrally broad IR pulse (usually about 300 cm^{-1} with a 100 fs pulse). Ultrafast IR spectra are obtained by interrogating the sample with this broadband pulse, which is then dispersed in a spectrograph and detected with a multichannel detector (e.g., a focal plane array MCT detector). Alternatively, the ultrafast IR absorbance is measured at a single wavelength and the pump-probe delay is scanned to obtain the complete temporal response of the sample. An example of this approach is the resolution of the ultrafast ligand transfer from the heme to the Cu_B of cytochrome oxidase. Application of ultrafast IR to this reaction showed that CO photodissociated from the heme appears on Cu_B in an astonishingly short time, less than 1 ps.[81,82] Considering the energetics and geometry of the problem, the photochemical transfer half-life of CO from the heme to Cu_B is essentially

as fast as it can physically be (although the thermal transfer lifetime almost certainly is slower). It is possible that nuclear tunneling is a factor in this extremely fast reaction. In any case, the ps TRIR result shows us that the binuclear site is elegantly arranged for facile transfer of ligands between the metal centers. This reaction is also of interest from a fundamental standpoint in understanding the elementary steps involved in atom transfer, bond formation and energy relaxation dynamics.

METHOD SUMMARY

Acronyms, Synonyms

- X-ray Absorption Fine Structure (XAFS)
- X-ray Absorption Near Edge Structure (XANES)
- Extended X-ray Absorption Fine Structure (EXAFS)

Measured physical quantities (initial/final states and selection rules)

- core electron excitation energies of absorbing atom
- scattering of X-ray photoelectron by electron density around neighboring atoms

Information available (strengths of technique)

- average oxidation state of redox active metals—XANES
- metal–ligand coordination geometry/symmetry for selected metals (Mn, Fe, Cu, etc.)—XANES
- highly accurate metal–ligand bond distances (±0.02 Å)—EXAFS
- metal–ligand coordination numbers—EXAFS
- types of coordinating atoms—EXAFS

Information not available (limitations)

- cannot directly distinguish type of scattering from adjacent elements in same periodic table row
- high error in accuracy of coordination numbers (error bars of at least ±0.5)
- precise coordination geometry is not available; only radial distances are determined
- structural information is constrained to within approximately a 5 Å radius from the absorbing atom
- insensitive to magnetic or isotopic properties of metal sites

Major advantages of technique

- can obtain highly accurate metal–ligand bond lengths
- can obtain structural information from samples in either the frozen solution or solid state
- technique is element selective; no interference from other types of metals

Major disadvantages of technique

- if the sample is heterogeneous, the scattering signal is the average of all sites of the same element; it is impossible to deconvolute scattering from these sites
- technique requires high intensity X rays from a synchrotron light source
- technique often does not give a unique determination of ligand environment; it depends on simulation/curve fitting

Questions that can be addressed using technique

- What is the oxidation state of the metal in the sample?
- Is the metal site affected by the presence of substances like substrate, inhibitors, and redox agents?
- What is the ligand environment around the metal site in the sample?
- Is the metal part of a multinuclear cluster?

Sample constraints

- sample concentration of at least 0.3 mM in excited element (typically the higher the better) is required
- sample volume should generally be between 50 and 140 μL (microliter volumes are required only in special cases)
- solution samples must be frozen quickly, typically with adition of glassing agents (glycerol, etc.)
- sample cells must fit cryostat being used
- atomic number of excited elements must be >19; lower values require special handling

1 INTRODUCTION

X-ray absorption spectroscopy (XAS) is quickly emerging as a premier tool for investigating the structure and redox properties of molecules. Utilizing the high-flux and broad energy range of X rays supplied by synchrotron sources, one can selectively excite core electron transitions for specific atoms in a molecule using XAS. Spectroscopic signals from these electronic transitions can be used to dissect the chemical architecture of molecules, providing a better understanding of their functionality. With the achievement of brighter energy sources, the field of XAS has grown as an application that can be utilized to solve more complex issues regarding the structure of molecules. Coupled to the growth of this technique is the push from many laboratories toward developing hardware and software to expand the utility of XAS. As this technique continues to grow in its capability and general ease of use, so does the demand for its application by chemists and biochemists alike.

XAS has historically been utilized to provide structural details of molecules, predominantly at metal centers in inorganic and bioinorganic systems. The ability to selectively excite electrons in specific atoms allows for the identification of metal–ligand coordination details at distinct positions in molecules. An inherent strength of the technique is that it provides highly accurate metal–ligand bond lengths for a molecule. In addition, information from the excitation edges provides an additional wealth of information regarding the electronic environment, the coordination geometry, and even ligand identity of specific atoms in molecules. This technique is generally easier to apply than other structural techniques, given one can characterize a molecule in the gaseous, solution, or solid state. Limitations of the technique (i.e., spectra are the average of all same element sites, etc.), however can hinder the unique identification of the metal environment particularly within a multinuclear complex.

When coupled with other techniques, XAS can often provide the additional key information required to decipher the chemical properties of a molecule. The high resolution and accuracy of structural details provided by this technique are perfectly suited when one is interested in solving structurally related questions. Highly accurate bond lengths derived from XAS can easily serve as metrical constraints when refining molecular structures by nuclear magnetic resonance (NMR) spectroscopy (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Metallobiomolecules***) or X-ray crystallography. XAS excitation edges can provide complementary electronic detail for electrochemical and electron paramagnetic resonance (EPR) studies if there is interest in understanding the electronic properties of metals in a molecule. The specificity of signals from different atoms can be used to complement metal analysis from techniques like atomic absorption or inductively coupled plasma-mass spectroscopy (ICP-MS) (*see* ***Metal Analysis***). Whether being used as a ‘‘stand-alone’’ technique or in combination with other methods, XAS can provide the unique structural and electronic details required to understand the chemical framework of many important molecules.

This article is directed toward providing the reader with a general understanding of the technique and to describe how it can be utilized to address specific questions. Numerous published reviews describe the physics behind the technique, therefore only a general overview of these

physical principles is provided in this article. Numerous examples illustrating how XAS was used to address specific questions are provided to help the reader gauge the utility of the technique regarding their research. Finally a summary of practical descriptions and important reference material regarding XAS are provided to assist the reader in applying this technique.

2 TECHNICAL BACKGROUND

XAS utilizes high intensity X rays provided by synchrotron radiation sources to excite core electrons in specific atoms within a molecule. By drawing X rays tangential to the circular electron path within a synchrotron, focused high intensity X-ray photons can be delivered over a broad energy range at a flux orders of magnitude higher than those provided by standard X-ray generators. Energies required to excite electronic transitions are atom specific, so the technique is selective for the element of interest. Energies below the absorption edge, too low to promote electron excitation, result in baseline noise within the low energy region of an XAS spectrum (Figure 1). When the X-ray energy matches the excitation energy of a core electron for the element of interest, this electron is promoted to unpopulated energy levels or dissociated, accounting for the large absorption edge seen in an XAS spectrum. The energy range immediately before and after the excitation edge is referred to as the *X-ray absorption near edge structure* (XANES) region of the XAS spectrum. At energies above the excitation edge, the electron is ejected to the continuum where it behaves as a photoelectron wave following a sinusoidal variation. This high-energy region of the XAS spectrum, covering the spectral oscillations, is defined as the *extended X-ray absorption fine structure* (EXAFS) spectral region.

The excitation edge in a typical XAS spectrum contains a wealth of information regarding different electron excitation events. The K-absorption edge, driven from the excitation of 1s core electrons, is often utilized to investigate elements ranging from sulfur to cadmium, since X rays required to induce these transitions often fall within the energy range provided by XAS monochromators. To characterize elements with atomic numbers above 48, one typically utilizes a lower energy L-absorption edge, where electron excitation for the L_{I} edge comes from a 2s electron and L_{II} and L_{III} edges come from exciting 2p orbital electrons. XANES spectra span the photon energy range immediately below and going about 40 eV above the excitation edge (Figure 2). The excitation edge in a XANES spectrum can provide information regarding the redox state of the excited element and the identity of ligand atoms around the excited element. Low intensity transitions, sometimes seen in a K-edge spectrum at photon energies below the large excitation edge, arise from the excitation of 1s electrons to vacant 3d or 4p (for first-row transition elements) energy levels. These excitation signals, often referred to as pre-edge transitions (Figure 2, inset), can be utilized to determine the geometrical arrangement of the atoms surrounding the absorbing element. When applied to molecules on a surface, the *near edge X-ray absorption fine structure* (NEXAFS) provides additional information regarding the orientation of the molecule based on the polarization dependence of the signal. Direct structural detail from the technique comes, however, from the EXAFS region of the XAS spectrum.

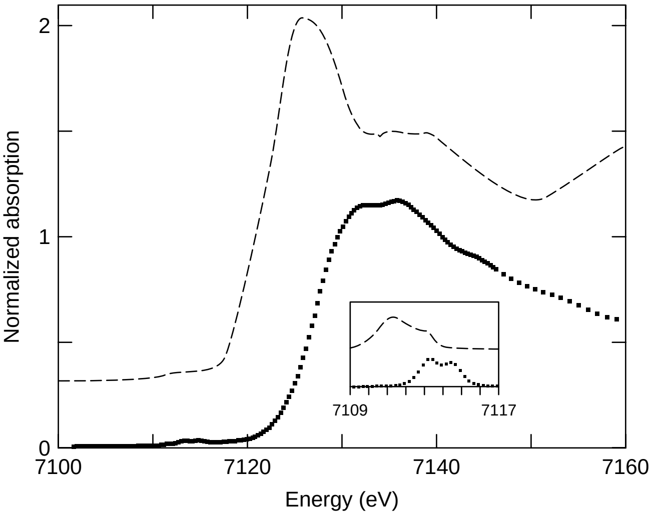

Figure 2 XANES comparison of Fe(II) (dashed line) and Fe(III) (dotted line) ammonium sulphate, offset vertically for clarity. First inflection energies for edges occur at about 7123 and 7127 eV, respectively. Inset: 1s → 3d transitions expanded and offset for clarity

The EXAFS spectral region is dominated by the damped sinusoidal oscillations in the absorption spectrum and generally refers to the energy region 40–1000 eV above the absorption edge (Figure 3). In this energy range, the photon energy is much higher than the core electron binding energy, resulting in substantial kinetic energy for the excited photoelectron. Following excitation and ejection of the core electron, the resulting signal can be viewed as an outwardly propagating wave traveling away from the absorbing atom. When neighboring atoms surround the absorbing element, the photoelectron wave will be backscattered by each neighboring atom, producing an inwardly propagating wave for each backscattering atom (Figure 3, inset). The outgoing and incoming waves can constructively or destructively interfere, perturbing the apparent absorption. The constructive and destructive overlap of waves gives rise to maxima (E_1) and minima (E_2) in the absorption cross-section (μ), hence producing the sinusoidal variations in μ versus individual photon energy value (E) that are known as EXAFS (χ). EXAFS data are converted from X-ray photon energy to photoelectron wave vector (k) values during quantitative analysis, according to equation (1):

$$k = \left[\frac{2m_e(E - E_0)}{\hbar^2}\right]^{1/2} \quad (1)$$

where E_0 is the threshold energy for excitation of the core electron, m_e is the mass of the electron and $\hbar$ is Planck's constant over 2π.

The overall EXAFS of a system can be broken down to the individual wave properties of each resolvable absorber–scatterer (as) interaction. The frequency of each EXAFS wave depends on the distance between the absorber and scatterer. During the forward and backscattering process, the photoelectron wave encounters a phase shift (Coulombic interaction) twice with the absorbing atom (i.e., once going out and once coming back) and once with the scattering atom. The amplitude of each EXAFS wave depends upon the number and backscattering strength of the scattering atom, as well as the bonding mode and distance between the absorber and scatterer. One can describe in k space the total EXAFS (χ_{Total}) for a multicomponent scattering system (equation 2) as the sum of the individual EXAFS ($\chi_i(k)$) observed when the photoelectron interacts with a unique scattering atom before returning to the absorbing atom (equation 3):

$$\chi_{\text{Total}}(k) = \sum_i \chi_i(k) \quad (2)$$

$$\chi_i(k) = \frac{N_s S_0^2 A_s(k)}{k R_{\text{as}}^2} \exp\left(-2k^2\sigma_{\text{as}}^2\right) \times \exp\left(\frac{-2R_{\text{as}}}{\lambda}\right) \cdot \sin(2kR_{\text{as}} + \phi_{\text{as}}(k)) \quad (3)$$

In equation (3), N_s is the number of scattering atoms at the bond distance (R_{as}) from the absorbing atom. The factor $A_s(k)$ is the backscattering strength of the scattering atom and S_0 is a passive electron reduction factor in the interaction. Within the two exponential components, σ_{as}^2 is the mean free deviation in R_{as}, often referred to as the Debye–Waller factor, and λ is the mean-free-path of the photoelectron. Finally, $\phi_{\text{as}}(k)$ is the phase shift the photoelectron wave undergoes when passing through the potentials of the absorbing and the scattering atoms. The Debye–Waller factor accounts for the reduction in scattering intensity due to thermal motion or static disorder of atoms about their equilibrium positions.[1] Data are often collected at low temperatures to reduce the vibrational component of this disorder.

While the amplitude of a scattering interaction can be difficult to accurately determine by EXAFS, the strength of this technique lies in the fact that the frequency components of the EXAFS wave are extremely well defined. Simulating the frequency component in EXAFS can therefore lead to highly accurate measurements in absorber–scatterer bond lengths (R_{as} uncertainty of ± 0.02 Å). Bond length determination is partially complicated by the uncertainty in E_0 for a specific system; however, methodologies for addressing this in a sample-specific manner (outlined in Section 4) increase the accuracy in this measurement. Imprecision in EXAFS amplitude measurements, often resulting from data analysis methodologies and the large number of parameters affecting scattering signal intensity, lead to a generally accepted accuracy in coordination number measurement of ± 0.5 for this technique. The EXAFS phase factor, which is strongly affected by uncertainty in E_0, complicates the specific identification of the scattering ligand, and this leads to a generally accepted accuracy in scattering element to only within the row of the periodic table (e.g., one can directly distinguish between oxygen and sulfur scattering but not between oxygen and nitrogen scattering).

3 APPLICATIONS

Owing to its unique advantages, XAS has been successfully applied in numerous situations to address structure and reactivity related questions regarding a variety of molecules. The deconvolution and characterization of overlapping XANES features has helped provide direct insight into the ligand coordination geometry and redox state of absorbing atoms in many relevant molecules. Since this technique can be applied in the solid, liquid, or gaseous state, XAS has had a selective advantage for structural characterization compared to other techniques. While practical limitations reduce the utility of this technique for only probing local structural environments in molecules, the high accuracy and resolution provided by XAS has been utilized to obtain precise structural details of molecules in their resting or under turnover conditions. Below we list a series of examples in which XAS was successfully applied to answer specific scientific questions. Each example illustrates a different aspect of the technique.

3.1 Coordination Geometry from XANES Pre-Edge Analysis

Analysis of many XANES spectra show sharp pre-edge features immediately prior to the general excitation edge arising from electron excitation to unoccupied low energy orbitals.[2] This region in the XANES spectrum often provides a sensitive probe for the electronic environment and structural geometry of the absorbing atom.[3] A careful, mechanistic, and quantitative evaluation of spectral patterns for these pre-edge transitions has proved useful when determining the coordination number and symmetry of metal centers at active sites in numerous metalloprotein and metal-containing compounds.[4–6]

For the first-row transition metals, this weak pre-edge transition originates from a 1s $\rightarrow$ 3d electron transition, observed for metals with open 3d orbital energy shells (see Figure 2, inset). In centrosymmetric structural environments, this transition is electric dipole forbidden, however electric quadrupolar coupling or mixing of the 4p and 3d orbitals distorts the centrosymmetric environment and provides 1s $\rightarrow$ 4p character, which in turn makes the transition more dipole allowed.[7] The intensity of the pre-edge feature provides a measurement of the metal site symmetry, with intensity increasing by almost two orders of magnitude as one proceeds from a centrosymmetric environment (e.g., octahedral, square planar, etc.) to a non-centrosymmetric environment.[8] An extensive study on the vanadium compounds by Lytle *et al.* in the 80's indicated that integrated intensity ''A'' of the 1s $\rightarrow$ 3d transition varies with the coordination geometry according to equation (4)

$$A \propto \left[\sum C_i R_i^2 \exp\left(-\alpha_i R_i^2\right)\right]^2 \qquad (4)$$

where C_i is the linear combination of atomic orbital (LCAO) coefficients of the final state molecular orbital, R_i is the bond distance and α_i is the orbital exponents of the i^{th} type ligand.[9] In addition, two other factors that provide geometry and spin-state information are: (i) the energy splitting and (ii) the intensity distribution along the pre-edge.[6] These factors have been characterized in great detail for high and low spin inorganic iron (ferrous and ferric) model complexes in various structural symmetries.[4,6] Using ligand field theory, the authors calculated the allowable multielectron excited states and the energies of these excited states were compared to the energy splitting of the 1s $\rightarrow$ 3d pre-edge features for the model compounds. The intensity distribution pattern of the pre-edge feature was also compared with the relative intensity for the transitions; the effect of distortion of symmetry and contribution of the electric dipole and quadrupole mechanisms to the intensity of the pre-edge feature were also analyzed. This detailed study helped establish a general trend for various geometries of iron complexes.[6] An additional piece of information obtained from the quantitative estimation of the intensity of the pre-edge transition is the coordination number. By comparing the area and shape of the pre-edge feature with iron model compounds of varied coordination numbers, the authors were able to estimate the iron-ligand coordination number. This approach was utilized when analyzing nonheme iron active sites where a change in the coordination number is reflected in the intensity of the 1s $\rightarrow$ 3d pre-edge feature, as a result of a change in the symmetry at the metal site.[5] Selective transition energy features between the ferric and ferrous high and low spin systems provided a qualitative measure of the spin-state for iron in these systems.[6,10] Although numerous studies exist, one excellent example for how pre-edge analysis was utilized to characterize structural and electronic properties of protein bound iron was in the published XAS characterization of the hydroxylase of methane monooxygenase.[11]

Additional intense pre-edge features can be observed for other first-row transition metals. In cuprous containing systems, this feature arises from the 1s $\rightarrow$ 4p transition. As with the 1s $\rightarrow$ 3d transition, the intensity of the 1s $\rightarrow$ 4p transition depends on the coordination number and symmetry of the cuprous metal site.[12–14] A weak 1s $\rightarrow$ 3d transition can also be observed for cupric systems. Our laboratory has successfully applied the methodology of quantitating both 1s $\rightarrow$ 3d and the 1s $\rightarrow$ 4p transition areas to elucidate the complex mixed valence copper environment in the multicopper active sites in particulate methane monooxygenase.[15]

For second row transition metals, the corresponding 1s $\rightarrow$ 4d transition requires very high energies. Low monochromator resolution and short core-hole lifetimes hinder the ability to detect this transition in many cases.[8] Other options to obtain information for these metals rely on intensity estimations of the 2p $\rightarrow$ 4d (allowed) transitions at the $L_{(\text{II,III})}$ edges.[8] Another promising approach, mentioned in

Section 3.6, is the use of ligand XANES.[16] Covalency in the interaction of a ligand 3p and metal 3d orbitals, for example, is reflected in the intensity of a pre-edge transition arising due to a ligand 3p hole character, produced as a result of the mixing of orbitals during bond formation.[16] Furthermore, changes in the ligand field and coordination number affect the 3d orbital energies, which, along with the ligand 1s core energy, affect the pre-edge transition energy, providing electronic structural information. Ligand XANES has been successfully used in many studies, particularly for Cl or S ligands.[16]

3.2 Oxidation State of Absorbing Atom from XANES

The dependence of electron excitation edge energies relative to the excited atom's valence state makes XANES a powerful tool for elucidating the average oxidation state in redox active elements. From XANES edge-energy analysis, one can gain a semi-quantitative understanding of the oxidation state of the averaged metal site. General trends show a shift to higher edge energies coupled to an increase in the element's oxidation state, based on the principle that it takes a higher energy to excite core electrons as the valence state of the element increases.[17] XANES can also be used as a tool to monitor changes in oxidation state coupled with substrate/ligand binding and/or catalysis. This principle is illustrated for iron in Figure 2, which showed the K-edge XANES spectra for hydrated iron at two oxidation states. Edge inflection energies for hydrated Fe(II) and Fe(III) occur at about 7123 and 7127 eV, respectively. In addition to oxidation state, ligands bound to the absorbing element also contribute to the general shape of the edge and apparent edge energy for the metal.[18,19] Hence, a robust methodology for characterizing the oxidation state of metal using XANES must include analysis of the edge shape and not just the inflection energy. As a result, relating edge energy to a metal's formal oxidation state is purely empirical.[7] Though it has been successfully used in many cases, unequivocal results are not always obtained from this analysis. This is particularly true in multinuclear complexes where edge shifts due to the oxidation of a single metal may be small and outside the resolution limit of the data. Furthermore, the XANES edge reflects the element's, averaged oxidation state in a multinuclear complex, so clarification of the specific oxidation state of a metal at each site is complicated. A classic example for how these obstacles were overcome in a multinuclear complex can be seen in the XAS studies of the multinuclear Mn center in the oxygen evolving complex (OEC) in photosystem II.

The OEC, along with several other proteins, comprise photosystem II (PSII) the reaction center involved in photosynthetic charge separation. Light energy absorbed from antenna systems (chlorophyll molecules) is initially transferred to the primary electron donor P680. Electrons released from P680 are transferred through an electron transfer chain and bring about the reduction of plastoquinone. Electrons from the OEC re-reduce P680. In the OEC, electrons are generated by a unique photo induced oxidation of water ($2H_2O \xrightarrow{4h\nu} O_2 + 4e + 4H^+$). The electrons are transferred to P680 through a redox active tyrosine residue, protons are ejected into the luminal space, and molecular oxygen is released into the atmosphere. Protons and electrons are ultimately used to convert carbon dioxide to organic molecules that constitute the biosphere and the oxygen released supports most life on earth.[20,21]

A tetranuclear manganese complex, along with two additional but essential inorganic cofactors (Ca^{2+} and Cl^-) form the catalytic center of the OEC.[20] The four-electron driven process of molecular oxygen formation presumably takes place as an independent event, where each photon absorption and charge separation provides a single oxidizing equivalent to the Mn center in the OEC. The intermediate oxidation states of OEC, known as S_n states ($n =$ number of oxidizing equivalents stored), accumulate these oxidizing equivalents and oxidize water only when $n = 4$. These oxidizing equivalents were proposed to be stored on the tetranuclear Mn cluster in the OEC.[21–23] A detailed understanding of the oxidation states of Mn is therefore crucial to gain an understanding of the mechanism of water oxidation as the OEC advances through the S states. Given that XAS can selectively probe each metal type within a complex system, the use of XANES was perfectly suited to help characterize the valence state changes in Mn within the OEC during molecular oxygen production. As a result, multiple groups applied this technique to characterize the Mn center in the OEC, often coupled with additional complementary electronic techniques like EPR. Three factors had to be accounted for in the XANES analysis when estimating changes in the Mn oxidation state during O_2 production. These factors were: (i) the position of the edge inflection energy, (ii) the shape of the edge, and (iii) the comparison of protein data to appropriate inorganic model complexes. A summary of these analyses is provided below.

Mn edge studies in the early 1980's indicated that a shift to higher energy is observed in the K-edge spectrum of the S_2 state relative to the S_1 state.[24] For the $S_0 \rightarrow S_1$ and $S_1 \rightarrow S_2$ transitions in the OEC, a 2.1 eV and 1.1 eV increase in edge inflection energies were observed indicating that Mn is oxidized during these transitions.[22] As previously stated, the method employed to quantify the edge energy affects the oxidation-state estimation to a great extent. Therefore, each of the three different approaches were tested to quantify the edge position to a single energy value. These approaches included: (i) utilizing only the inflection point energy (i.e., edge energy = inflection point energy), (ii) utilizing the edge half-height (i.e., the edge energy = energy corresponding to the normalized absorption (y-axis of XANES) value of 0.5), and (iii) the integral method (i.e., the edge energy = mean energy value of the edge region).[25] In one study, the K-edge energies of various mixtures of Mn(III)O–Mn(IV)O_2 inorganic compounds was determined by all the three methods mentioned above.[25] It was shown that the edge energy

remains constant at the Mn(III) value until the mixing ratio of Mn(III) and Mn(IV) reaches 50%; it then jumps to the Mn(IV) value. Though the additional two approaches showed a comparatively better linear progression, no method was strictly linear. This clearly illustrates that no single method is unambiguously applicable to all systems. Smoothing of XANES spectra is required in most cases, as noise contributions cannot be completely avoided. Hence the method of choice for edge-energy determination must take into account the sensitivity of the approach to extensive smoothing and the experimenter should be cautious when employing only a single method for oxidation-state analysis. This study also highlights the usefulness of calibrating complex protein data with well-characterized inorganic model compound simulations.

Comparisons of the different S states with Mn model XANES spectra was a useful method to help clarify the oxidation state differences that occur during the OEC's calalytic cycle. Mn K-edge spectrum of the OEC in the S_{-1} state, produced by a two-electron reduction from S_1, was best fit with Mn(II_2,IV_2) oxidation states for the four Mn atoms.[26] The second derivative of the S_0 XANES spectrum is again not only different from the S_1 state, but also shows distinct spectral features at 6548 eV, similar to the second derivative XANES spectrum of Mn(II)-containing model compounds. As model complex comparison and other data indicated the presence of Mn(II) in the S_0 state, Mn(II,III,IV_2) was also proposed for the S_0 state.[22,23] Studies on model compounds showed inflection point energy shifts for Mn(II) $\rightarrow$ Mn(III) were greater than those for Mn(III) $\rightarrow$ Mn(IV), indicating that application of this methodology toward characterizing the higher states would be less direct.[22] XANES studies, coupled with other spectroscopic techniques, indicated the possibility of Mn(III_2,IV_2) oxidation states in S_1.[22,27] Mn is oxidized in the transition from S_1 to S_2 in a single electron event, so a global oxidation state of Mn(III,IV_3) would be plausible. The $S_2 \rightarrow S_3$ state transition is more ambiguous and hence controversial, placing it beyond the scope of discussion in this report. Thus XANES studies on the multinuclear Mn center in the OEC show this is a valuable technique for identification of metal oxidation states, even though a final consensus on Mn oxidation states in OEC has not been reached.

3.3 Ligand Identity from EXAFS

Practical limitations discussed earlier reduce the ability of EXAFS to directly determine the identity of scattering atoms between elements within the same row of the periodic table. Ligand scattering from oxygen and nitrogen atoms are nearly indistinguishable in their phase and amplitude, making direct identification impossible. In addition, metal–ligand environments are often constructed by a combination of similar elements, often at nonresolvable bond distances, further complicating their identification. Direct ligand identification is therefore constrained to the row of the periodic table. However, in some cases, even these criteria cannot be achieved. Under cases where the k space for the data is limited, and interference from multiple ligand environments exists,[22] distinguishing a metal–metal interaction from a metal–sulfur interaction can also be complicated. In many cases, it is impossible to determine a unique identification of the ligand environment, so extreme caution should be taken to verify ligand identification without over-interpreting the data. In many cases, having an understanding of the general coordination chemistry for model systems has led to the selective identification of ligand environments within systems with similar ligand types.

An emerging occurrence in metalloproteins is the presence of dinuclear metal centers, with dimetal centers constructed by μ-oxygen bridged ligands anchored to the protein using carboxylate oxygens and imidazole nitrogens from Asp/Glu and His residues, respectively. The short metal–oxygen distance is often (but not always) distinguishable from carboxylate ligation, as illustrated in the oxidized forms of the dinuclear iron proteins hemerythrin and ribonucleotide reductase.[28] Under ideal conditions, identification of the progressive protonation of the oxo-bridge can also be monitored, as illustrated in a series of dinuclear Mn model compounds with unique bridging schemes.[29] In the case of the dinuclear iron protein methane monooxygenase, distinguishing between ligand environments constructed of carboxylate oxygens and imidazole nitrogens was possible, given the generally long Fe–N imidazole bond distance relative to the shorter Fe–O carboxylate ligation in the protein.[30] Correct identification of the independent but similar scattering atoms in these cases was accomplished in part because data were collected over a large k range (hence very high resolution). Ligand identification was additionally confirmed by coupling XAS studies with additional complementary techniques like Mössbauer and ESEEM.

3.4 Multiple Scattering

Further clarification between nearest-neighbor oxygen and nitrogen scattering can be obtained when a subset of these atoms are structurally restricted within a rigid ligand cage. Nitrogen atoms, constrained in an imidazole ring or as part of a porphyrin ring, often serve as direct ligands to metals. Unlike normal single scattering signals (i.e., absorber $\rightarrow$ scatterer 1 $\rightarrow$ absorber) generally observed for nearest-neighbor ligands, scattering from rigid ligand cages is much more complex and generally involves multiple scattering events. In this case, EXAFS oscillations from a multiple scattering pathway (i.e., absorber $\rightarrow$ scatterer 1 $\rightarrow$ scatterer 2 $\rightarrow$ absorber) can be as much as an order of magnitude more intense than single scattering. Overlap of multiple scattering pathway signals often results in a distinct fingerprint of a group of resolvable signals in the overall EXAFS, especially in the case of metals bound to imidazoles or porphyrin rings.[31] These linked scattering signals can often be directly simulated

for the entire rigid ligand unit, and upon removing this scattering contribution, it is often possible to deconvolute scattering signals from additional similar atoms. As an example, in biological samples, EXAFS scattering from water oxygens and imidazole nitrogens are virtually identical, as they occur at similar bond lengths, and phase differences between O and N are minimal. Classic examples where a multiple scattering deconvolution methodology was successfully applied to isolate metal–histidine imidazole ligation were in characterizing the Ni site structure of urease[32] and in Cu site structure of the peptidylglycine alpha-amidating enzyme.[33]

Multiple scattering will also significantly enhance observable metal···metal scattering in systems that contain structurally rigid multinuclear metal centers that are indirectly coordinated. As discussed previously, two metals constrained in dinuclear metal compounds are often structurally linked by bridging atoms (often μ-oxo, μ-hydroxo or carboxylato bridging ligands); in the case of iron–sulfur clusters, the two iron are linked by bridging sulfur atoms. A general property of EXAFS multiple scattering is that it is extremely angle dependent. When scattering angles between the absorber $\rightarrow$ scatterer 1 $\rightarrow$ scatterer 2 atoms are less than 150°, multiple scattering is generally weak and can be neglected. In this scenario, if the absorber and scatterer atoms are the two metals in a dinuclear metal complex, direct simulation of the metal···metal interaction using a single scattering approximation would provide accurate structural characteristics of the molecule. If the multiple scattering angle is between 150° and 180°, multiple scattering interactions are more prevalent, and a consequence of direct simulation of the dinuclear center using single scattering models would result in distorted metal···metal bond lengths and coordination numbers. Hence multiple scattering modeling in this system would be required for an accurate fit. Although there are many, one example where multiple scattering was required to simulate a metal···metal interaction in a dinuclear protein is in the iron center of the hydroxylase of methane monooxygenase.[11]

3.5 Mixed Metal Compound

In cases where molecules contain multinuclear metal centers, XAS can be used to probe the unique structural and oxidation-state properties of each site independently. These conditions were successfully achieved in characterizing Cu/Zn superoxide dismutase, although the close proximity of the Zn excitation energy to the Cu edge limited the ability to extend the copper data to high resolution (Cu and Zn K-edge excitation energies occur at 8980 and 9659 eV, respectively). The Zn K-excitation edge limits the resolution of the copper data by introducing a severe distortion in the Cu EXAFS at k of ca. 13 Å^{-1}. Practical use of the Cu EXAFS was therefore limited to a k limit below 13 Å^{-1}. As zinc is a ubiquitous metal found in numerous metal amalgams, very low-level Zn contamination is often an issue when collecting Cu EXAFS. In spite of these difficulties, the identification of the Cu/Zn center in bovine superoxide dismutase proved to be somewhat straightforward.[34,35] XAS studies aided in the identification of Cu and Zn ligands, the exact coordination number of each, and the symmetry of the metal center. Additional X-ray crystallographic studies combined with a series of spectroscopic techniques (EPR, ENDOR, NMR *see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Metallobiomolecules***) helped confirm the identity of the exact coordination environment of the copper atom.[36,37] The identity and position of the zinc atom was further identified on the basis of X-ray structure of heavy metal replaced protein (i.e., Hg for Zn).[38] The nearest-neighbor environment (i.e., presence of histidine and oxygen ligations for both atoms) were identified from the high resolution X-ray structure (*see* ***Electron Paramagnetic Resonance (EPR) Spectroscopy*** and ***Electron-Nuclear Double Resonance (ENDOR) Spectroscopy***).[36]

3.6 Sulfur XAS

Although complicated in experimental setup, sulfur XAS is emerging as a powerful tool for characterizing oxidation state and structure of sulfur atoms in molecules. Sulfur is often a ligand to a metal, so these analyzes provide a complementary analysis to metal–ligand XAS in an appropriate system. Experimental hardware requirements include a low energy monochromator and a beamline path entirely under vacuum to reduce absorption of soft X rays from the air. Distinct differences in the shape and first inflection energies for multiple reduced and oxidized sulfur compounds proved early on that sulfur K-edge can be used to identify the oxidation state and structural environment of sulfur in molecules.[39,40] Sulfur K-edge EXAFS has also been used to elucidate the structure and ligand coordination in numerous model compounds and metalloprotein active sites, especially regarding metal–thiolate interactions from the viewpoint of the thiol.[41]

3.7 Heavy Metal Site Structure

Although core electron binding energies for K-edge transitions occur at energies up to 115 606 eV (uranium), hardware limitations reduce the range of achievable high-energy values for XAS studies. Many XAS experimental stations have hardware with upper energy limits of roughly 40 000 eV. In addition, insertion devices used to increase the spectral brightness of the beamlines, often decay dramatically at intensities above 50 000 eV, further restricting the achievable K-edge excitation range to elements within the second row of the transition elements in the periodic table. However, L-edge excitation energies for the third row transition elements and higher are within the achievable range for current hardware; these edges yield strong signals and as a result have been utilized in several studies to characterize heavy elements (i.e., Hg, Pb, Gd, etc.).[42–44] A good example of one such study includes the mercury-binding

metalloregulatory protein MerR.[45,46] L-edge XAS studies provided evidence for a novel tridentate Hg-cysteine receptor complex at the protein's active site that helped address the protein's selectivity for mercury over the other metals of group IIB, since Hg prefers tetrahedral cysteine coordination.[46]

In addition to providing direct structural information at the metal, XAS can be used to derive anomalous scattering parameters during structure determination by multiwavelength anomalous diffraction (MAD) for heavy element systems. Anomalous scattering is a manifestation of the X-ray diffraction in specific electron resonant frequencies. As incident photon energies approach an L-absorption edge, electrons bound in atomic orbitals exhibit resonant frequencies corresponding to dipole allowed transitions. Anomalous scattering breaks down the equation for X-ray diffraction as follows:

$$\boldsymbol{F} = \mathbf{F}_p + \mathbf{f}_h + f' + f'' \tag{5}$$

where $\boldsymbol{F}$ = total scattering vector, $\mathbf{F}_p$ = sum of scattering from light atoms, $\mathbf{f}_h$ = normal scattering from heavy atom, f' = real component of anomalous scattering, and f'' = imaginary component of anomalous scattering. Components $\mathbf{F}_p$ and f_h remain constant while f' and f'' change, as the X-ray radiation scans across a heavy atom's absorption edge. MAD takes advantage of these differences in scattering across the absorption edge. The imaginary component of anomalous scattering is a source of phase information in macromolecular crystallography and is proportional to the atomic absorption coefficient. Anomalous dispersion factors are sensitive to the chemical environment of an atom and can be extracted from the oscillations of an XAS spectrum. The MAD signal can therefore be estimated from these dispersion factors.[47]

A specific case where XAS was utilized to determine anomalous scattering factors from a MAD signal was in the structural characterization of guanosine monophosphate synthetase (GMPS).[48] GMPS belongs to a family of glutamine amido-transferases and catalyzes the final step of the *de novo* guanine nucleotide biosynthesis. GMPS uses ATP to catalyze the amination of xanthosine-5′-ribonucleotide. Free thiol groups of GMPS cysteine residues were labeled with mercury. X-ray absorption data were measured as fluorescence excitation through the L_{III} edge of mercury at 12 284 eV (the K-edge occurs at over 83 000 eV). The L_{III} energy made this experiment feasible using synchrotron radiation; furthermore L-edge anomalous scattering is stronger, making it applicable for large protein structures. In the case of GMPS, an average spectrum was constructed from fluorescence spectra and after subtracting the background, the experimental spectrum was fit to the theoretical absorption spectrum of mercury. As mentioned earlier, the imaginary component (f″) is directly proportional to the atomic absorption coefficient and Kramers-Kronig transformation was applied to the hybrid f″ spectrum to get the real component f′ of the anomalous scattering factors. Structure determinations are more direct and rapid in this way as compared to isomorphous replacement, where data are collected from multiple heavy atom derivatives.

3.8 XAS Applied with Additional Structural Techniques

Although structural details provided by XAS are localized to a narrow region of a molecule (ca. <5 Å from the absorbing atom) with limited information regarding metal–ligand geometry, the high accuracy in bond lengths obtained can be used to construct an overall 3D structure of a molecule in combination with other structural techniques. This is especially true in cases for which the metal is generally considered to be spectroscopically silent (e.g., Zn). In the case of GMPS,[48] metal–ligand bond lengths obtained from XAS provided extremely high resolution structural detail of the mercury–sulfur center in the crystal. During NMR structural characterization, when an active site contains an element with a non spin-active nucleus, XAS bond lengths can be utilized to provide the structural constraints in this local region of the molecule.[49] The paramagnetic behavior of many metals often complicates the identification and structural characterization of even commonly detectable spin-active nuclei surrounding the metal (at ca. <10 Å), due to significant line broadening effects. XAS can be used to significantly enhance the structural detail of a molecule's solution structure by providing metrical details of the metal site. This was true in the example of the ubiquitin binding motif protein Npl4 zinc finger (NZF). Zinc–sulfur bond lengths determined by XAS for the Zinc–$(Cys)_4$ zinc finger site provided interatomic distance constraints for solving the solution structure of this protein domain.[50]

3.9 Structural Changes Coupled to Molecular Reactivity

Metalloproteins exploit the redox and coordination chemical properties of metals to catalyze reactions. With bond-length resolution capabilities of ± 0.02 Å,[51] XAS is ideal for monitoring subtle changes at metal centers during catalysis. Interrogating the oxidation state and coordination environment of active site metals using XAS can provide a mechanistic picture of the system being studied. An excellent example of this was in the characterization of nickel containing superoxide dismutase (SOD). SODs are widely distributed in prokaryotic and eukaryotic cells[52] and catalyze the breakdown of superoxide. These proteins contain metal ions at their catalytic centers which are usually constructed of Mn, Fe, Ni, Cu, and/or Zn metals.[53] In many cases, the active site metal is maintained in the oxidized form during the enzyme's resting state. The metal binds superoxide and, following a subsequent proton transfer event, molecular oxygen is released leaving the metal in the reduced state. This reduced form of the enzyme will bind a second superoxide anion and a proton to release peroxide, hence returning back to its resting state (i.e., the oxidized form).

Ni-SODs are a novel group of SODs in that they share a much lower sequence homology to other metal-containing SODs, even though they have similar catalytic rates.[53] In order to elucidate the mechanism of this enzyme, the nickel site was examined using XAS. Ni K-edge XAS data were

collected on the as-isolated and dithionite-reduced enzyme.[54] XANES data indicated the metal–ligand site changes from a four-/five-coordinate square-pyramidal environment to a planar environment as the metal goes from an oxidized Ni(III) to a reduced Ni(II) state.[54] Subsequent crystallographic studies confirmed this structural change.[55] EXAFS analysis suggested a unique five-coordinate site with three sulfur donors, one nitrogen donor, and one O/N-donor in the oxidized state. Sulfur ligation was unexpected due to its susceptibility to oxidant dependent modification and the fact that none of the other previously studied SODs had sulfur ligation. Recent additional studies, using complementary techniques, have further expanded the understanding of the structure and mechanism of NiSOD.[55]

3.10 Time-resolved X-ray Absorption Spectroscopy

The ability to collect electronic snapshots on subsecond timescales is a currently expanding branch of XAS being used to probe dynamic chemical systems. XAS studies covering timescales in the millisecond to seconds range are becoming routine.[56] Time-resolved XAS is currently being applied for elucidating ‘‘in situ’’ the chemistry of dynamic systems and the structural characterization of reaction intermediates. Application of this technique to metalloproteins is still in early stages, although it has been successfully applied to study slower reactions.[8,56,57] Several approaches to utilizing XAS to address time resolution studies include the following techniques: quick-extended X-ray absorption fine structure (QEXAFS), dispersive-energy extended X-ray absorption fine structure (DE-EXAFS), turbo-EXAFS, piezo-XAFS, and laser-initiated time-resolved XAS.[56,58,59] In general, these techniques have been developed but are surprisingly under-utilized, a fact that will certainly change as exposure to these techniques becomes more publicized.

QEXAFS samples a single energy at a time and hence retains the point-by-point mode of data acquisition; however, a double crystal monochromator utilizes a high-geared stepper motor with encoder that continuously moves to complete an entire scan in a matter of seconds.[56] The time resolution is generally in the range of about 30–60 s. This approach has been predominantly utilized to study catalysis, solid and liquid phase chemistry, and surface-mediated electrochemical processes.[56] A good example of a homogenous liquid phase system where QEXAFS was used to obtain quantitative kinetic data of halogen exchange in 2-bromopropane with sodium iodide.[60] Using highly concentrated samples, accurate kinetic data were derived from the structural data obtained in these studies.[60] The QEXAFS approach can yield high quality data often in all modes of detection (transmission, fluorescence, etc), however, this technique does have temporal limitations.[56] DE-EXAFS on the other hand uses dispersive geometry and focuses a polychromatic X-ray beam on the sample using a curved crystal, which allows for sub-millisecond time resolution as the effective time for single point accumulation.[8,56] Detection is only possible in the transmission mode, thus limiting the applicability of the technique to highly concentrated samples.[56] Turbo-EXAFS is a hybrid approach that retains the positive features of Q- and DE-EXAFS. Sequential energy scanning is made available by incorporating a slit that scans across the wide spectral energy range provided by a dispersive monochromator. Hence, all modes of detection are possible and good quality data can be collected.[56,61] Piezo-XAFS makes use of piezo tilt tables mounted below crystals that provide for fast XANES data collection, where a large eV range can be scanned with repetition frequencies of 10 Hz; in this case, EXAFS data can be collected in the millisecond time scale.[58] Laser-initiated time-resolved XAS uses a laser pulse to initiate a physical or chemical process, while X-ray pulses probe the structural response.[59] All the above-mentioned techniques have been successfully applied, mostly in the areas of materials science, and detailed reviews for each technique are available.[56,58,59]

In addition to applications in materials sciences and catalysis, time-resolved XAS is making steady inroads into metalloprotein research. The potential of time-resolved XAS for characterizing changes occurring at catalytic sites in metalloenzymes, especially for generally spectroscopically silent metals like zinc, is bright.[8] In one such laudable study, the evolution of catalytic intermediate states during enzyme turnover were characterized for the zinc metalloenzyme alcohol dehydrogenase.[62] Alcohol dehydrogenase, from *Thermoanerobacter brockii*, catalyzes the conversion of secondary alcohol to a corresponding ketone using nicotinamide adenine dinucleotide phosphate ($NADP^+$) as a cofactor.[62] Two mechanisms were proposed for catalysis at the zinc site based on numerous previous studies. In one mechanism, the zinc-bound water plays a catalytic role by serving as a transient proton transfer site. In this case, zinc coordination changes from four to five upon substrate binding. According to the other mechanism, water is displaced upon substrate binding and hence coordination of zinc would not change. Enzyme–substrate complexes were rapidly frozen using isopentane at different intervals of time ranging from ~2 ms to 110 ms following mixing. Using high intensity single-wavelength beam, they observed two pentacoordinate intermediate states in the first 70 ms, one of which had a very short lifetime, supporting the mechanism in which water plays a catalytic role.[57,62]

3.11 Surface Electronic Structure

With the emergence of the new generation synchrotrons and the extremely high flux they provide, new techniques that utilize X rays for structural studies are just beginning to flourish. One such technique, resonant inelastic X-ray scattering (RIXS), can utilize either soft or hard X rays to investigate low energy electronic and magnetic excitations in metal-containing compounds.[63] In the soft X-ray regime, this technique often operates at the L_{II} and L_{III} absorption edges for 3d transition metals in compounds, as these resonant

excitation and de-excitation events allow one to measure the energy of excited states that are unreachable by direct electric dipole transitions. In the hard X-ray regime, this technique can be applied to the K-absorption edge of elements. RIXS has been used to study the momentum dependence of various electronic excitations in strongly correlated electron systems. This technique shares the chemical specificity and sensitivity of X-ray absorption spectroscopy although it requires an extremely high-flux beam.

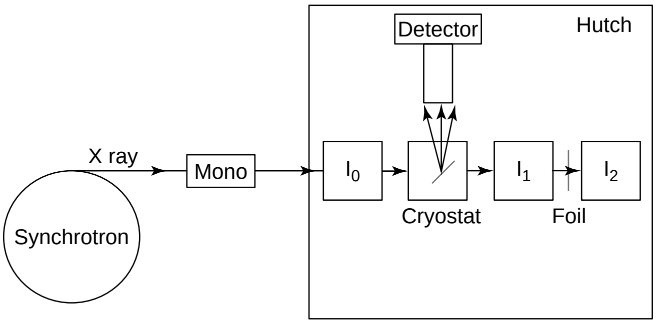

Figure 4 Schematic of an XAS beamline. Cryostat is placed between I_0 and I_1 ionization detectors to allow for absorption measurements. In the cryostat, samples can be place at a variety of angles to allow for absorption or fluorescence measurements. A fluorescence detector is placed tangential to the X-ray path. A metal foil is placed between I_1 and I_2 for energy calibration

4 REFERENCE MATERIAL

4.1 Data Collection and Analysis

The availability of experimental stations at many major synchrotrons provides an opportunity for users to apply XAS to study more sophisticated problems. The knowledge and experience in the field accumulated over the past approximately 40 years has resulted in well-developed methodologies and technical resources geared for obtaining optimal XAS data at these sites in very little time. Today, more than 65 radiation facilities around the world utilize electron beams at energies up to 7 GeV, and these can provide a large range of both soft (<2000 eV) and hard (>2000 eV) X rays. Radiation facilities continue to be upgraded and grow as the demand for beam brilliance and experimenter time rises. The general design of XAS experimental stations (or beamlines) has, however, remained fairly constant.

4.1.1 Generation, Storage and Delivery of High Intensity X Rays

The schematics of the different synchrotrons may be different, but the components are usually the same. The general schematic of an XAS beamline from the storage ring into the hutch is shown in Figure 4. A heated cathode emits electrons and these electrons are often accelerated in the direction of the storage ring utilizing a linear accelerator. Booster rings further contribute to the acceleration and focusing of the electrons; however, these electrons are eventually dumped into the storage ring (the synchrotron). X rays are drawn tangentially from the synchrotron electron path at beamline stations to allow for the attainment of extremely high intensity X rays. X rays, depending on the demands of the different beamlines, are further collimated and focused through a series of slits, mirrors, and monochromators until they enter the corresponding experimental stations (hutches). Mirrors are often placed before or after the monochromator to focus the X-ray beam or to reject monochromator harmonics. Mono or multicrystal monochromators are used to sort the energy of the incoming X rays. Slits are used to adjust beam size and provide energy resolution. In the physical experimental station (usually a Pb-lined hutch), the exposed beam travels first through a series of slits to define the final beam size. The beam then proceeds through an ionization detector (I_0), which measures the intensity of the incident X-ray beam. Immediately downstream of I_0 is the sample cryostat. The cryostat is usually under constant liquid helium flow to ensure low temperature; lower temperatures reduce thermal disorder and help prevent sample degradation. Two additional ionization detectors are placed in series downstream of the cryostat, the first (I_1) can be used to measure absorption spectra of the sample, when coupled with the signal in I_0, or when a metal foil is placed between I_1 and I_2, to provide a standardized internal reference spectrum. Fluorescence spectra can be obtained by placing a fluorescence detector perpendicular in position to the beam path, but directly adjacent to the cryostat. Fluorescence detectors range from simple photomultiplier tubes, to fluorescent ion chamber detectors like those designed by Dr. Farrell W. Lytle, to complex multielement Ge detectors. When using fluorescence detectors, samples are positioned such that the angle of incidence and exit are 45° to minimize elastic scattering into the detector and maximize fluorescent signals.

4.1.2 Applications to Obtain Access to the Radiation Laboratories

Requesting time at the different synchrotrons requires careful planning and thorough implementation. A comprehensive list of the different XAS beamlines available in the U.S. and Europe is included on the following website: http://www.df.unibo.it/iucr/beamlines.htm. In the case of most national laboratories, applications can be submitted twice a year and require three to six months of processing before time is allotted. Proposals are scored using a peer review panel and time allocation depends on the relevance and score of proposed projects. Hardware and energy capabilities of

each beamline are unique, and since proposals request time on specific beamlines, one should confirm the capabilities of the requested beamline match one's desired need. Training courses are available (Section 4.2.2).

4.1.3 Sample Preparation

As with all techniques, proper sample preparation is essential for collecting high quality data. XAS samples can be prepared in solid, liquid, or gaseous form. Signals are the average of all forms of the excited element present, so special care should be taken to remove adventitious forms of the element under investigation. For optimal data collection, samples should be between 0.5 and 1 mM in metal concentration, often prepared with about 30% (v/v) glycerol as a glassing agent. Sample cells are typically constructed from metal free material (i.e., Lucite) and wrapped with a transparent tape (i.e., Kapton, Mylar tape). The size of the sample cell is specific to the sample holder in the beamline cryostat. Small molecule samples are often collected in transmission/absorption mode utilizing a rectangular sample cell with a rectangular hole bored in the middle similar to the Lucite holder in Figure 5(a). Solid inorganic samples are also often diluted with inert boron nitride to ensure that sufficient photon flux travels through the sample so that a reference spectrum can also be collected. Solution sample cells are also often rectangular with a long bore in the face that resembles a trough. A solution sample cell (shown in the Figure 5(b)) made of Lucite, has a hole drilled in one side for sample injection and has an active volume of around 80 μL. This cell was designed with no top for easy cleaning and to allow almost direct access of the incident beam to the sample, so it must be wrapped with tape to prevent sample loss, should thawing occur. Liquid sample cells are immediately frozen in liquid nitrogen or an isopentane (2-methylbutane)–liquid nitrogen mixture. Given the variability of sample holders for different cryostats at each beamline, the reader is suggested that as much information as possible be gathered about the beamline setup, before the samples are prepared.

4.1.4 Data Reduction and Analysis

Programs for XAS data reduction, analysis and presentation are plentiful and available on all computer platforms. Software packages Athena/Artemis, EXAFSPAK and numerous others are well documented and guide experimenters through the process of data reduction and simulation. A summary of these programs and where they can be located is given in Section 4.2. Data processing and reduction proceeds along the following strategy: calibrating spectral energies and averaging blocks of spectra, fitting and subtracting a background from the pre-edge region of the averaged file, fitting and subtracting a spline from the EXAFS region of the averaged spectrum, converting the χ data from energy to k space, and calculating a Fourier transform (FT) for visualization. Spectral energy calibration links the inflection edge of the internal reference foil to a standard edge foil energy value for each element. Pre-edge fitting assures removal of any background noise. Removal of the low frequency components in the EXAFS involves fitting a spline function such that the EXAFS itself won't be removed. EXAFS is converted from energy to k space using equation (1), and k^3 weighted to enhance the high k components, allowing for better FT visualization. A Fourier transform is often applied to the EXAFS data to provide a radial distribution function of the ligand environments surrounding the absorbing atom for easy visualization of the different ligand environments.

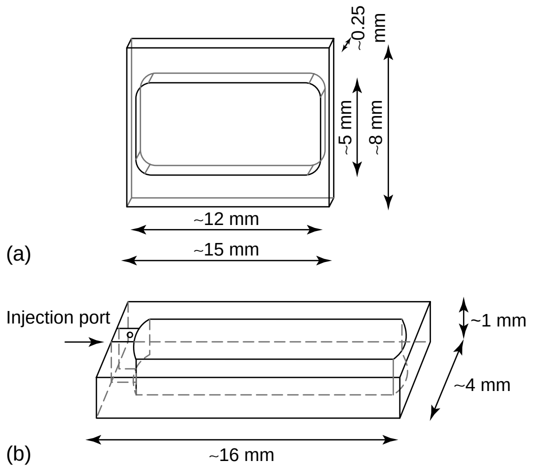

Figure 5 Common dimensions and design of transmission (a) and fluorescence (b) XAS sample cells

4.1.5 Data Simulations

EXAFS simulations can provide accurate structural parameters (N_s, σ_{as}, and R_{as}) for the metal–ligand system under investigation, assuming proper measures have been taken to calibrate the parameters that define the scattering in equation (3) ($A_s(k)$, S_0^2, $\phi_{as}(k)$, and $\lambda(k)$). Calibration of these parameters is greatly assisted by supplementation from data collected on crystallographically characterized model compounds; calibrated spectra from model compounds can therefore be used to simulate EXAFS for uncharacterized systems. However, advances in theoretical methods for quickly and accurately calculating these structural parameters have improved dramatically in recent years, thus providing a second, and currently the standard, approach for simulating EXAFS for uncharacterized systems. Ab initio calculations that provide the structural parameters required for accurately simulating EXAFS data typically come from three main programs, each involving different approaches: FEFF, EXCURVE, and GNXAS. Regardless of the theoretical approach, it is extremely beneficial to still calibrate

theoretical parameters by first fitting data for well-defined crystallographically characterized model compounds.

Current data analysis protocols consist of fitting experimental data according to equations (2) and (3) using theoretical amplitude and phase functions for different atoms and appropriately calibrated values for S_0^2 and often E_0. The simulation procedure involves performing a nonlinear least-square fit in which (a subset of) typically three parameters N_s, $\sigma_{as,}$ and R_{as} (and in some cases, E_0) are varied. While general approaches involve simulating the global EXAFS data, it is often useful to apply the Fourier transform to the data and filter the EXAFS for a specific ligand environment by back-transforming the data within selected bond-length regions in the Fourier transform spectrum. Fourier transforms are however often misleading, given the prevalence of destructive scattering between nonresolvable ligand environments and complications due to nonlinear, multiple scattering systems; so, when published, data should only include fit results from simulating raw data.

Fitting strategies vary from laboratory to laboratory; however, a general standard approach involves initially simulating the scattering from atoms directly coordinated to the absorbing atom (i.e., the nearest-neighbor environment). Although typical coordination complexes can have numerous independent nearest-neighbor atoms, these atoms are often similar in nature (same row in the periodic table) and in absorber–scatterer bond distance. Spectral resolution (ΔR) is a direct consequence of the energy range for which the data are collected (equation 6).[7,8]

$$\Delta R = \frac{\pi}{2\Delta k}; \quad (\Delta k \text{ is the } k \text{ range of the data used during the simulation}) \qquad (6)$$

For example, if fitting data between $k = 2–12\,\text{Å}^{-1}$, $\Delta R \approx 0.15\,\text{Å}$. So in many cases, it is often impossible to distinguish between scattering from atoms within this local environment. Therefore, initial simulations involve fitting all nearest-neighbor ligands as a single environment shell at approximately the same distance to obtain an averaged coordination number and bond length for this environment. Given the phase differences between ligand atom types within the different rows of the periodic table, is it usually very straightforward to distinguish between an average ligand environment constructed predominantly of oxygen versus sulfur atoms, and this should be taken into account during the simulation. Additional fitting shells are then progressively added to the simulation to account for resolvable independent ligand environments. Each simulation is scored by a ‘‘goodness of fit’’ parameter that measures the mean-square deviation between empirical and theoretical data. Since data are available over a finite k range, and since there is always inherent noise in the data, especially at high k, it is often difficult to distinguish if there is a general improvement in the quality of the fit upon adding additional ligand shells. This is especially true because there will be an inherent direct improvement in the fit in any case, on account of additional variables being added in the simulation. It is therefore useful to measure the fit quality using a reduced chi-squared statistic (ξ^2) that weights the quality of the fit relative to the number of degrees of freedom in the data, as outlined in equation (7).[28]

$$\xi^2 = \frac{(N_{idp}/\nu)\sum_{i=1}^{N}(\chi_{\text{obs}}(k_i) - \chi_{\text{calc}}(k_1))^2/\varepsilon_i^2}{N} \qquad (7)$$

In equation (7), ν is the number of degrees of freedom calculated according to equation (8), using N_{idp} as the number of independent data points and N_{var} as the number of refined variables.

$$\nu = N_{idp} - N_{\text{var}} \qquad (8)$$

The sum in equation (7) is calculated over all measured data points, N, and the deviation at each point is weighted by $1/\varepsilon_i^2$, where ε_i is the root-mean-square uncertainty in the observed EXAFS (χ_{obs}). The $1/\nu$ weighting introduces a penalty for adding additional, unnecessary, scattering shells. A complete description of ξ^2 and how it is applied can be found elsewhere.[8] By building upon the progressive addition of independent but justifiably included ligand shells, keeping in mind the resolution limit of the data, one can develop a detailed description of the average ligand environments surrounding the scattering atom out to a generally reliable radius of 5 Å. Results from EXAFS simulations can be presented during publication with a table of fitting results, and with the corresponding raw and simulated k^3-weighted EXAFS and their corresponding Fourier transforms.

4.2 Resource Material

Prospective XAS users have numerous excellent resources available that provide a more detailed description of the technique and which will assist them in their training. There is a wealth of information available through books, websites, and summer courses, some of which are described below. In addition, each beamline has support staff that can provide specific information regarding the beamline and regarding the technique in general. It is beneficial to have a good understanding of the physics driving the technique, and to gain experience preparing samples, collecting data, and operating one of the multiple analysis and simulation programs under the direction of a trained user or at a hands-on workshop. The following text directs potential users to this information.

4.2.1 Description of the Technique

New XAS users will likely want to gain an advanced understanding of the physics behind the technique. Numerous excellent books and reviews are available.[64–68]

In addition, multiple web pages are available that compile extremely valuable information. A few are:

- http://xafs.org/ (XAFS Organization)
- http://www.i-x-s.org/ (International XAFS Society)

4.2.2 Training Courses Offered

Many synchrotrons offer XAS training courses. These are typically summer workshops that train students in the theoretical and practical use of the technique. Information regarding these can be gained at the following web pages:

- http://lightsources.org/cms/?pid=1000510
- http://xafs.org/Workshops
- http://smb.slac.stanford.edu/public/news/summer_school/

4.2.3 Data Collection/Analysis Protocols and Analysis Software

Numerous reviews are available that provide a detailed description of data collection/analysis protocols.[8,69]

Data analysis software packages are available on all platforms. The two most widely used are Artemis/Athena and EXAFSPAK. Both software packages were written to utilize the theoretical code FEFF. Excellent manuals are available for both, significantly helping shorten the learning curve. Artemis/Athena were developed by Dr. M. Newville and Dr. B. Ravel (2005). EXAFSPAK was developed by G. George (2001). These programs can be found at:

- http://cars9.uchicago.edu/∼ravel/software/ (Artemis/Athena)
- http://www-ssrl.slac.stanford.edu/∼george/exafspak/exafs.htm (EXAFSPAK)

5 ABBREVIATIONS AND ACRONYMS

DE-EXAFS = dispersive-energy extended X-ray absorption fine structure; EPR = electron paramagnetic resonance; EXAFS = extended X-Ray absorption fine structure; FT = Fourier transform; GMPS = guanosine monophosphate synthetase; ICP-MS = inductively coupled plasma-mass spectroscopy; LCAO = linear combination of atomic orbital; NEXAFS = near edge X-Ray absorption fine structure; NMR = nuclear magnetic resonance; NZF = Npl4 zinc finger; OEC = oxygen evolving complex; PSII = photosystem II; QEXAFS = quick-extended X-ray absorption fine structure; RIXS = resonant inelastic X-ray scattering; SOD = superoxide dismutase; XAS = X-Ray absorption spectroscopy; XAFS = X-Ray absorption fine structure; XANES = X-Ray absorption near edge structure.

METHOD SUMMARY

Acronyms, Synonyms

- X-Ray Diffraction (XRD)
- Powder X-Ray diffraction (PXRD)
- X-Ray Powder Diffraction (XRPD) pattern.

Measured physical quantities

- angular values of XRD peaks
- X-ray peak profiles
- intensities as areas under peak profiles
- X-ray peak heights.

Information available

- identification of crystalline phases from the X-ray peak angular positions and intensities
- unit cell dimensions from peak angular positions
- density of crystals if formula is known
- quantitative analysis of phase mixtures
- crystallite size from peak broadening
- lattice strain
- type of solid solution
- coefficients of thermal expansion
- crystal structure as positions of atoms within the unit cell, bond distances and bond angles.

Information not available, limitations

- elemental analysis
- limited information from poorly crystalline materials
- PO may limit information obtainable from X-ray pattern
- complex structures may prove difficult to solve by powder methods.

Examples of questions that can be answered

- Is this a crystalline substance?
- What compound is this?
- Is this a mixture of compounds?
- What are the compounds in this mixture?
- How much of each compound is in this mixture?
- Is this polymer crystalline?
- Is this polymer isotactic or syndiotactic?
- Will this compound change structure upon heating?
- Does this material have a large, small or zero coefficient of thermal expansion?
- Does this metal or ceramic suffer from strain?
- Does this catalyst contain small crystallites?
- What is the structure of this compound?
- Have we synthesized the right crystalline phase of this compound?

Major advantages

- nondestructive technique—sample can be recovered
- small samples may be used
- large databases available for phase identification.

Major disadvantages

- The method yields very limited information from amorphous or poorly crystalline materials.

Sample constraints

- The samples must be finely ground and packed properly in holder.
- Some samples may be air sensitive and require encapsulation in argon or nitrogen.
- Layered compounds may suffer from PO.

Related techniques

- X-ray crystallography
- Neutron diffraction.

1 INTRODUCTION

The term Powder X-ray Diffraction (PXRD),[1] as the name implies, is a diffraction pattern obtained by the interaction of X-rays (usually monochromatic) from a collection of crystallites (powder), which are statistically oriented in all possible crystallographic directions satisfying the Bragg condition:

$$n\lambda = 2d\sin\theta \quad (1)$$

The sample usually is in the form of finely divided polycrystalline powder, but depending on the nature of the application, the sample also can be a thin film or bulk material.

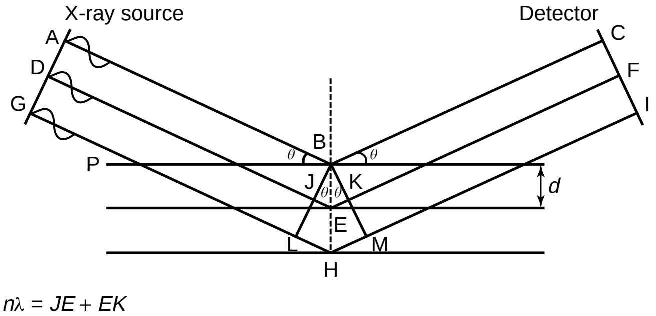
1.1 Brief History

XRD was first observed by Max von Laue in 1912. Von Laue, in a discussion with Paul Ewald, a Ph.D. candidate in physics, concerning the interaction of light with crystals, realized that if X-ray wavelengths were of the order of the distances between atoms in the crystal, then diffraction should occur. The effect is similar to that of a ruled grating where light passing through the slits in the grating forms a series of bright and dark lines. The separation of the lines depends upon the wavelength (λ) of the radiation and the spacing (d) between the slits. If two slits are placed at right angles to each other, the pattern takes the form of a spot pattern. The distances between the spots are now two-dimensional and reflect the

distances between the ruled lines on both diffraction gratings. Crystals are three-dimensional in nature and therefore behave as a three-dimensional grating.

X-rays were discovered by Wilhelm Conrad Röntgen in 1895. He observed a green glow on the glass envelope of a cathode ray tube, which he surmised, darkened the film enclosed in its protective wrapping. Subsequently, Röntgen showed that a hand placed in front of the film in a darkened room produced a picture of the bone structure of the hand. He understood that the X-rays must be very penetrating and therefore possess small wavelengths. However, there was no way to measure these wavelengths until von Laue's discovery.

In 1914 the father and son team, William Henry Bragg and William Laurence Bragg, simplified the three-dimensional theory of diffraction developed by von Laue, by considering the diffracted radiation as being reflected by sets of parallel planes of atoms. The condition for diffraction from a set of parallel planes of interlayer spacing d is described by equation (1), where θ is the angle of incidence of the X-rays to the planes and λ is the X-ray wavelength (Figure 1). When the wavelets of the X-ray beam leave the source all the wavelets are in phase. As the wavelets enter the crystal, they travel longer distances than the wavelet reflected from the surface. These distances are dependent on the interlayer spacing, d. The wavelets are in phase at the line BJL drawn parallel to ADG (Figure 1). The pathlength difference between the wavelets ABC and DEF is JE + EK and for the wavelet GHI, LH + HM. The condition for diffraction is that the wavelets be in phase at BKM. This requires that the distance JE + EK = nλ, that is, the path difference is an integral number of wavelengths. If JE + EK = λ, then LH + HM = 2λ, etc. and all the layers in the stack scatter in phase and intensity of diffracted photons is recorded by the detector. If the wavelets are slightly out of phase, destructive interference occurs because there are hundreds of layers with the out of phaseness increasing by degrees.



$$n\lambda = JE + EK$$

$$\sin\theta = \frac{JE}{BE} = \frac{EK}{BE}$$

$$BE = d$$

$$2\sin\theta = \frac{JE + EK}{d}$$

$$n\lambda = 2d\sin\theta$$

d = distance between planes, waves are in phase at BJL ($\parallel ADG$), Path length diference = $JE + EK$

Figure 1 Illustration of Bragg reflection from a set of parallel planes

Applying this equation, the Braggs were able to solve the crystal structures of NaCl and KCl. Subsequently, the structures of many simple inorganic compounds were solved. Single crystals are largely used for structure determination. However, upon consideration of equation (1), it was realized that powdered solids may also be used to provide diffraction data. In a finely divided powder containing millions of particles their orientation is normally chaotic. That is, they will statistically have large numbers of crystallites in every possible orientation to the X-ray beam. Placing such a sample in the X-ray beam generates diffraction from all the sets of planes simultaneously but at angles that depend upon the values of d. Application of the powder technique has tremendous value, as not all solids can be obtained as large enough (order of tenths of millimeters) single crystals.

Powder diffraction is widely used throughout industry, academia, or wherever a knowledge of solids is required. With the great advances in electronics, computers, and software, the accuracy of the data, the ease of obtaining it, and data interpretation have progressed accordingly. In the last two decades, a large effort has been put forward to determine crystal structures from X-ray powder data. This effort has been largely successful to the point where a great deal of information on structure may be obtained even from solids as complex as crystalline proteins.

2 APPLICATIONS

Powder diffraction, although used by most as a tool for identification (or finger printing), remains a powerful technique, which can be used for a range of applications to obtain a great deal of information.[1] From the chemists' point of view, qualitative phase identification, quantitative phase analysis (for samples containing more than one phase), structure solution, and structure refinement (popularly known as Rietveld refinement) are considered. For materials scientists and engineers, in addition to the above, crystallinity studies, particle size, strain and texture analysis in thin films and bulk materials are some of the objectives. In situ diffraction under forced conditions such as temperature, pressure, humidity, etc., gives powder diffraction a strong advantage. The information for the various applications is extracted from different types of details in the powder diffraction pattern: As given in the table below, the quantity measured is given in the first row and the applications derived from that quantity are presented in their respective columns[2]

Peak position	Peak intensity	Peak shape/width
Phases present	Unit cell contents	Size of crystallites
Unit cell	Point symmetry	Microstrain
Crystal system	Quantity of various phases present	Extended defects

3 TECHNICAL BACKGROUND

3.1 Generation of X-rays

X-rays are most often generated by means of cathode ray tubes of the type shown in Figure 2. The cathode consists of a tungsten filament through which a current is passed to excite electrons in the filament. The electrons are accelerated by a high potential between the filament acting as cathode and a metal anode. When the electrons strike the target, they are rapidly decelerated by multiple collisions. Most of the energy of deceleration is evolved as heat, but a small amount is converted into radiation. To prevent meltdown, cold water is run across the target. The smallest wavelength possible, at a given voltage, would be obtained when an electron is brought to a complete stop by one encounter. However, interactions of the high speed electrons with the electromagnetic field of the target atoms can lead to their gradual deceleration with transfer of energy to the target. Some of this energy is reemitted as X-ray photons and since all quantities of energy less than the single encounter maximum are allowed, a continuum of radiation is obtained (Figure 3).

Obviously, the intensity-wavelength curves depend upon the kinetic energy of the electrons, which is given by the relationship

$$\tfrac{1}{2}\,\mathrm{mv}^2 = \mathrm{eV} \tag{2}$$

where e = the charge of an electron and V = the applied voltage. The smallest wavelength obtainable at a particular voltage is known as the short-wavelength-limit (SWL) and can be calculated by recognizing that:

$$\mathrm{E} = h\upsilon = \mathrm{eV} \tag{3}$$

Since $\upsilon = c/\lambda$ and h = Planck's constant, the SWL is

$$\lambda_{\mathrm{SWL}} = \frac{hc}{eV} \tag{4}$$

Substituting the values of the constants to yield the answer in angstrom units, this equation takes the form

$$\lambda_{\mathrm{SWL}} = \frac{12\,400}{V} \tag{5}$$

At a voltage of 40 000 V, $\lambda_{\mathrm{SWL}} = 0.310$ Å. Figure 3 illustrates how the intensity and wavelength range of the general radiation varies with the applied voltage. The intensity also depends upon the tube current in milliamperes (mA) and the target atomic number.[3,4]

In addition to the general or white radiation, X-ray spectra show a number of intense lines whose wavelengths are fixed and characteristic of the target material (Figure 3). Their origin lies in the ejection of electrons from the ground state orbitals of the target atoms by the bombarding cathode electrons. Electrons from upper orbitals then fall into the vacancies created, and in the process, radiation of energy equal to the difference in orbital energies are emitted. This effect is the basis for determination of elemental composition by X-ray fluorescence analysis. Each element has a unique spectrum of characteristic lines.

We wish to use the Kα radiation (Figure 3) because it is the most intense of all the spectral lines. In addition, Bragg's law was derived based on use of monochromatic radiation. For most purposes Kα, which consists of two lines: Kα_1, and Kα_2, is sufficiently accurate. However, for the most exacting procedures Kα_2 needs to be removed to have truly monochromatic radiation.

Kα, Kβ radiation arises from ejection of electrons from the K-shell of the target atoms by impact with the bombarding electrons. Electrons from the L-shell then replace

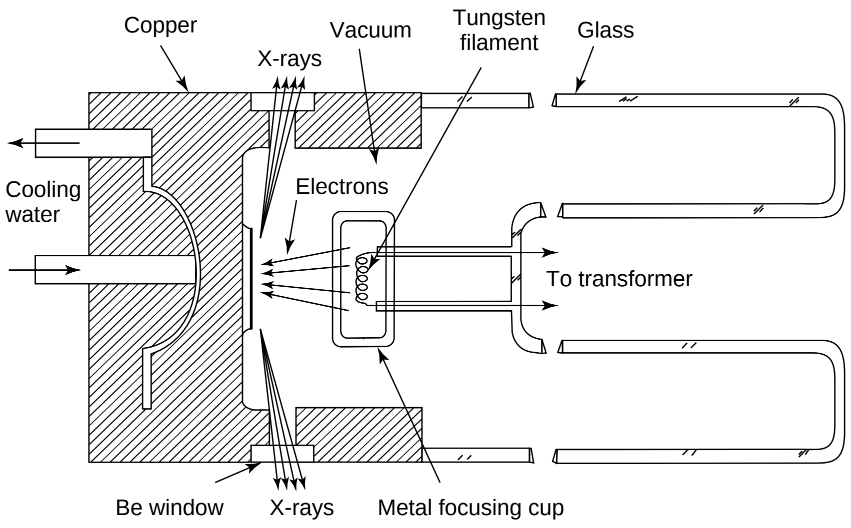


Figure 2 Cross section of a sealed X-ray tube (schematic)

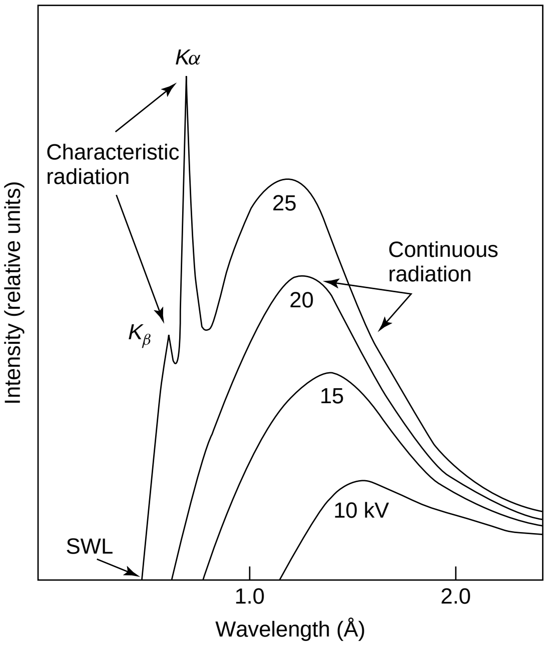

Figure 3 Schematic Mo X-ray spectrum as a function of applied voltage. Line widths are not to scale

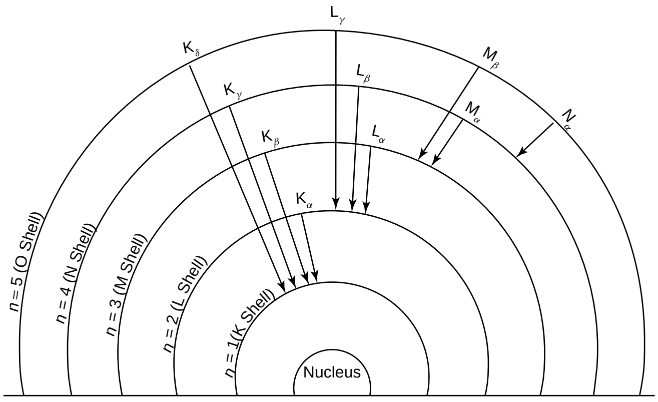

Figure 4 Electron energy transitions giving rise to X-radiation

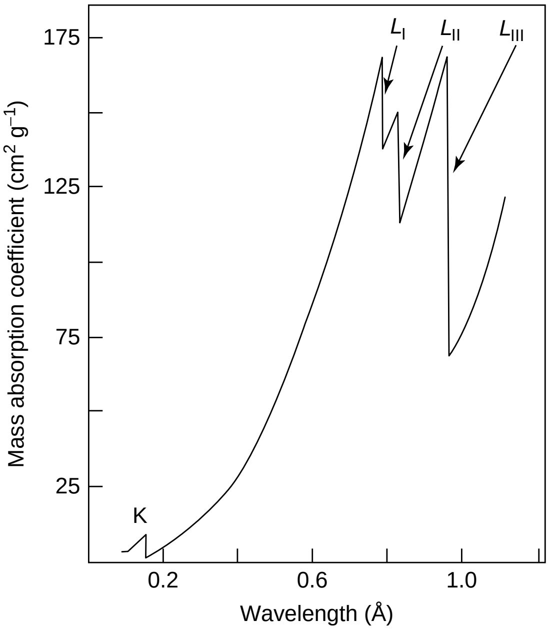

Figure 5 Variation of mass absorption coefficient with wavelength for Pb

the lost electrons, emitting radiation specific to the energy of the electronic transitions. The electrons in the L-shell are arranged into three energy states according to their total angular momentum or J states. The situation is treated as a one-electron problem. For the $2s$ electrons, $\ell = 0$, $s = 1/2$, $J = \ell + s = 1/2$. Similarly, for the $2p$ electrons, $\ell = 1$ and we have two J states, $J = 1/2$, $J = 3/2$. These states are identified in the energy level diagram as L_I, L_{II}, and L_{III} respectively. The allowed transitions are L_{II} and L_{III} to K (see Figures 3, 4, and 5). There are two electrons in the L_{II} state but four electrons in the L_{III} state so that $K\alpha_1$ is always twice as intense as $K\alpha_2$. Note that the $L_{III} \rightarrow K$ transition is the more energetic one so its accompanying wavelength is always slightly shorter than that of $K\alpha_2$. $K\beta$ arises from similar transitions from the M shell to K.

3.2 Monochromatic X-rays

For modern crystal diffraction studies, a nearly monochromatic beam of X-rays is required. This may be achieved by using a crystal monochromator. The direct beam from the X-ray tube is reflected from a large crystal in such a way as to give a very narrow (almost monochromatic) beam. This technique will become easier to explain after we have discussed diffraction procedures. Another method in common use is that of filtering. We wish to use only the $K\alpha$ wavelengths in a diffraction experiment because they are the most intense. A metal absorber is placed in front of the beam which absorbs the unwanted radiation. Absorption of X-rays follows the equation:[4]

$$\frac{I}{I_0} = e^{-\mu_l X} \qquad (6)$$

where μ_ℓ = linear absorption coefficient, in units of cm^{-1}, X = path length of X-rays in the absorber, and I_0 = initial intensity. In equation (6), it is understood that the particular value of μ depends upon the wavelength of the incident radiation. Therefore, it is necessary to determine μ as a function of λ. For a given element, this dependence follows a curve such as that shown in Figure 5. At high energies absorption is low, but increases in a nonlinear way with increasing wavelength (decreasing energy). The sharp breaks in the curve are called absorption edges. These discontinuities occur at the wavelength at which an incident X-ray photon

is just energetic enough to knock an electron out of an atomic orbital. For example, at very high energies, photons readily pass through the absorber since the probability of their interaction with electrons in the absorber is small. However, increased attenuation occurs as the wavelength of the photons increase. Maximum absorption is achieved when this wavelength is equal to the energy required to just dislodge a K electron. This energy is equal to the transition $K \rightarrow \infty$ and is therefore larger than that of any of the characteristic X-ray lines of the absorber. At slightly higher wavelengths, or lower energy, a large drop in the value of μ occurs because the photons are now unaffected by the K electrons. Once again, μ increases as λ decreases until at the L absorption edge, three discontinuities are observed. These result from electrons in the L_I, L_{II} and L_{III} energy levels being dislodged, respectively.

A suitable filter is one whose K absorption edge falls between the $K\beta$ and $K\alpha$ wavelengths of the X-ray target. Usually, an element of atomic number Z-1 or Z-2 satisfies this condition, Z being the atomic number of the tube target. For example, nickel foil is used to filter copper radiation. The proper thickness can be calculated from equation (4). Not all of the white and $K\beta$ radiation is eliminated (Figure 6), so filtered radiation is not strictly monochromatic.

3.3 Recording an XRPD Pattern

Consider a set of parallel atomic planes within the crystal to be oriented to the incident X-ray beam as in Figure 7(a). The incident beam is at an angle θ to the set of planes. The incident beam passes through the sample and strikes the detector at $\theta = 0°$. It is immediately apparent that the reflected beam is at angle 2θ to the zero point. If the detector were placed at the angle of reflection 2θ, it would record the diffracted intensity for this set of planes. Imagine that the set of crystal planes precesses around the incident beam while always maintaining an angle θ to it. The diffracted radiation then forms a cone of radiation about the incident beam as cone axis (Figure 7b). If a film is placed at the bottom of the cone, the radiation would form a black circle on the film. Since many sets of parallel planes with different d-spacings are present in the sample, a set of concentric circles would be recorded simultaneously on the film. A moment's reflection should convince you that only those cones whose base is less than the film length would be recorded. Debye and Scherrer independently developed a simple camera that would record all the data. They chose a steel hollow cylinder into which a strip of film is placed around the inside periphery. The sample is held in the center of the cylinder and is rapidly rotated to ensure uniformity of distribution of the crystallites. All the concentric circles of diffracted radiation are now recorded on the 360° strip of film. The developed film appears as shown in Figure 7(c). Portions of the base of each cone are recorded on the film as pairs of arcs that are proportional to 4θ the circle diameter. More properly we know that the angle subtended in radians is given by the arc divided by the camera radius. Cleverly the radius of the camera was made to be 57.3 mm, so that one mm in arc measured linearly is 1° in θ. From the measured θ values, Bragg's equation allows us to determine all the recorded d-spacings. In its simplest use the list of d-spacings serves as a fingerprint to identify the crystalline phase.

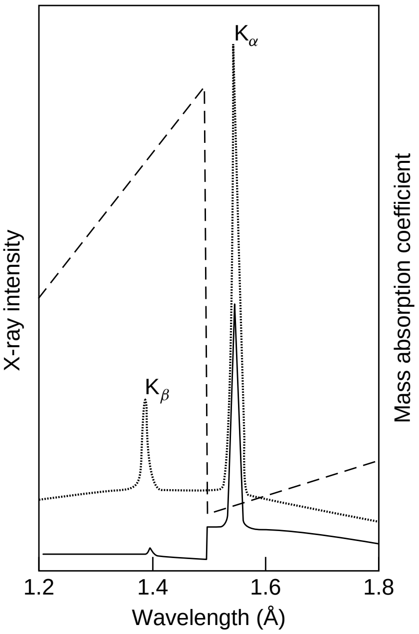

Figure 6 Comparison of the spectra of Cu-radiation before (dotted line) and after (continuous line) passage through a Ni-filter (schematic). The dashed line indicates the mass absorption coefficient of Ni

Film methods are tedious to apply. Careful measurements of all the arc-pairs may take several hours, in addition to development of the film, drying, and correcting for film shrinkage. Fortunately, automated diffractometers were developed that obviate the use of film. Such instruments are able to move the detector around the focusing circle recording the X-ray intensities one at a time. One can think of it as photometering the film pattern from 0 to 90° in θ to produce a pattern as shown in Figure 8. This powder pattern is a one-dimensional recording of the intensity of diffracted radiation from all the sets of parallel planes as a function of the angle 2θ within the angular range measured. We shall show later that from knowledge of the θ values we can derive the interplanar spacings of the individual set of planes. For example, the first peak in the pattern shown in Figure 8 is at $2\theta = 10.467°$. Theta is therefore 5.2335° and the radiation used was Cu $K\alpha_1$ for which $\lambda = 1.54056$ Å. Rearranging Bragg's equation to solve for the interlayer spacing gives

$$d = \frac{n\lambda}{2\sin\theta} = \frac{1.54056}{2\sin 5.2335} = 8.4451\,\text{Å}$$

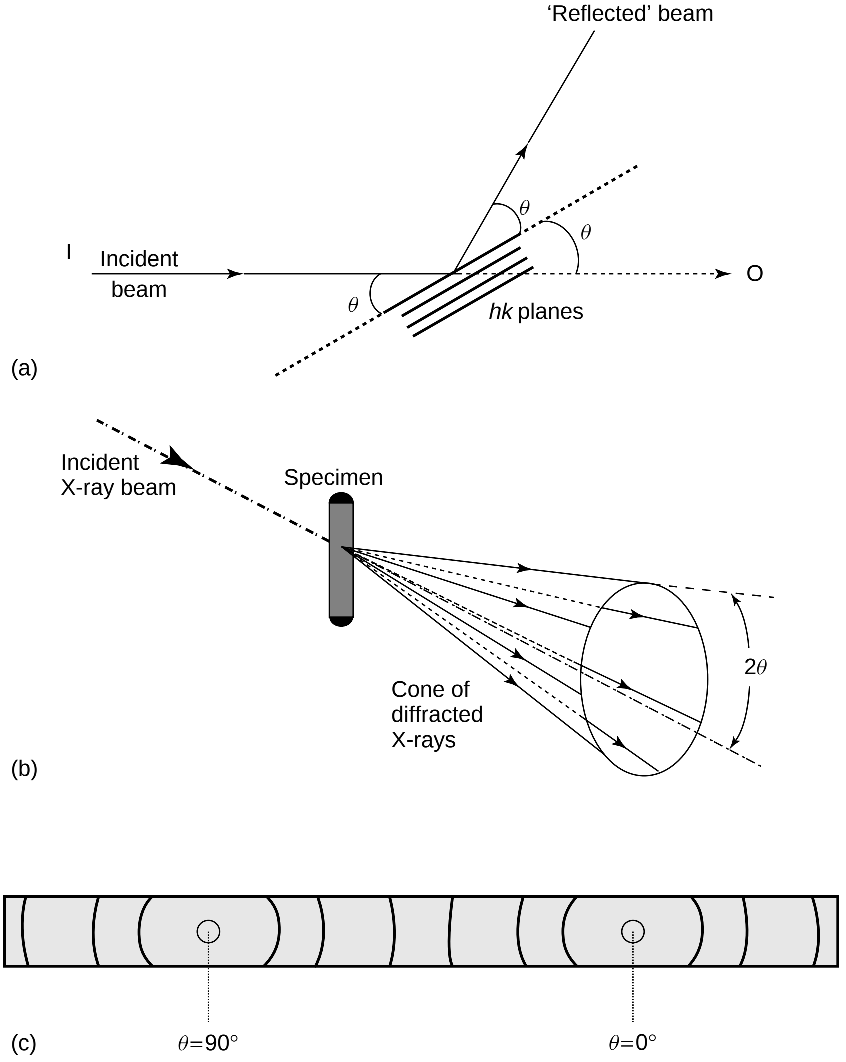

Figure 7 (a) Bragg reflection from a set of lattice planes. (b) The cone of diffracted X-rays from a powder specimen. The cone contains all X-rays reflected from one particular family of lattice planes in all crystals which are correctly oriented. (c) The form of a powder pattern (asymmetric film mounting)

The next peak is at 14.066° and $d = 6.2911$ Å. Note that as θ increases, d decreases, a result of the inverse relationship of these quantities in Bragg's equation.

3.4 The Diffractometer

The basic components of an X-ray diffractometer are

(i) The X-ray source or generator
(ii) The specimen holder
(iii) The detector

There is a specific arrangement of these three components as shown in Figure 9. The specimen for which the pattern is recorded is held at the center of a circle termed the diffractometer circle. The X-ray source is fixed at the circumference of the circle. The X-ray detector is also on the circumference of the circle. When the detector is at zero, the source, the specimen, and the detector are in the same plane with the angle between source and detector 180°. In a typical run, the specimen rotates at an angle θ while the detector rotates an angle 2θ and so is always in position to record the diffracted beam. This is popularly termed the "$\theta - 2\theta$" method. In a second type of diffractometer the X-ray source moves as well as the detector, but in opposite directions toward each other. In this case the specimen does not move, so the powder pattern is recorded as a function of θ. In both diffractometers the focusing circle changes in diameter as the moving parts change position.[3,4]

3.5 Instrument Optics

The optical components of the diffractometer are shown in Figure 10. A line source of the X-ray tube is used

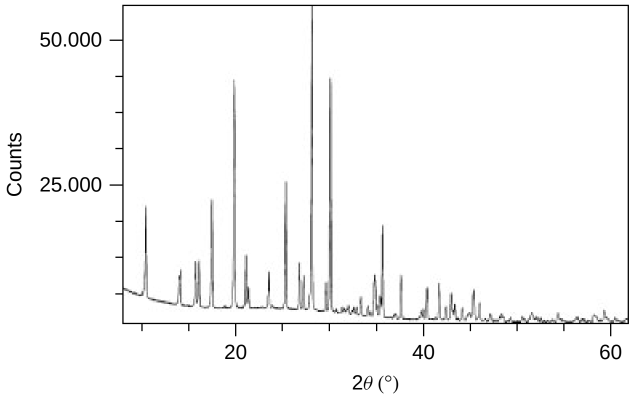

Figure 8 Plot of 2θ vs. X-ray intensity

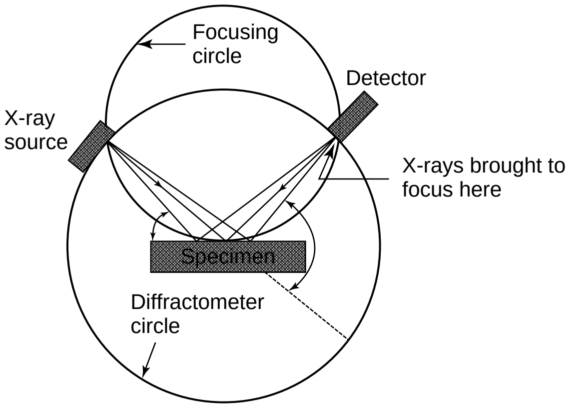

Figure 9 Schematic representation of the geometry of an X-ray diffractometer

for most powder work. As soon as the X-ray beam exits from the tube, it begins to diverge. Bragg's Law requires that a parallel beam strike the sample. Therefore, the line source is passed through a system of slits. Soller slits are a series of closely spaced parallel metal plates that collimate the incident beam. The Soller slits prevent in-plane or lateral divergence and a second slit termed *the divergence slit* defines the width of the incident beam. The diffracted beam is then subjected to another series of slits. The antiscatter slit reduces the background radiation by eliminating stray radiation and any radiation scattered outside the specimen. The receiving slit defines the width of the beam admitted to the detector. An increase in slit width increases the intensity, but at a loss of some resolution.[3,4]

3.6 Preparing the specimen

The first step toward powder diffraction (assuming a goal of ab initio structure determination) is making a pure phase. There is no clear and definite way to define a phase as pure unless proven otherwise. A good starting step would be to look at the sample under the microscope before any processing (e.g. grinding, washing, etc.) has been done. This serves two useful purposes: first, if there is any obvious impurity, based on color or morphology, it will give a lead to look for impurities. The second is to look for any possibility to find a single crystal. Though the powder diffraction analysis methods are advancing rapidly, even a small inferior quality crystal would give a great deal of information on unit cell parameters, possible space groups, and perhaps a good starting structural model. Any knowledge known or gained about the sample would help further analysis a great deal.[4–6]

For data collection the specimen should be ground, using an agate mortar and pestle to reduce the particle size to 10–50 μm. This is a requirement to ensure sufficient particles will occupy each of the many possible orientations equally. In the case of a mixture, it is necessary to ensure that the phases are uniformly distributed throughout. The simplest procedure is to grind about 50 mg of sample in ethyl acetate to which a small amount of cellulose acetate has been added. The fluid

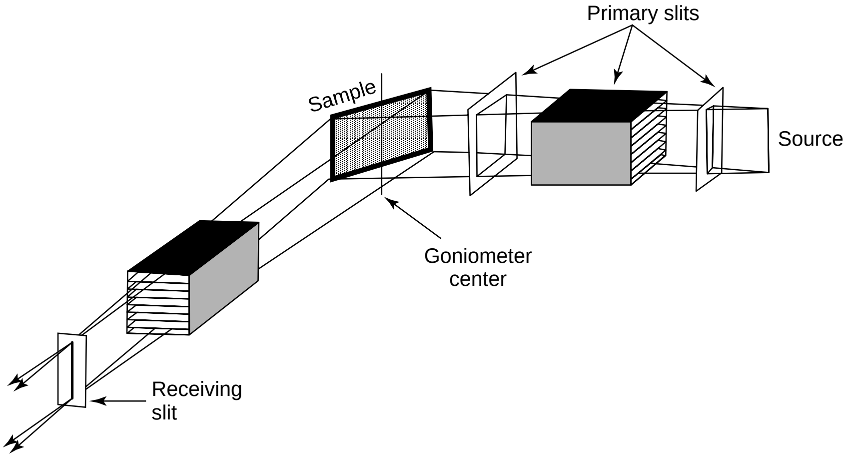

Figure 10 Arrangement of slits in a powder diffractometer

mix is then cast out on a glass slide and dried slowly, a little above room temperature. The idea is to have a small, flat layer of sample. Reference to Figure 9 shows that the X-rays at the surface of the sample are focused to the detector. The thinner the layer, the more accurately the position of the peaks recorded. However, it should be recognized that this technique does not yield accurate values of the peak intensities because such a thin sample layer will allow the X-ray beam through to the glass. The more common specimen holder will contain a well a few mm thick as shown in Figure 11. The well must be filled flush to the top. This assures that the sample is in the plane of the source and detector. Otherwise an error in the peak position or 2θ will be incurred.

Usually a 3 mm-deep well is sufficient to keep the X-rays from passing through to strike the bottom of the well. However, when the sample consists of elements of low atomic number such penetration will occur and scattering from the sample holder will increase the background. However, it is also not good practice to have a deep well sample holder. X-rays that penetrate deeply into the sample will be focused slightly behind those at the surface causing broadening of the peak and a slight displacement of the 2θ angles. However, because diffraction is occurring from a larger portion of sample the intensities will be increased.

To avoid scattering from the bottom of the sample one may use a procedure called back-loading. The holder is prepared with the bottom of the well cut away. A glass slide is taped to the top of the holder, turned upside down and loaded from the bottom pressing the sample against the glass. The glass is then carefully removed to leave a smooth surface. Any radiation passing through the sample is not scattered back. However, some samples have a tendency to fall out of the holder if some binder is not added to the sample.

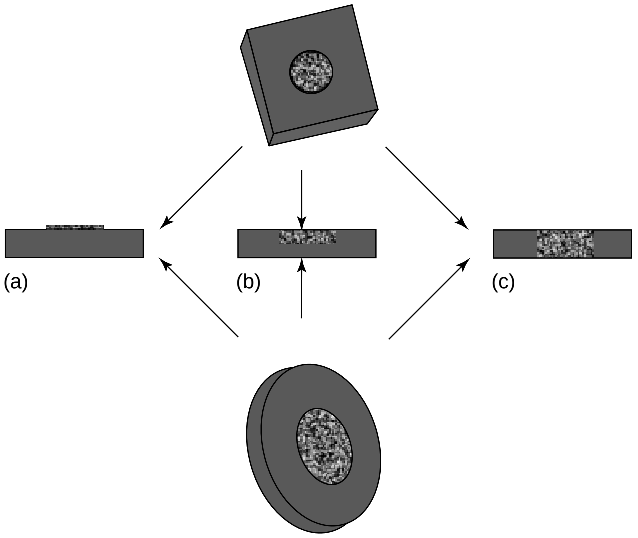

Figure 11 Common types of rectangular and circular specimen holders: (a) zero background, (b) top-loaded, and (c) back-loaded configurations

Some diffractometers can accommodate samples held in capillary tubes usually made of glass or quartz. Only a few milligrams of sample are required. The capillary is rapidly rotated to help insure the distribution of the particles in all possible crystallite orientations. The X-ray beam is perpendicular to the sample and passes through it (transmission method). Some discretion must be used, as the presence of heavy elements in the sample will increase the absorption.

3.7 The Detector

Detectors in use today are of three types: proportional, scintillation, and solid state. The proportional counter consists of a tube filled with a noble gas such as xenon. A thin tungsten wire runs down the center of the tube and is positively charged. A thin window of low-absorbing glass allows the X-ray photons to enter the tube. The photons displace electrons from the xenon atoms. Each such photoelectron loses its energy by ionizing other xenon atoms causing a cascade of electrons. The released electrons are drawn to the positively charged wire giving rise to a charge pulse. The size of the pulse is proportional to the energy of the incident photon, which allows X-rays of different wavelengths to be distinguished.[3,4,6]

Scintillation counters usually consist of a sodium iodide crystal doped with 1% thallium. The incident X-ray photons cause the crystal to fluoresce producing a flash of light for every photon absorbed. The size of the light pulse is proportional to the energy of the photon and is measured by a photomultiplier. A deficiency associated with scintillation counters is that they do not provide as good energy resolution as proportional or solid state detectors.

Solid state detectors consist of three layers, a layer of pure silicon sandwiched between a p-type and an n-type conductor. We recall that an example of an n-type conductor is germanium to which is added P or As, an impurity. The extra electron in the phosphorus or arsenic atoms is thought of as being in an energy level close to the conduction band. These electrons are readily thermally excited into the conduction band increasing the conductivity. A p-type semiconductor may be silicon to which a trivalent element such as boron or aluminum is added as an impurity. This creates holes close to the valence band. Electrons are readily promoted to these holes leaving positive holes in the valence band that provide for a conduction pathway.

The p- and n-type conductors are necessary in the solid state detector because silicon crystals are very difficult to obtain pure. Usually they contain impurities such as boron, which would make it a p-type semiconductor. This situation would allow thermal electrons to cross the silicon energy gap to the low lying hole state. However, we want only electrons that are excited by X-ray photons to act as conductors. Interference of thermal electrons is avoided by a process called drifting in which a small amount of lithium is added, usually by thermal diffusion, to one side of the Si crystal and a larger amount to the opposite side. The lithium ionizes within the silicon

crystal neutralizing the holes that were present. The high concentration lithium side is the n-type conductor and the low concentration side the p-type conductor, because not all the holes were neutralized. The center of the crystal behaves as pure silicon.

The incoming X-ray photons excite electrons into the valence band creating an electron-hole pair. A negative charge is applied to the p-type part of the crystal and a positive charge to the n-type side. This creates a charge pulse of electrons. The number of electron-hole pairs is given by equation (7)

$$n = \frac{\text{photon energy}}{\text{energy of electron—hole pair formation}} \qquad (7)$$

Because the numerator is large (e.g. Cu Kα is 8.04 keV) and the denominator small, that is, of the order of electron volts, a large number of electron-hole pairs are produced by each photon. The Si(Li) detectors must be kept at liquid nitrogen temperature at all times in order to minimize thermal excitation of electrons and to prevent lithium thermal diffusion. Either a Dewar vessel or a Peltier thermoelectric device is used in conjunction with the solid state detector.

Two new detectors marketed by the Bruker Corporation provide sensitivities much greater than the detectors already described. The Lynx Eye is a linear silicon strip detector that is claimed to have sensitivity 200 times that of the standard scintillation detector. The Vantec is a linear microgap/wire detector. It is an ultra-low noise detector and is about 100 times more sensitive than the scintillation detector.

3.8 Monochromators and focusing devices

We have already discussed the use of filters to achieve a monochromatic X-ray beam. Filters do not remove all of the white radiation and sometimes a small amount of β-radiation leaks through. This extraneous radiation may result in the presence of extra weak peaks or higher background radiation. For strictly monochromatic radiation a high quality single crystal is used. The crystal is usually placed behind the sample at a specific angle θ so as to diffract the X-ray beam from the sample into the detector (Figure 12a). This angle depends upon the d-spacing of the crystal plane chosen to allow only a specific wavelength such as Cu Kα_1 to diffract. The crystal angle may be reset for other wavelengths. If the crystal is curved as shown in Figure 12(b), the focusing of the beam is much better producing a gain in intensity. With a back end monochromator there is no need for a metal filter so the beam striking the sample is very intense. The loss of intensity from the monochromator may not be as great as from the filter. Another advantage of the back end monochromator is that it eliminates fluorescent radiation and Compton or incoherent radiation resulting in a very low background. Fluorescent radiation arises from excitation of sample electrons by the X-ray beam. For example, first row transition elements strongly fluoresce, especially Fe and Co, when the radiation is Cu Kα.[4,6]

A disadvantage of the back end monochromator is its inability to separate Kα_2 from Kα_1. For very precise unit cell determinations this separation is desirable. For this purpose a front end or primary beam monochromator is used (Figure 12c). This monochromator is the only type that can be used with area detectors. Their disadvantages include a high intensity loss, the need for precise alignment and nonremoval of fluorescent radiation.

A number of new optical devices that increase the intensity of the X-ray beam are worth mentioning. The use of slits eliminates a large portion of the X-ray beam before it strikes the sample. However a much larger proportion of the incident beam may be delivered to the sample by the use of optical fibers. Each optical fiber consists of a large number of tiny hollow glass capillaries. These capillaries act as wave guides in which the X-rays undergo total reflection from the capillary surfaces and are led to the sample with very little loss of intensity.

Unlike optical light, X-rays cannot be reflected or deflected easily by mirrors. But specially deposited multilayers of low-Z and high-Z materials can be used to reflect and monochromatize the X-rays based on Bragg's condition. Typically combinations of W-B_4C, W-Si, Ni-C and combination of such layers are used. By using Göbel mirrors, the diverging X-ray beam from conventional sources could be made into parallel or focused. The major advantage of Göbel mirrors is the near removal of sample displacement error ($\sim \pm 200\,\mu$m). Besides, removal of the K_β component, increased intensity, removal of fluorescent radiation (when used in the diffracted beam side) are some of the benefits. These mirrors are extensively used in thin film studies, and in stress/strain analysis.

4 PHASE IDENTIFICATION

The simplest application of powder diffraction is to identify a crystalline phase. One merely runs the powder pattern of the solid and records either 2θ values or d-spacings or both. This information is given by the program and can be printed directly on the pattern. Then one may consult a database such as the JCPDS file. These initials refer to the JCPDS. As a result of the complexity of keeping pace with the ever growing list of known phases, the operation grew and was renamed the International Centre for Diffraction Data (ICDD), headquartered in Newton Square, Pennsylvania.

The database was formerly a card file on which the data for each phase was printed on $3'' \times 5''$ cards, but now this information is available on CD-ROM. A typical data card is shown in Figure 13. Each card is identified by a number such as 25–1495. A search manual is provided in which the d-spacings of eight peaks for each compound are listed in order of decreasing intensity with the most intense peak in the pattern listed first. The cards are listed in groups of d-spacings such as 7.99–7.00. There are 40 such groups from very high to very low d-spacings. One searches through the proper group

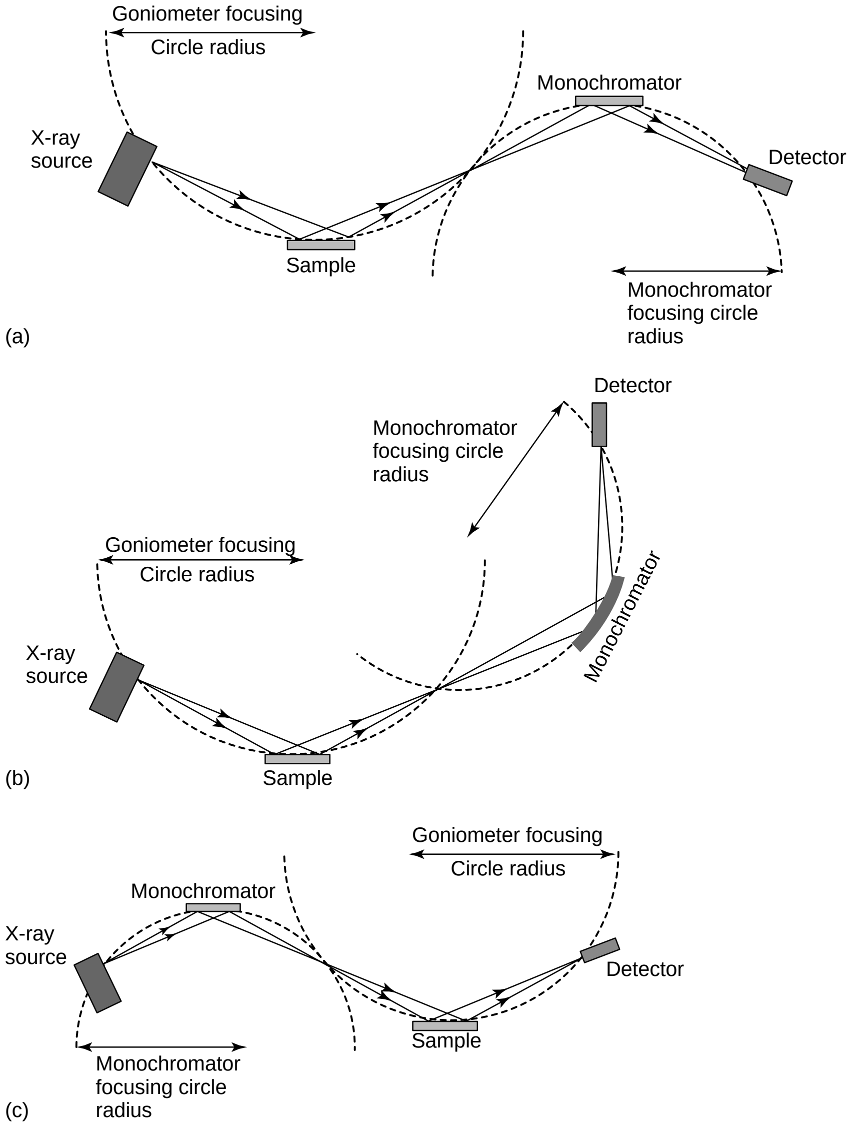

Figure 12 Three different monochromator/sample geometries used in powder diffraction: (a) flat diffracted beam monochromator, parallel arrangement, (b) curved diffracted beam monochromator, angular arrangement, and (c) flat primary beam monochromator, parallel arrangement

for a match. When one is found, then the remaining peaks are compared. Relative intensities are listed with the largest represented as 100 and the others as a percent, in comparison with the most intense peak. A total match is sufficient to have identified the phase. If the data are available on CD-ROM, the observed d-spacings, already on a computer may be utilized in a search–match procedure. Inclusion of some or all of the chemical elements in the sample, if known, speeds up the search. Books listing all the phases in alphabetical order are also available. If, for example, elemental analysis indicates that you are dealing with a calcium phosphate you can check your X-ray pattern with the many listings of all the calcium phosphates in the volume. For information on purchase of the various databases available from ICDD, refer to www.icdd.com. The databases are categorized as inorganic (with some organic), organic and organometallic (with some inorganic) and minerals. In all, more than 500 000 entries are listed. The entire file is automated. A great deal of information is listed for each phase. For example, many entries include unit cell dimensions, and atomic coordinates. These can be used in Rietveld techniques (to be described in a later section) to carry out a quantitative assessment of the phases present in a mixture. It is perhaps wise at this stage to describe problems that may arise leading to difficulty of identification.

4.1 Preferred Orientation

A major problem in dealing with powder patterns is PO. Crystals with texture may prefer to orient in favored

ways, instead of randomly. This feature increases the intensity of diffracted radiation from certain planes and reduces it from others. The most egregious examples are layered compounds that tend to lay flat, thin films and cold-worked metals. Even compounds that are not layered may exhibit some PO due to their odd shape. In such cases side loading of the sample may be sufficient. Side loading coupled with rotation of the sample in the plane is better and may produce satisfactory results. A more effective technique is to fill a capillary with the sample and rotate the sample rapidly. The beam is passed through the sample in transmission mode. Not every diffractometer has this option. Additions of fine grains of starch are also somewhat effective. The best way to eliminate PO is to use a vacuum chamber.[7] It consists of a glass container filled with small glass beads to which the sample is added. By mixing the two thoroughly the sample particles cling to the glass spheres. The layers are tangent to the spheres and thus take every possible orientation over the sphere surfaces. A vacuum is then applied and the solid sample is pulled into a chamber containing a filter paper that catches the particles. Happily, the particles maintain the orientation they took on the glass surface, producing a sample free of PO Software is available to correct for PO mathematically, but this is best done on samples treated by one of the above-mentioned methods to remove the bulk of the PO.

4.2 Indexing the Powder Pattern

The determination of previously unknown unit cell constants (*viz.*, a, b, c, α, β, γ) from the various interlayer spacing values obtained from the powder diffraction profile and assigning each peak with a certain set of Miller indices (hkl) is known as indexing. The most general equation for the lowest symmetry triclinic system is given by:

$$\frac{1}{d^2} = \frac{1}{V^2}[h^2b^2c^2\sin^2\alpha + k^2a^2c^2\sin^2\beta + l^2a^2b^2\sin^2\gamma + 2hkabc^2(\cos\alpha\cos\beta - \cos\gamma) + 2kla^2bc(\cos\beta\cos\gamma - \cos\alpha) + 2hlab^2c(\cos\alpha\cos\gamma - \cos\beta)]$$

where, d is the interplanar spacing, and V is the volume of the unit cell. When considering higher symmetry systems, some of the angles are constrained to 90° and the equation simplifies. Although, every step in powder diffraction is crucial and important, the process of indexing is generally accepted as the bottleneck toward structure determination from powder diffraction data.

The ICDD cards or data sheets contain a column with a heading *hkl*. This column contains three integers associated with each d-spacing. These trios of integers are termed Miller indices and reveal the positioning of the different sets of planes within the crystal. Indexing the crystal planes is important from several points of view. If you indeed are dealing with a single phase, then every reflection or peak in the powder pattern should be assignable to a Miller index. The indices are assigned on the basis of a unit cell which is also listed on the ICDD sheet.

4.2.1 Bravais Lattices and Unit Cell Axes

You will recall that in solids the atoms have fixed positions about which they vibrate. If the atoms are replaced by points, a point lattice results. In Figure 14, we show such a

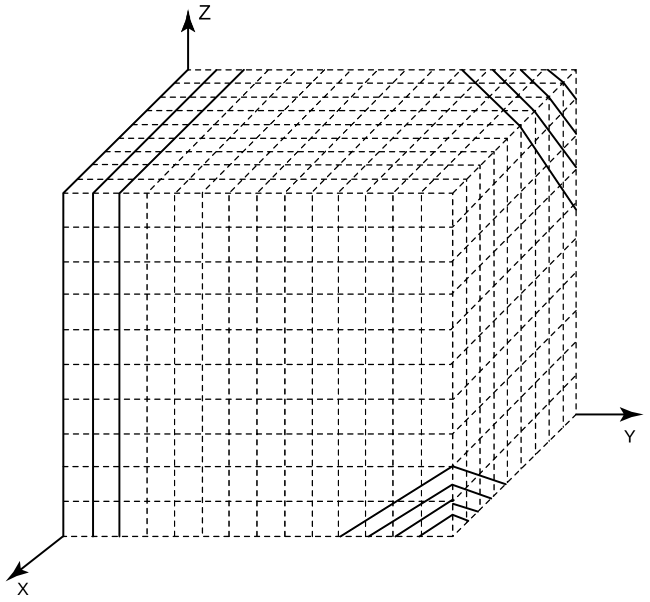

Figure 14 A three-dimensional point lattice and some examples of set of parallel planes of points

point lattice with sets of planes drawn through the points. It is evident that a large number of such sets are possible. In order to be able to identify the individual planes, each of which will give rise to a peak in the powder pattern, we require an axial system. The choice of axial system depends upon the symmetry of the crystal. The allowed symmetry elements are axes, mirror planes and an inversion center. Fortunately, the only axes that need be considered are 1-, 2-, 3-, 4-, and 6-fold. This limitation arises from the condition that the crystal must fill the space it occupies. The combination of all these symmetry elements leads to six axial systems as listed in Table 1.

Table 1 Crystal axis systems

System	Minimal symmetry	Axial conditions
Triclinic	1 or $\bar{1}$	$a \neq b \neq c$, $\alpha \neq \beta \neq \gamma$
Monoclinic	2 or $\bar{2}$	$a \neq b \neq c, \alpha = \gamma = 90° \neq \beta$
Orthorhombic	222	$a \neq b \neq c, \alpha = \beta = \gamma = 90°$
Tetragonal	4 or $\bar{4}$	$a = b \neq c, \alpha = \beta = \gamma = 90°$
Cubic	Four 3s or $\bar{3}$s	$a = b = c, \alpha = \beta = \gamma = 90°$
Hexagonal	3 or 6 ($\bar{3}$ or $\bar{6}$)	
(a) Rhombohedral	3	$a = b = c, \alpha = \beta = \gamma \neq 90°$
(b) Hexagonal	6	$a = b \neq c$, $\alpha = \beta = 90°$, $\gamma = 120°$

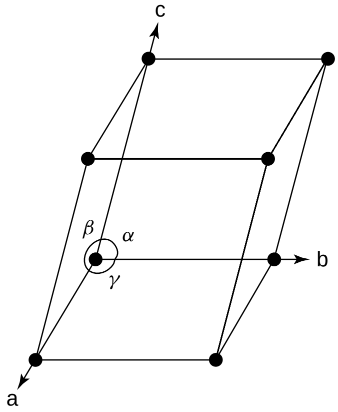

Figure 15 Representation of a unit cell indicating the correct positioning of the axes and angles

The axes may be designated by X, Y, and Z, that are infinite in length in both the positive and negative directions. a, b, c in Table 1 are listed unit lengths along X, Y, Z, respectively and α, β, γ, the angles between the axes as shown in Figure 15. These unit lengths and angles define a unit cell. The unit cell contains a portion of the crystal that is unique and when the unit cell is repeated by the vectors $\vec{a}$, $\vec{b}$, $\vec{c}$, they reproduce the crystal. The point lattices we mentioned earlier must be compatible with the symmetry of the axial systems and this gives rise to 14 lattices termed Bravais lattices (Figure 16). The positioning of the points in the lattice is constrained by the requirements that each point have the same environment. Consider the triclinic unit cell. Reference to Table 1 indicates that the symmetry elements are a one-fold axis, that is, rotation by 360° which brings the point acted upon back to itself, and a center of symmetry designated as one bar, $\bar{1}$. Thus all the axes are of different length and none of the angles are equal. The only arrangement of points possible is a set occupying the corners of the unit cell. Because each point is equally shared by eight unit cells and there are eight such points, there is only one point contained in the unit cell. Such a cell is termed primitive, designation P. Consider the orthorhombic unit cell. It has three mutually perpendicular two-fold axes (222 in Table 1) so that all the angles are 90°. There is no restriction on the length of the axes therefore they are all of unequal length. The simplest unit cell is primitive but more complex cells, termed *centered cells* are possible. One such cell has a point in the body center or at 1/2a, 1/2b, 1/2c in addition to those at the corners. This cell is termed body-centered with symbol I. Similarly, a face centered cell has a point in the center of each face. Note that the body-centered cell has a total of two points, one represented by those points at the corners and one in the center. Similarly, the face-centered cell has four points. Each point in the face is shared with another unit cell so the six faces produce three points in addition to the one at the corners. Finally we have a side centered cell. In the figure the points are in the ab

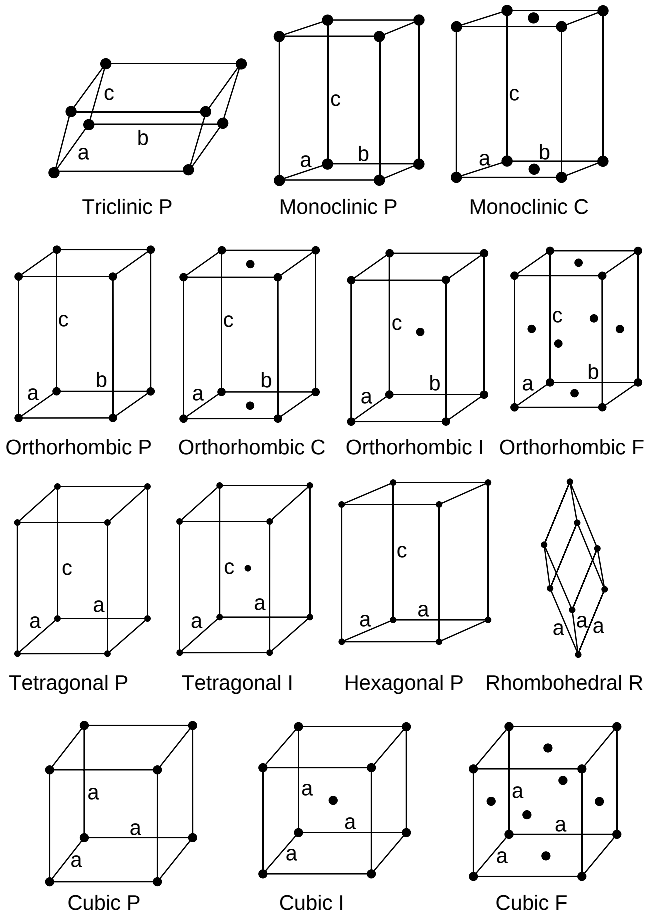

Figure 16 Representation of the 14 Bravais lattices of three-dimensional space

plane and so it is designated as C-centered. A more complete treatment of Bravais lattices can be found in many texts.

4.2.2 Relationship between Miller Indices and Interplanar Spacings

In order to index the powder pattern we need to show the relationship between the axial system and the individual planes. Consider a plane oriented as shown along the X, Y, Z-axes (Figure 17). The perpendicular to the plane from the origin O is the d-spacing because a parallel plane touches the origin. Another way to define the plane is by its intercepts along the three axes. If h is three, then the intercept along the X-axis is 1/3a. Similarly if k is 1, then the plane cuts the Y-axis at b. The intercepts are given as fractions of the unit cell but the Miller indices are reciprocals of the intercepts that the first plane of the set makes with the axes. This is illustrated by the following example. Suppose the plane cuts the axes at 2a, 1/2b, 1/3c. These are the intercepts but the Miller indices are the reciprocals 1/2, 2, 3 respectively. We clear fractions so the Miller indices are 1, 4, 6. This designation tells us that the first plane from the origin was not chosen initially. The first plane cuts the axes at a, 1/4b, 1/6c and would have half the d-spacing as the initially chosen plane. One other point, if the plane is parallel to an axis it cuts the plane at infinity and the reciprocal is zero. 200 cuts the X-axis at 1/2a and is parallel to the bc plane.[3,4,6]

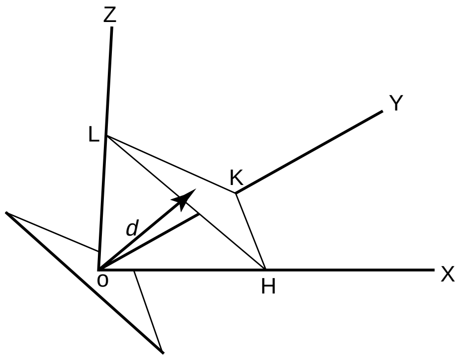

Figure 17 The plane cuts the crystallographic axes at H, K, L giving rise to the normal to the plane ON. A parallel plane passes through the origin illustrating that ON $= d$, the interlayer spacing

There is a direct relationship between the d-spacing of a set of planes and its intercepts. It is beyond the scope of this article to derive such an expression. However, the simplest relationship is for a cubic unit cell that can be simply stated as

$$d_{hkl} = \frac{a_0}{[h^2 + k^2 + l^2]^{\frac{1}{2}}} \tag{8}$$

Similarly for the orthorhombic system we have

$$d_{hkl} = \left[\frac{h^2}{a^2} + \frac{k^2}{b^2} + \frac{l^2}{c^2}\right]^{-\frac{1}{2}} \tag{9}$$

Table 2 contains the relationships for all the axial systems.

What these equations tell us is that if we know the value of a_0 for a cubic unit cell, we can determine indices for all the reflections. For example, if $a_0 = 8.00$ Å, then for the 111 plane $d_{111} = 8.00/\sqrt{3} = 4.62$ Å (equation 8) and from Bragg's law

$$\sin\theta = \frac{n\lambda}{2d} = \frac{1.542\,\text{Å}}{2 \times 4.62\,\text{Å}} = 0.1669$$
$$\theta = 9.60^\circ,\ 2\theta = 19.2^\circ$$

The peak at 19.2 in 2θ is labeled 111. However, what we have to work with is the powder pattern from which we wish to determine a_0. Most laboratories have programs that automatically determine the unit cell dimensions from the powder pattern. To avoid mistakes some fundamentals that help the experimenter to judge the correctness of the result is in order. Consider the pattern of aluminum in Figure 18. We notice that there are very few peaks compared to the powder pattern in Figure 8 even though the pattern was recorded out to very high $2 - \theta$. Also we note that the first and strongest peak is at a high value of $2\theta = 38.52^\circ$, $d = 2.337$ Å. The prognosis

Table 2 Values of the interplanar spacing (d_{hkl}) in the six crystal systems

System	d_{hkl}
Cubic	$\left[\frac{1}{a^2}(h^2+k^2+l^2)\right]^{-1/2}$
Tetragonal	$\left[\frac{h^2+k^2}{a^2}+\frac{l^2}{c^2}\right]^{-1/2}$
Orthorhombic	$\left[\frac{h^2}{a^2}+\frac{k^2}{b^2}+\frac{l^2}{c^2}\right]^{-1/2}$
Hexagonal	$\left[\frac{4}{3a^2}(h^2+hk+k^2)+\frac{l^2}{c^2}\right]^{-1/2}$
	$\left[\frac{1}{a^2}\frac{(h^2+k^2+l^2)\sin^2\alpha+2(hk+kl+lh)(\cos^2\alpha-\cos\alpha)}{1-2\cos^3\alpha+3\cos^2\alpha}\right]$
Monoclinic	$\left[\frac{\frac{h^2}{a^2}+\frac{l^2}{c^2}-\frac{2hl\cos\beta}{ac}}{\sin^2\beta}+\frac{k^2}{b^2}\right]^{-1/2}$
Triclinic	$\left[\frac{\frac{h^2}{a^2}\sin^2\alpha+\frac{k^2}{b^2}\sin^2\beta+\frac{l^2}{c^2}\sin^2\gamma+\frac{2hk}{ab}(\cos\alpha\cos\beta-\cos\gamma)+\frac{2kl}{bc}(\cos\beta\cos\gamma-\cos\alpha)+\frac{2lh}{ca}(\cos\gamma\cos\alpha-\cos\beta)}{1-\cos^2\alpha-\cos^2\beta-\cos^2\gamma+2\cos\alpha\cos\beta\cos\gamma}\right]^{-1/2}$

is that we are dealing with a very small cell, probably cubic, because of the small number of peaks. The more complex the relationship between d and hkl, the more complex is the powder pattern. For example, in the cubic system 100, 010, 001 occurs at the same 2θ value but in the orthorhombic system these indices would each yield separate peaks.

4.2.3 *Procedure for Indexing a Cubic Unit Cell*

We will illustrate how a_0 for a cubic system may be determined that will lead to further information concerning powder patterns. From equation (8) we can determine the allowed values of $h^2+k^2+l^2$. Let $\mathrm{N}=h^2+k^2+l^2$, then the allowed values of N are given in Table 3. We note that no combination of *hkl* gives 7 or 15 as the sum of their squares.[8]

However, this numbering sequence only holds for primitive cubic unit cells. Certain systematic absences occur for centered cells of which we need consider only I and F in the cubic system (the allowed Bravais Lattices). These absences arise in the following way. Let us assume that we have a cubic unit cell with $a = 5.00$ Å. Normally we expect the 100 reflection to have $d_{100} = 5.00$ Å for which $2\theta = 17.74°$. The angle of incidence of the X-ray beam for this plane is θ, 8.87°. However, there is an exactly similar plane of atoms 200 at (5.00 Å/2) = 2.50 Å. When the angle of incidence is 8.87°

for Cu Kα radiation, the pathlength difference between any two such planes d_{100} with 5-Å spacings, is one wavelength. But the exactly similar plane at $d_{200} = 2.50$ Å has a pathlength difference of one-half wavelength and is exactly out of phase with the 100 plane. This is true for all the planes in the (100) set of parallel planes. However, for d_{200} the angle of diffraction is (from Bragg's law) 17.96° and the peak is at 35.93°. Now the pathlength difference for the plane at 2.50 Å to the one passing through the origin is one wavelength, etc., so all the planes are in phase and a strong reflection is observed.

The rule for body centering is that the sum of the indices must be even to appear and are absent if the sum is odd. For face-centering the rule is the *hkl* values must all be even or all odd to appear, those with mixed indices are absent. A useful summary of the nature of the several types of cubic X-ray patterns is given in Figure 19. Similar absences appear for any body and face-centered unit cell so that by indexing any powder pattern one may be able to tell the lattice type.

4.2.4 Deriving the Unit Cell Dimension

We are now in a position to determine the value of a_0 for a cubic unit cell. By now the observant reader should have noted that the d-spacings decrease with increasing values of θ. This feature of the powder pattern is a direct result of Bragg's law, $\sin\theta$ and d have a reciprocal relationship. For the calculation it is convenient to use Bragg's law in the form of its square

$$\sin^2\theta = \frac{\lambda^2}{4d^2} \tag{10}$$

From the equation for d as a function of h, k, l we see that

$$\frac{1}{d^2} = \frac{h^2+k^2+l^2}{a_o^2} \tag{11}$$

substituting this result into equation (10) yields

$$\sin^2\theta = \frac{\lambda^2}{4a_o^2}(h^2+k^2+l^2) \tag{12}$$

Because h, k, l must be integers we may substitute $N = h^2+k^2+l^2$ into equation (12). Let $K = \lambda^2/4a_0^2$ so that equation (12) may be rewritten as

$$\frac{\sin^2\theta}{N} = \frac{\lambda^2}{4a_o^2} = K \tag{13}$$

A table is prepared by dividing the measured $\sin^2\theta$ values by allowed values of N. There should then arise a recurring value of K from which a_0 may be derived. Such a table for aluminum is provided as Table 4 from which it is shown that K is 0.0363. The derived value of a_0 is then

$$a_o = \frac{1.54056}{2\sqrt{K}} = 4.049\ \text{Å}$$

4.2.5 Indexing Procedure for Tetragonal Unit Cell

Although indexing powder patterns for crystals with more unit cell parameters than cubic may be carried out by similar procedures as just described, the task increases in difficulty with the number of parameters to be determined. For example, in the case of tetragonal crystals, we have

$$\sin^2\theta = \mathrm{A}(h^2+k^2) + \mathrm{C}l^2 \tag{14}$$

Where A and C are constants involving the a and c unit cell dimensions. The permissible values of (h^2+k^2) are 1, 2, 4,

Table 4 Calculation of the common quotient for Aluminum (Cu Kα radiation; $\lambda_{K\alpha 1} = 1.54056$ Å). (From *X Ray Diffraction, A Practical Approach,* 1998, C Suryanarayana & M Grant Norton. With kind permission of Springer Science & Business Media)

Peak #	2θ (°)	$\sin^2\theta$	$(\sin^2\theta)/2$	$(\sin^2\theta)/3$	$(\sin^2\theta)/4$	$(\sin^2\theta)/5$	$(\sin^2\theta)/6$	$(\sin^2\theta)/8$
1	38.534	0.1089	0.0544	**0.0363**	0.0272	0.0218	0.0181	0.01361
2	44.774	0.1451	0.0725	0.0484	**0.0363**	0.0290	0.0242	0.01813
3	65.124	0.2897	0.1448	0.0966	0.0724	0.0579	0.0483	**0.03621**
4	78.244	0.3981	0.1991	0.1327	0.0995	0.0796	0.0664	0.04977
5	82.438	0.4342	0.2171	0.1447	0.1086	0.0868	0.0724	0.05428
6	99.085	0.5789	0.2895	0.1930	0.1447	0.1158	0.0965	0.07237
7	112.008	0.6874	0.3437	0.2291	0.1718	0.1375	0.1146	0.08592
8	116.560	0.7236	0.3618	0.2412	0.1809	0.1447	0.1206	0.09045

5, 8 etc. Therefore $\sin^2\theta$ values are divided by these integers until a match is found. To obtain C a search for $00l$ reflections may be tried which are in the ratio of 1, 4, 9, 16 etc. for $l = 1$, 2, 3, 4, respectively. Alternatively we use the differences

$$\sin^2\theta - \mathrm{A}(h^2 + k^2) = \mathrm{C}l^2 \qquad (15)$$

to find a consistent set of $\mathrm{C}l^2$ values in the above ratio. Today, sophisticated softwares are available for determining unit cell dimensions for all crystal systems. Usually about twenty prominent reflections obtained over a range of 2θ values are used as input to the program. The correct unit cell should have reasonable values of the parameters in conformity with the symmetry of the crystals.

4.2.6 Automated Indexing Procedures

With the computing abilities of modern day computers increasing rapidly, indexing by manual means is almost not necessary even for the simplest systems.[9] However, the user is left with a large set of possible unit cells and corresponding Miller indices for them to decide which one to choose based on the a priori knowledge of the system in question. Information on the purity of the sample and acquiring best possible data are very essential to succeed using auto-indexing programs. Also, the figures of merit usually given by M_{20} and F_{20} help the user to choose between the various possible resulting unit cells.

Some of the common programs used are TREOR,[10] DICVOL,[11] and ITO.[12] TREOR is one of the fastest indexing programs and is based on trial-and-error methods. The program examines the data from higher to lower symmetry lattice, proceeding in steps. Trial parameters for various lattice constants are obtained from a set of baselines with standard Miller indices. DICVOL uses successive dichotomy approach for indexing. This program is usually more accurate and exhaustive but takes a lot of computing time. It is also very sensitive to systematic errors. ITO is a method based on reciprocal lattice zones. This program has been successfully used even for low-symmetry systems including triclinic unit cells. All three programs along with other indexing programs have been conveniently employed as subroutines in CRYSFIRE; thus having one input file for all the indexing programs is a major advantage. Newer software such as McMaille,[13] and EFLECH,[14] have also been used successfully in some difficult problems.

Recent software, taking advantage of fast computing, directly use the powder diffraction profiles instead of peak positions for indexing. Softwares such as X-Cell[15] (based on successive dichotomy approach similar to DICVOL) and TOPAS-I[16] (based on Monte Carlo methods) are examples.

The success rates of the modern indexing programs are very encouraging and provide the users with the ability to work even on lower symmetry systems.

4.3 Accurate Unit Cell Determination

Many applications require accurate unit cell determinations such as solid solutions studies and thermal expansion coefficients. We discuss the case of cubic crystals first. Precision in a_0, the unit cell parameter, depends upon accurate values of d. The key in this determination is to have accurate values of $\sin\theta$. Fortunately, $\sin\theta$ varies very slowly for θ angles near 90°. For example, an error of 1° in θ leads to an error in $\sin\theta$ of about 0.3% at 80° but to a 1.0% error at 60°. Therefore the approach is to measure the high angle reflections very accurately and carry out a linear extrapolation of a_0 as a function of θ.[6]

The proper extrapolation function depends on the type of diffractometer used for the measurements. Generally such functions are provided in the software provided with the instrument. Several sources of error need to be taken into account to insure that they are dealt with before undertaking the measurements.

1. Misalignment of the instrument. Proper alignment of the instrument is detailed in the company literature. An experienced operator should align the instrument and check to see that the incident beam intersects the diffractometer axis and the 0° position of the detector slit.
2. Displacement of the sample from the diffractometer axis. This is usually the largest error so care must be taken to properly place the sample.
3. Use of a flat specimen rather than a curved one to conform to the focusing circle. This error can be minimized by decreasing the irradiated width of the sample by decreasing horizontal divergence of the incident beam.
4. Vertical divergence error—may be decreased by decreasing the vertical opening of the detector slit.

With proper technique, and use of high angle data extrapolated to $\theta = 90°$ a precision of 0.001 Å in cell dimensions is possible. Use of a modern Guinier camera is advisable when the highest accuracy is required. This camera makes use of a focusing monochromator and a back reflection technique that is able to focus the reflected beam to a narrow line. This focusing results in excellent resolution and high accuracy. The data are recorded rapidly in digital form. Proper extrapolation of the data to $\theta = 90°$ removes systematic errors inherent in the data. However, extrapolation of the lattice parameter versus θ is not linear. Therefore, a function is required that can result in a linear extrapolation and the exact nature of such a function depends on the kind of equipment used to record the diffraction data. In most cases one of two extrapolation functions[17] may be used. They are as follows:

1. Bradley–Jay function, $\cos^2\theta$.
2. Nelson–Riley function $\dfrac{\cos^2\theta}{\sin\theta} + \dfrac{\cos^2\theta}{\theta}$.

The Nelson–Riley function has a greater range of linearity than the Bradley–Jay function. It is appropriate to use a least

squares procedure to obtain the best straight line through the data.

The extrapolation function $\cos^2\theta$ is best if the flat sample effect is the principal error, while $\cos^2\theta/\sin\theta$ for specimen displacement error. Using this latter function, it can be shown that

$$a = a_0 + a_0 \mathrm{k}\frac{\cos^2\theta}{\sin\theta} \tag{16}$$

where k is a proportionality constant. A plot of a values, determined at each measured θ as a function of $\cos^2\theta/\sin\theta$, yields a straight line. Extrapolation by a least squares procedure to $\theta = 90°$ provides the desired a_0 value. Similarly, if a Nelson–Riley function is used the corresponding equation is

$$a = a_o - a_o k\left[\frac{\cos^2\theta}{\sin\theta} + \frac{\cos^2\theta}{\theta}\right] \tag{17}$$

In this case values of a are plotted as a function of the term in brackets. Extrapolation to 90° yields $a = a_0$, the desired value. Examples of extrapolations as a function of $\cos^2\theta$ and $\cos^2\theta/\sin\theta$ are given in Figure 20.

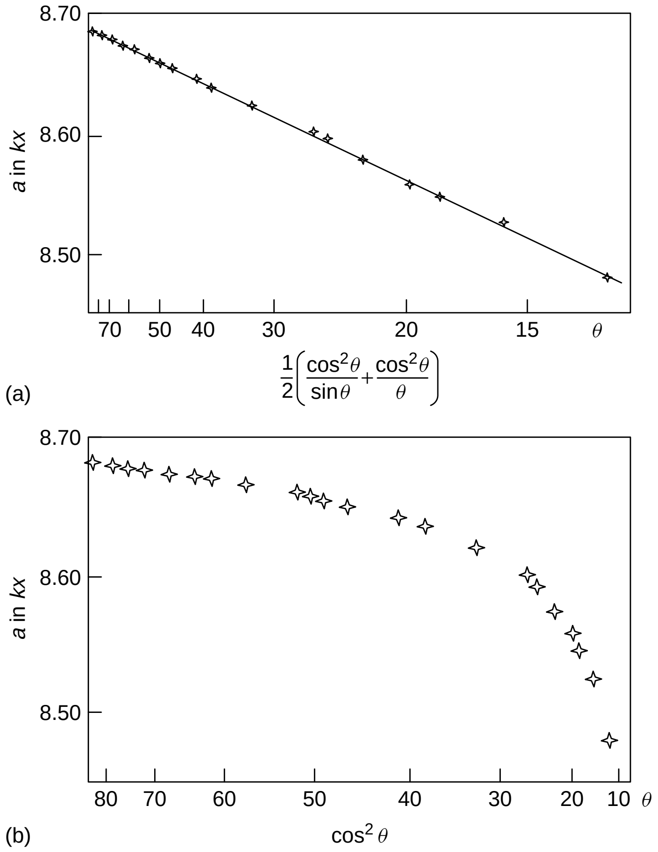

Figure 20 Plots of unit cell dimension a as a function of two different extrapolation functions. (Reprinted from Nuffield.[17] © John Wiley & Sons, Inc)

The Nelson–Riley function is linear over a broad range of θ angles, whereas the Bradley–Jay plot is linear only above about $\theta = 60°$. The B-J function is best when absorption is the largest error but where observational errors are large it is recommended that extrapolation as a function of $\cot^2\theta$ be used.[17]

4.3.1 General Procedure for Noncubic Unit Cells

As we have indicated the data with the lowest error in angle values is obtained at high θ, 50 to 80° in θ. Data at higher angles are not available so for the best accuracy an extrapolation must be made. For tetragonal and hexagonal systems hk0 data are required for the a-axis and 00l for the c-axis parameters. There may be very few such data at high angles leading to poor extrapolations. The procedure here is to use all the data and carry out a linear least squares procedure to obtain the best values. First the powder pattern must be indexed. If there is a set of unit cell dimensions in the ICDD file or in the literature, start with those values. The powder pattern should be run on a well ground pure sample, making sure to properly place the sample and calibrate the instrument with standard samples of Si or quartz. One of several programs may be used to index the powder pattern assigning *hkl* values to each peak. High resolution of the peaks is necessary. Use a step size of 0.02° or less and a count time of 10 s or more. Several iterations of the refinement may be necessary to obtain the best agreement between θ_{obs} and θ_{calc}. The least squares procedure is then applied to the data to obtain the best unit cell parameters.[3,6,8]

5 SOLID SOLUTIONS

5.1 Interstitial Solid Solutions

Solid solutions are classified as either interstitial or substitutional. Interstitial solid solutions occur when one of the components is very small and can fit into the interstices of the larger component. These are commonly formed between metals and carbon, nitrogen, hydrogen or boron. These solid solutions are always accompanied by an increase in volume of the unit cell. If the larger sized component A is cubic, then the value of a_0, its unit cell size must increase as the smaller component B is added. If a standard curve of a_0 as a function of the weight percent of its B content is prepared, this curve can be used to determine the level of B in any other sample of the solid solution. An example of such a solid solution is austenite, an interstitial solid solution[18] of carbon in face-centered γ-iron. A standard solid solution curve is shown in Figure 21 where it is seen that the increase in a_0 is a straight line function of the amount of carbon in the solid phase. If the solid solution is not cubic, one cell length may decrease while

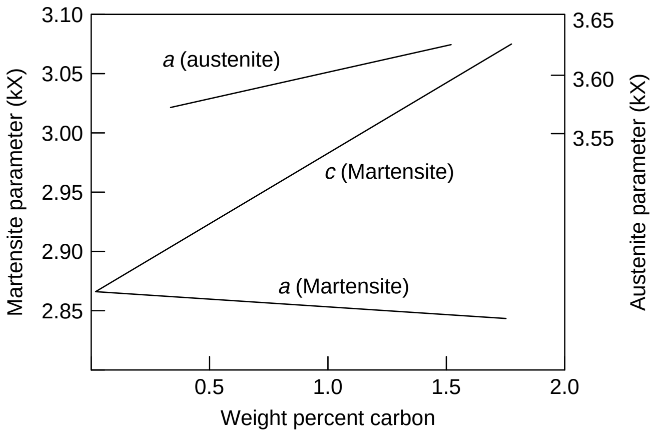

Figure 21 Variation of cubic austenite unit cell dimension a as a function of carbon content and that of tetragonal martensite in which the a-axis decreases as the c-axis increases with carbon loading

another increases, but the volume must always increase. This fact is illustrated for martensite, an interstitial solid solution of carbon in α-iron. α-iron is body centered tetragonal and as shown in Figure 21, the a-axis unit cell parameter decreases as the carbon content increases whereas the c-axis parameter increases.[3]

5.2 Substitutional Solid Solutions

Far more numerous are the substitutional solid solutions. They may be random or ordered. In the case of a random solid solution of B substituting for A there is a linear increase or decrease in volume depending on whether the B atom is larger or smaller than the A atom. This is Vegards Law, which in most cases is only approximate. For cubic unit cells, a plot of a_0 versus the percent B may be prepared over the solid solution range and used as a standard curve. The unit cell parameters need to be measured to four significant figures or at least three decimal places, as the increases in a_0 may be very small. For noncubic crystals one may plot the dimension of the axis that changes the most or unit cell volumes versus the atomic percent of B. The same parameter, cell dimension or volume may be used to determine the composition of the unknown sample.

It often occurs that the disordered or random solid solution has a limited composition range. This is heralded by the appearance of a new phase of $A + B$ by a change in slope of the plot. Alternatively a solid solution of B in A is accompanied by the appearance in the X-ray pattern of pure B, marking the limit of solubility of B in A. Another phenomenon that the reader should be aware of is ordering of a disordered structure. This usually occurs when a rational stoichiometry is reached such as AB_2 or AB_3. A classic case is the copper-gold alloy $AuCu_3$. In the disordered state the gold and copper atoms are randomly distributed so that on average each atomic position scatters as though it were occupied by a portion of a gold atom and a portion of copper

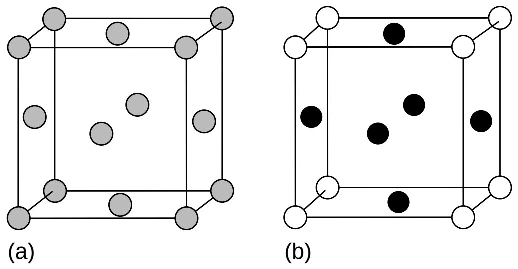

Figure 22 Depiction of the arrangements of metal atoms in solid solutions of gold copper alloys: (a) disordered structure in which the metal atoms are statistically distributed and (b) the ordered structure with copper atoms (filled circles) are in the face centers and gold atoms (open circles) at the cube corners

atom (Figure 22a). In this disordered state the crystals are face-centered cubic and thus there are four total atoms within the unit cell. The gold atoms provide 1/4 Au at each site and Cu supplies 1/4 Cu, but there are three coppers; so each site has a contribution of 3/4 Cu. Each site has the same occupancy and the X-ray pattern exhibits the systematic absences of a face centered cubic (FCC) lattice. In the ordered state the Au atoms occupy the corners of the unit cell, whereas the Cu atoms occupy the face centers. Now the pattern resembles that of a primitive unit cell with reflections at 2θ values at the angles of previously absent ones. These reflections are weak for the following reason. The arrangement of atoms is as shown in Figure 22(b). The 100 reflection will appear because the plane halfway between the gold and Cu atoms in the (100) planes are all copper atoms. Thus the scattering power of the two atomic planes is not equal and the reflection will not be extinguished. The (200) planes will be strong as in a true FCC unit cell because all the planes will now be in phase. However, in this primitive unit cell all the reflections normally absent in a face-centered cell will be weak, revealing the nature of the structure.

6 CRYSTALLITE SIZE DETERMINATION AND LATTICE STRAIN

6.1 Crystallite Size Determination

When the crystallites within a sample are smaller than 100 nm (0.1 µm) the X-ray reflections are broadened. Diffraction theory indicates that the diffraction peaks should be extremely thin, just a few seconds of a degree. However, all diffraction peaks have a measurable width, as illustrated in Figure 23. This width arises from the divergence of the incident beam and the width of the X-ray source. These factors are termed instrumental broadening and depend upon the instrument used. There is another factor that influences the peak width known as domain size. Even highly ordered crystals are thought to consist of small domains that are

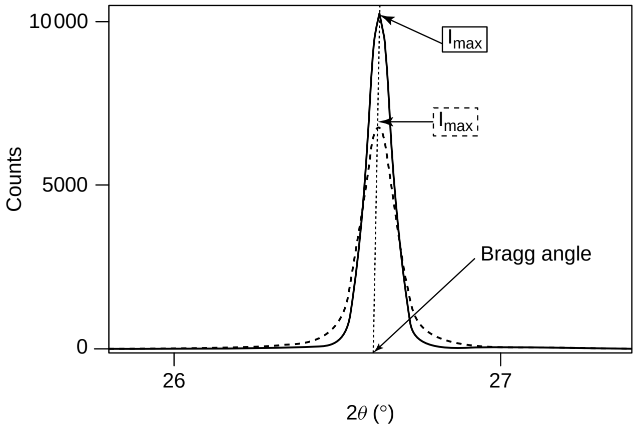

Figure 23 The relative broadness of powder diffraction peaks based upon theory (dotted line) and instrumental broadening (continuous line). The effect of reduced crystallite size in lowering I_{max} and widening of the peak (increasing FWHM) is shown with dashed line

slightly disoriented relative to each other. Some domains are in a position to diffract slightly before the Bragg angle and the others slightly behind. This has the effect of broadening the peak over that predicted by diffraction theory. However, the effect of small crystallite size is not detectable if it is below about 200 nm. Figure 23 shows the effect of peak broadening due to small crystallite size. The peak height is reduced, but the FWHM is increased. Sherrer provided an equation for the crystallite size in terms of peak broadening.[3,8]

$$t = \frac{0.9\lambda}{B\cos\theta} \tag{18}$$

where, θ is the Bragg angle, λ is the wavelength, B is the FWHM, and t is the crystallite size.

For more precise values, especially for crystallites larger than 500 Å, the instrumental broadening should be subtracted. The value of B is measured in degrees, but the equation requires that it be given in radians.

Example: Suppose a peak at $\theta = 10°$ gave a measured B value of 0.20°. Dividing by 57.3°/radian yields 3.49×10^{-3} radians with $\lambda = 1.542$ Å for Cu Kα.

$$t = \frac{0.9 \times 1.542\,\text{Å}}{3.49 \times 10^{-3} \times \cos 10°} = 404\,\text{Å}$$

The size of the crystallite perpendicular to the planes indexed at $2\theta = 20°$ is 404 Å. If the indices are known, say the peak was the 111 reflection, the perpendicular is along the unit cell diagonal.

Let us now see what the effect of subtracting the instrumental broadening has on the calculation of the crystallite size. The best procedure, if it is possible to do so, is to anneal the compound of interest at elevated temperature so that the peaks no longer show a broadening effect. The FWHM of the 111 peak is then used as the value of B_{inst}. Barring this, a compound such as ceramic alumina may be used, choosing a peak near the same 2θ value as for the compound under investigation. For Lorentzian-shaped peaks the subtraction is straightforward,

$$B = B_{\text{meas}} - B_{\text{inst}}$$

The measured B_{inst} was 0.03°, yielding $B = 0.20 - 0.03° = 0.17°$ and $t = 484$ Å. Similarly, for Gaussian shaped peaks the correction is

$$B^2 = B^2_{\text{meas}} - B^2_{\text{inst}}$$

For the same measurements we have

$$B^2 = (0.2)^2 - (0.03)^2 = 0.04 - 9 \times 10^{-4} = 0.0391$$
$$B = 0.1977 \text{ and } t = 408\,\text{Å}$$

It is seen that the correction for Gaussian peaks is small. However, most peaks have contributions from both Gaussian and Lorentzian shaped peaks. Programs are available to map the shape of X-ray reflections as a combination of the two shape functions. Suppose we find that the peak shape is two-thirds Lorentzian and one-third Gaussian. Multiplying the results for each type by their respective fractions give a value of 459 Å. The larger B_{meas} is, the less the influence of the instrumental correction because we are subtracting a small width from a much larger one.

To obtain a more complete picture of the crystallite size it is good to measure about three peaks with indices that place the plane normals in different directions, for example 111, 200, 220, or 202. The value of the cosine function does not change much at low values of θ, but changes more rapidly above $2\theta = 40°$.

It should be remembered that the accuracy with which the crystallite size may be determined decreases with increasing crystallite size. The limit is about 2000 Å with careful and accurate measurement of the peak profile, the FWHM and the instrumental broadening. Furthermore, the result is an average over all the crystallite sizes, as the method does not provide the distribution of sizes in the sample.[19]

6.2 Determination of Strain

There is another factor affecting peak broadening that should be considered, lattice strain.[20] Strain may result from ball milling, compression of small particles into larger aggregates for use as catalysts, and plastic deformation of metals. Strain may be either uniform or nonuniform in the direction of a set of parallel planes. If the grain is then given a uniform tensile strain at right angles to the set of parallel planes, the interlayer spacings of this set of planes will increase slightly. This increase has the effect of shifting the peak to a lower two θ value. If the strain is nonuniform, the grain bends and the set of parallel planes will have a nonuniform change of d-spacing. On one side the d-spacing will increase, in the middle it will be the same as the nonstandard state, and on

the bottom the planes will have a smaller d-spacing. The net effect is a broadened X-ray peak. The relationship between the broadening, b, and the nonuniformity of the strain is obtained by differentiating Bragg's equation

$$b = -2\frac{\Delta d}{d}\tan\theta \tag{19}$$

The total broadening is a combination of equation (19) and equation (18), broadening by crystallite size and by strain

$$B_{\mathrm{Total}} = B_{\mathrm{Crystallite}} + b_{\mathrm{Strain}} \tag{20}$$

The left hand side of equation (20) is the same as $B\cos\theta$ in the Sherrer equation (18). If the peak broadening is only due to particle size, then the value of $B\cos\theta$ should be constant with variation of θ. If strain broadening is important, then $B\cos\theta$ should change as a function $\sin\theta$. Measurement of the FWHM over a range of θ values is required. A plot of $B\cos\theta/\lambda$ versus $\sin\theta/\lambda$ is shown in Figure 24. Extrapolation to $\sin\theta = 0$, yields the value of $B\cos\theta$ due to particle size only. Dividing by λ makes the curve independent of wavelength. The slope of the line is $-2(\Delta d/d)$ that provides the broadening resulting from strain.

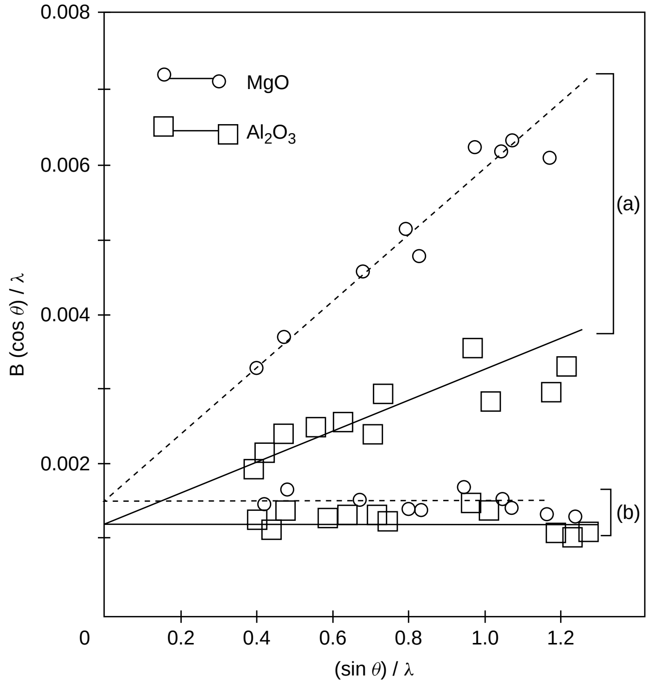

Figure 24 Plot of B $(\cos\theta)/\lambda$ as a function of $(\sin\theta)/\lambda$ for (a) oxides ball milled to introduce strain and (b) the same oxides heated to 1350 °C to remove the effects of strain. (Reprinted from Langford and Louer.[2] © Pearson Prentice Hall)

7 QUANTITATIVE ANALYSIS

7.1 Background Theory

The central problem in carrying out quantitative analysis of a mixture of phases by X-ray powder diffractometry is that the intensity of the peaks is not linear with concentration. For quantitative analysis of binary solid solutions, see the section on solid solutions. Here we concern ourselves with mixtures of two or more phases. In such cases the intensity depends upon the absorption of the sample. We assume that the two phases have already been identified from prior knowledge or from the powder pattern. The expression for the intensity of a reflection from a set of parallel planes hkl, I_{hkl} is a very complex equation. For our purpose we will use a simplified form.[3,4,21]

$$I_a = \frac{K_a V_a}{\mu_\ell^m} \tag{21}$$

where K is a constant, V_a is the volume fraction of phase a in the mixture, and μ_ℓ^m is the linear absorption coefficient of the mixture. Each element in the mixture has its own value of μ_ℓ. We recall from equation (6) that passage of an X-ray beam through a slab of an element of thickness x reduces the intensity of the initial beam I_o as $e^{-\mu_\ell x}$, where μ_ℓ is the linear absorption coefficient. The absorption coefficient depends upon the number of atoms in the path of the beam because it is the electrons that scatter the X-rays out of the path of the incident beam. Therefore we may rewrite equation (21) as

$$I_a = \frac{V_a}{\sum_1^n V_n \mu_\ell^n} \tag{22}$$

The denominator is the sum of the volume fraction of each element, V_n, multiplied by its respective linear absorption coefficient μ_ℓ^n. To facilitate calculations based upon absorption coefficients, a second coefficient was defined as

$$\mu_m = \frac{\mu_\ell}{\rho} \tag{23}$$

where, μ_m is the mass absorption coefficient and ρ is the density of the absorber.

Tables of μ_m values, based upon measured μ_ℓ for each element divided by their respective densities, are collected in the International Tables for Crystallography Vol. C. The variation of μ_m with wavelength has the general form shown in Figure 5. Because volume times density equals weight we may rewrite equation (21) in terms of weight fraction

$$I_a = \frac{K_a W_a/\rho_a}{\sum_1^n (W_n/\rho_n)\mu_\ell^n} \tag{24}$$

applying equation (23), equation (24) may be rewritten as

$$I_a = \frac{K_a W_a/\rho_a}{\sum W_n \mu_m^n} \tag{25}$$

However, our aim is to determine the weight fraction of a phase in a two-component mixture. Therefore, in terms of two phases 1 and 2 the intensity due to phase 1 is

$$I_a = K_a \frac{W_a/\rho_a}{W_a\mu_m^a + W_b\mu_m^b} \tag{26}$$

where μ_m^a, μ_m^b are the mass absorption coefficients of the two phases, respectively and W_a, W_b are their weight fractions. Mass absorption coefficients need to be calculated for each phase. In general, for a compound the mass absorption coefficient is given by summing up the individual mass absorption coefficients of each component multiplied by their respective weight fractions

$$\mu_m^{cp} = W_a\mu_m^a + W_b\mu_m^b + W_c\mu_m^c \cdots \tag{27}$$

Example: What is the mass absorption coefficient of LiCl for Cu Kα radiation? According to equation (27),

$$\mu_m^{LiCl} = W_{Li}(\mu_m^{Li}) + W_{Cl}(\mu_m^{Cl}) \tag{28}$$

The necessary mass absorption coefficients for the elements are taken from the tables for the particular wavelength used in the analysis; in this case Cu Kα.

$$\mu_m^{Li} = \frac{1.10\,\text{cm}^2}{\text{g}}, \quad \mu_m^{Cl} = \frac{109.3\,\text{cm}^2}{\text{g}}$$

These units arise from the fact that the linear absorption coefficient has the units of cm^{-1}. Therefore,

$$\mu_m = \frac{\mu_\ell}{\rho} = \frac{\text{cm}^{-1}}{\text{g/cm}^3} = \frac{\text{cm}^2}{\text{g}} \tag{29}$$

The formula weight for LiCl is 42.392 g, therefore

$$\mu_m^{LiCl} = \frac{6.939\,\text{g}}{42.392\,\text{g}}(1.10) + \frac{35.453\,\text{g}}{42.392\,\text{g}}(109.3) = \frac{91.40\,\text{cm}^2}{\text{g}}$$

7.2 External Standard Method

If the phases within the mixture are known or were identified from the powder pattern of the mixture, we can calculate the mass absorption coefficients in equation (26). The most common method of determining W_a is to compare a peak in the mixture with the same peak in the pure phase. For a pure phase we may write from equation (21)

$$I_a^p = \frac{K_a}{\rho_a\mu_m^a} \tag{30}$$

Dividing equation (30) into equation (26) gives

$$\frac{I_a}{I_a^p} = \frac{W_a\mu_m^a}{W_a\mu_m^a + W_b\mu_m^b} \tag{31}$$

To eliminate W_b, we use the fact that $W_b = 1 - W_a$, from which we derive our required equation by making this substitution

$$\frac{I_a}{I_a^p} = \frac{W_a}{W_a(\mu_m^a - \mu_m^b) + \mu_m^b} \tag{32}$$

The meaning of equation (32) is that the intensity of any peak hkl in the mixture I_a divided by the intensity of the same peak in the pure sample of phase a, I_a^p is given by the right hand side of the equation. The mixture and the pure phase measurements are carried out exactly in the same way. It is assumed that the phases have been identified prior to the intensity measurements, so their mass absorption coefficients may be calculated. As an example we will consider a mixture of LiCl and $CaSO_4$. The mass absorption coefficient of calcium sulfate is 77.37 cm^2/g. Let us assume that the mixture contains 10 weight percent $CaSO_4$. The mass absorption coefficient of the mixture is then

$$\mu_m^m = 0.1 \times \frac{77.37\,\text{cm}^2}{\text{g}} + 0.9 \times \frac{91.40\,\text{cm}^2}{\text{g}}$$

$$\mu_m^m = \frac{7.737\,\text{cm}^2}{\text{g}} + \frac{82.26\,\text{cm}^2}{\text{g}} = \frac{89.997\,\text{cm}^2}{\text{g}}$$

The ratio of the observed peak in the mixture to that peak in pure $CaSO_4$ is

$$\frac{I_a}{I_a^p} = \frac{0.1 \times 77.37\,\text{cm}^2/\text{g}}{89.997\,\text{cm}^2/\text{g}} = 0.0859$$

By calculating this ratio over a range of weight fractions of phase 1, a standard curve is obtained. The best fit of the experimental ratios for several reflections fixes the actual percentage of phase 1. In Table 5 we have tabulated the intensity ratios for increasing ratios of $CaSO_4$ to LiCl in a mixture of the two compounds. The results are plotted in Figure 25.

We note in Figure 25 that the intensity ratios for $CaSO_4$ are slightly below the line for pure $CaSO_4$. This is a common effect. When the absorption coefficient of the compound in question is lower than that of the other member of the binary mixture, the curve dips below the line. The phase with the larger μ_m value will produce a curve that falls above the line (Figure 26).

The method just described suffers from the disadvantage that two separate XRPD patterns must be

Table 5 Cumulated standard curve for intensity ratios of increased ratio of $CaSO_4$ in a mixture of Calcium Sulphate and Lithium Chloride ($\mu_m^{LiCl} = 91.4$, $\mu_m^{CaSO_4} = 77.37\,\text{cm}^2/g$)

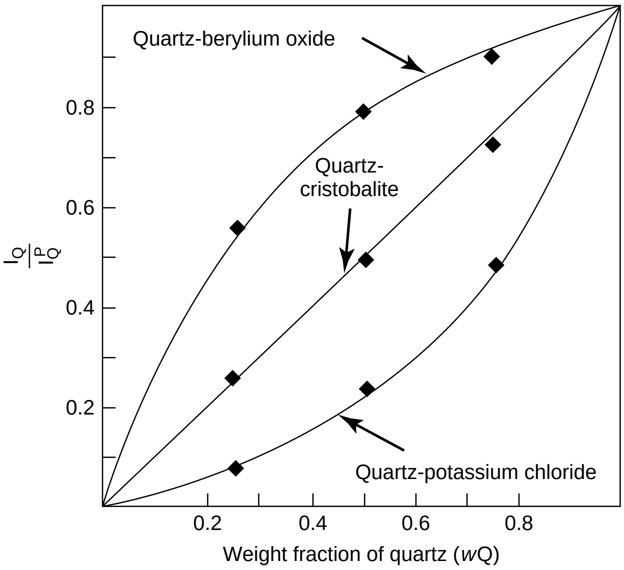

Figure 26 A plot of the intensity of quartz in three binary mixtures compared to the intensity of the same plane in pure quartz as a function of the weight fraction of quartz in the mixtures. Conditions: Cu Kα, $d = 3.34$ Å, mass absorption coefficients, BeO 8.6; SiO_2 34.9; KCl 124 cm^2/g. (Reprinted from Nuffield.[17] © John Wiley & Sons, Inc)

recorded, one for the mixture and another for the pure phase. Both patterns must be taken under identical conditions requiring a certain amount of operator care. However, the use of an internal standard avoids this problem.

7.3 Internal Standard Method

Suppose we wish to determine the weight fraction of a phase A in a mixture of phases A, B, C, D, ... This can be done by mixing a weighed amount of a standard compound with a known amount of the sample. While the absorption coefficient for the entire mixture may be unknown, if we consider the ratio of the intensity of a peak from phase A, I_A, to that of a peak from the standard, I_s, the μ_m drops out of the equation because it is the same for both peaks. Physically, this means that variations in absorption due to variations in the sample have no effect on the ratio I_A/I_s. In other words, the total absorption affects both intensities equally. The working equation is then a simple one

$$\frac{I_A}{I_s} = KW_A \quad W_A = \text{weight fraction of phase } A \tag{33}$$

Equation (33) states that the ratio of intensities from a peak from phase A and one from the standard is a linear function of the weight fraction of phase A. A calibration curve can be set up containing known concentrations of A and a constant concentration of a suitable standard phase. Then the concentration of phase A in the unknown is obtained by measuring I_A/I_s in which the same amount of the standard was added to the unknown as was used to prepare the standard curve. Good standards to use are α-Al_2O_3, a synthetic corundum marketed as Linde A and CaF_2, fluorite.

7.4 Practical Difficulties

In dealing with powders, accurate sampling and homogeneous mixing is necessary to obtain accurate results. Examination of the sample for homogeneity may be effected with a low power binocular microscope. Further grinding the sample with an agate mortar and pestle is recommended to achieve a fine textured uniformity. If the sample was taken from a larger prepared quantity then good sampling techniques are in order.[4] PO will result in some peaks being inordinately intense and others being weak. Rotation of the sample in a capillary tube improves the situation by presenting more crystal orientations.

8 HIGH AND LOW TEMPERATURE POWDER PATTERNS

Temperature controlled powder patterns at higher or lower temperatures than room temperature are useful for tracking phase changes, obtaining improved intensity data, measuring coefficients of expansion, tracking dehydration, etc.

8.1 Background and Theory

There are many factors that determine the intensity of a diffracted beam. For simplicity we shall indicate the equation as

$$I = k|F^2|(LP)\frac{T}{A} \tag{34}$$

where k is a constant containing many terms, F is the structure factor, *Lorentz and polarization* (LP) is the LP factors, T is the temperature factor and A is the absorption factor. We have already seen that the absorption effects are quite profound and need to be considered when dealing with intensities. The structure factor is the only term that arises from the positions of all the atoms in the unit cell. It shall be dealt with in detail in the next section. L (for Lorentz) is a geometric factor that depends upon the way in which the data are obtained, and P stands for the polarization effect. When X-rays are diffracted, partial polarization of the beam takes place. If a monochromator is used, the beam is polarized twice, once from the monochromator crystal and once from the sample. However, in this section we are interested in T the temperature factor. In its simplest form

$$T = \exp\left[-B\left(\frac{\sin^2\theta}{\lambda^2}\right)\right] \tag{35}$$

where B is a temperature coefficient. It is related to the mean square amplitude of vibration ($\bar{u}^2$) as

$$B = 8\Pi^2\bar{u}^2 \tag{36}$$

The atoms within a solid vibrate as a function of temperature. The greater the vibration the larger is B and the greater is the reduction of the intensity. The decrease in intensity is also angle dependent. This contribution is attributable to the finite size of the electron clouds of the atoms. The larger this cloud, for a given number of electrons, the greater the decrease in the atoms scattering effectiveness. Units of $Å^2$ are assigned to B so that the exponent in equation (35) is unitless. B has values between 2 and 5 $Å^2$ for most atoms at room temperature. As an example, suppose we determine that an overall temperature factor, B, for a compound is 3 Å and that the (111) reflection occurs at $\theta = 15°$. Then for Cu Kα using equation (35)

$$T = \exp\left[-3\,Å^2\left(\frac{0.2588}{1.542\,Å}\right)^2\right] = \exp(-0.08452) = 0.919$$

Thus, the intensity is reduced by this amount. At higher angle of 60° for the (824) reflection $T = 0.388$, a significantly larger reduction of the intensity. As the temperature is reduced, B reduces proportionately because the atoms vibrate less energetically and the intensities correspondingly increase. Conversely, as the temperature is raised the atoms vibrate more vigorously, increasing $\bar{u}^2$ and the intensities are lowered.

8.2 Thermodiffraction

We shall illustrate the use of recording XRD patterns at elevated temperatures with some practical examples. The diffractometer was a Siemens D-5000 fitted with a special goniometer permanently equipped with an HTK 10 heating chamber. The samples were mounted directly on Pt foil, which is both the heater and the sample holder. The patterns were scanned over the angular range of 3 to 38° in 2θ with a step size of 0.05° and counting for 15 s per step.

The sample studied was a cobalt bis(phosphonate) of composition $Co_2(O_3PC_6H_4OC_6H_4PO_3)\cdot 2H_2O$. It is one of the series of first row transition element compounds with the same general formula, but different water contents.[22] The Cu(II) compound structure was solved from its powder pattern, unit cell dimensions $a = 8{:}1012(5)$, $b = 5.3109(3)$, $c = 29.2595(5)$ Å. It has a layered structure in which the layers are spaced at half the c-axis dimension. The reason for the doubling of the c-axis is that in one layer the rings are tilted around the ether oxygen to the left and in the next layer to the right. The Cu atoms are 5-coordinate with square pyramidal structure.

The unit cell dimensions for the Co derivative could not be determined because of the poor quality of the powder pattern (Figure 27, RT). The first diffraction peak is at $2\theta = 6°$, $d_{001} = 14.73$ Å, a value that is very close to half the c-axis of the copper compound. Thermal analysis showed that two moles of water are lost at 160 °C. The thermodiffraction patterns in Figure 27 are similar from room temperature to 120 °C. The pattern taken at 160 °C is characterized by a reduction in intensity of all the peaks, a small shift in the position of the first peak to higher 2θ indicative of a small decrease in the interlayer spacing. The sample color changes from purple to blue. The same X-ray pattern persisted to 240 °C. Upon cooling to room temperature the original color was restored and the original X-ray pattern restored but with lower intensities. These changes indicate that the original coordination of the Co was octahedral and became tetrahedral upon loss of the two water molecules at 160 °C. Diffuse reflectance measurements confirmed this coordination transition. It was then possible to construct a model structure for the cobalt compound.[22]

A second example involves an aluminum phenylphosphonate whose composition was found to be $Al_2(O_3PC_6H_5)_3\cdot 2H_2O$.[23] A combined thermogravametric analysis (TGA) and differential thermal analysis (DTA) gave an endothermic event at ~80 °C and three exotherms centered at 600, 840 and 950 °C. The X-ray thermodiffractometric powder patterns are presented in Figure 28. The equilibration time at each temperature was 15 min before obtaining the pattern. The highest d-spacing recorded at room temperature is very weak with $d_{001} = 26.1$ Å and the second very intense peak is at 13.2 Å and very likely the 002 reflection. A phase change begins at ~45 °C and both phase I and II coexist to 60 °C, whereupon only phase II remains. In phase II, the dehydrated phase, the d_{001} and d_{002} peaks shift to 23.2 and 11.7 Å. Once again, we expect that the layer separation in both cases is half d_{001}, but the unit cell dimension is doubled. This is apparently due to a large difference in arrangement of two contiguous layers such that they largely diffract out of phase, but at half the distance all the layers diffract in phase, accounting for the weak–strong effect. Exposure of the dehydrated phase at room temperature results in rehydration.

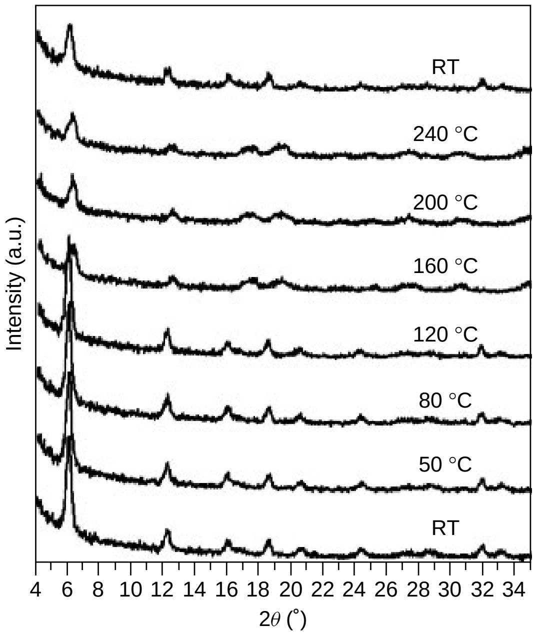

Figure 27 X-ray thermodiffraction powder patterns for $Co_2(O_3PC_6H_4OC_6H_4PO_3)\cdot 2H_2O$ showing dehydration takes place between 120 °C and 160 °C and rehydration at room temperature

Upon heating the sample above 500 °C, combustion of the organic phase occurs, accounting for the large exotherm. The X-ray pattern is amorphous above this temperature. Crystallization to a mixture of $AlPO_3 + AlPO_4$ occurs at 950 °C. The overall reaction is

$$2Al_2(O_3PC_6H_5)_3 \cdot 2H_2O + 450_2 \longrightarrow Al(PO_3)_3 + 3Al\,PO_4 + 36CO_2 + 19H_2O$$

A knowledge of the end products obtained at 950 °C allows confirmation from the total weight loss of the formula of the synthesized compound.

8.3 Determination of Thermal Expansion Coefficients

Thermal expansion studies are not frequently pursued, but can give valuable insight into the behavior of solids. Because the increases in unit cell dimensions over a range of temperatures are very small the data must be extremely accurate. This requires that the furnace have a constant temperature zone surrounding the sample with thermocouples touching the sample holder. Because of the possible movement of the sample during heating, it is advisable to have an internal standard such as α-Al_2O_3 or TiO_2,[24,25] whose peak positions can be used to correct the 2θ values. A back reflection digital Guinier camera is recommended for the measurements. However, it is convenient to do the measurements at a synchrotron such as NSLS at Brookhaven National Laboratory. There is a current interest in low and negative thermal expansion coefficients.[24–26] Figure 29 presents some data for cubic low expansion behavior by $TaOF_2$ and normal expansion behavior by NbO_2F. The expansion data for NbO_2F were measured from 20 K to 300 K. The total expansion over this temperature range was 0.0113225 Å and the initial unit cell dimension was 3.888226 Å. The linear expansion coefficient is the observed expansion value divided by the initial unit cell dimension divided by ΔT, 280 K. The value obtained for NbO_2F is 104×10^{-7}/K. We note that for TaO_2F there is almost no change in cell dimension even over a very large temperature range. The three data sets give values of $1 - 6 \times 10^{-7}$/K. Sleight has discussed mechanisms of low and negative thermal expansion coefficients involving movement or rocking of metal oxygen polyhedra which reduces the space between the polyhedra (Figure 30).

For noncubic unit cells, the expansion or change of each cell dimension is required. The coefficients may be presented as linear for each cell dimension or as volume expansion coefficients, in which case the total volume change is divided by the initial volume. Division by the temperature

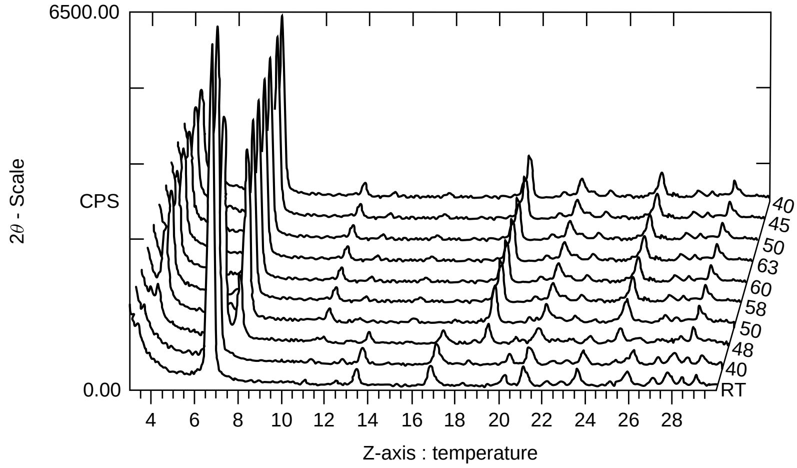

Figure 28 X-ray Thermodiffraction patterns for $Al_2(O_3PC_6H_5)_3.2H_2O$ showing a phase change occurring between 40 °C and 50 °C

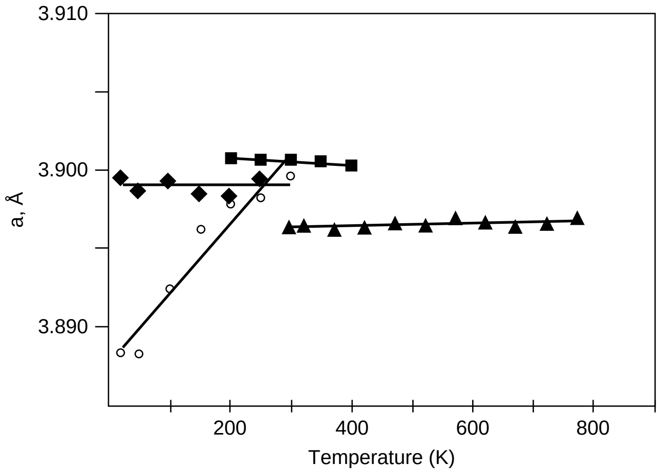

Figure 29 Changes in cubic unit cell dimensions for a phase, NbO_2F, with positive cell expansion and TaO_2F showing near zero expansion. (Reprinted from Tao and Sleight[24] © Elsevier 2003)

over which the measurements were made yields the desired volume expansion coefficients.

9 AB INITIO STRUCTURE DETERMINATION FROM POWDER DIFFRACTION DATA

With the advancement in many facets of powder diffraction including sources, sampling techniques, detectors and software, in particular, with the availability of high speed computing, ab initio structure determination from PXRD data has become increasingly feasible even for systems of reasonable complexity.[6,27] Also, the structure determination is becoming progressively automated starting from the raw powder data all the way to the structure refinement, with minimum assistance from the user, for at least simple structures. Complexity of the structures that can be solved with the availability of synchrotron X-ray sources is also ever increasing. We discuss below some of the fundamental aspects of ab initio structure determination. A flow chart on the different steps involved in ab initio structure determination is given in Figure 31.

9.1 Software Available for Different Steps Toward ab initio Structure Determination

Data collection software is generally supplied by the instrument manufacturers. This data collection software would also normally be equipped to perform preliminary analysis including peak finding routines and search/match of powder diffraction patterns from a database. The most popular database for powder diffraction data is maintained by the International Centre for Diffraction Data.[28]

Although approximate peak positions could be obtained from many different types of software, programs which use peak shape functions to fit the powder diffraction peak profiles are more appropriate to determine the peak position more precisely. Some of the common programs are XFIT,[29] TOPAS,[30] etc.

For autoindexing software, see Section 4.2.5 for details.

Space group possibilities based on systematic absences can be obtained from the International Tables for X-ray Crystallography, or can also be determined using CHEKCELL.[a]

For structure solution software, see Section 9.3 for details.

A number of software programs are known for structure refinement. The most common programs used are FULLPROF,[b] GSAS,[c] RIETAN,[31] and TOPAS.[30]

Some of the software can perform several steps toward structure determination, for example, DASH,[32] TOPAS,[30] POWDERSOLVE,[33] etc.

Various programs have specific advantages and limitations. The website www.ccp14.ac.uk maintains a list of public domain software and their details. It also gives the most recent advancements in current and new software.

9.2 Profile Fitting

There are a multitude of applications for profile fitting: accurate peak position determination, stress and strain

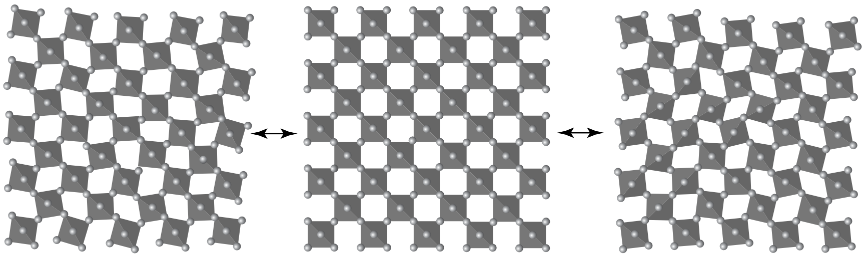

Figure 30 Rocking of the ReO_3 structure indicating possible correlation of the transverse thermal motions of the oxygen atoms. The octahedra do not change volume on rocking, but the distance between the octahedra decreases as they rock away from the structure in the middle producing negative thermal expansion. (Reprinted from Tao and Sleight[24] © Elsevier 2003)

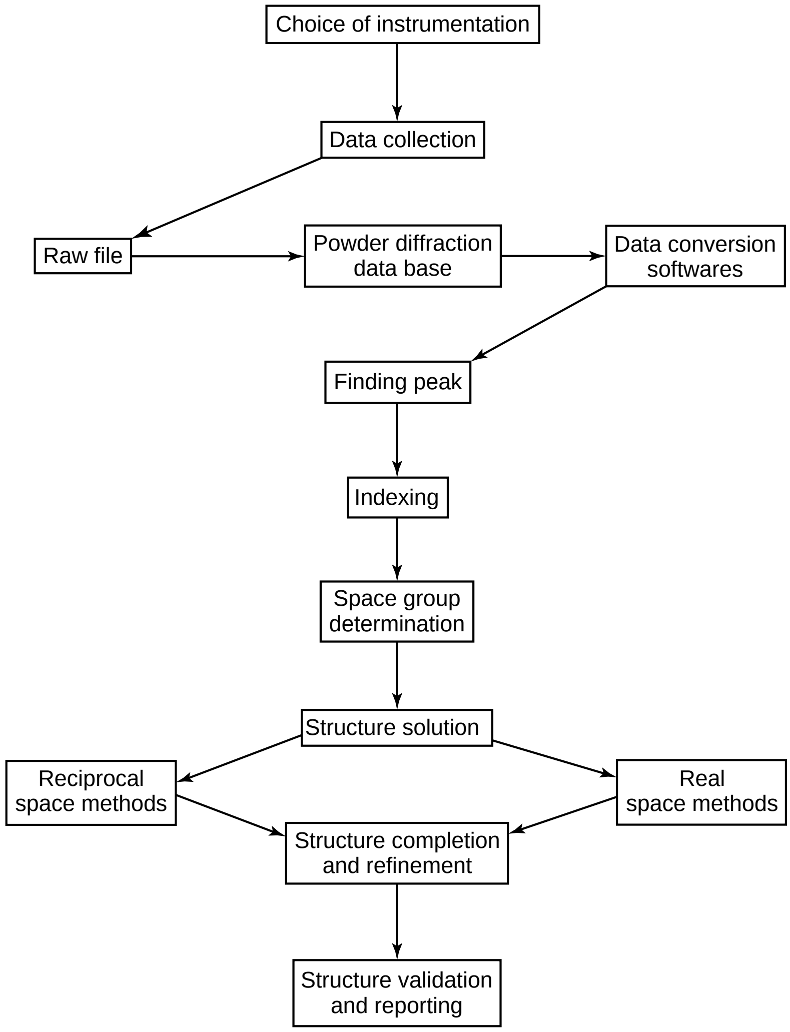

Figure 31 Various steps involved in ab initio structure determination from PXRD

analysis, intensity extraction for ab initio structure solution, etc.[6,34]

9.2.1 *Peak Position determination*

Accurate peak position is very important for determining the unit cell constants using various autoindexing programs. The peak position obtained by visual judgment of the peak height maximum suffers in samples showing (i) pronounced asymmetry, (ii) significant transparency, (iii) considerable peak overlap, etc. Under such circumstances, profile fitting individual or overlapping peaks using one of the common peak profile functions, namely, Gaussian, Lorentzian, Pseudo-voigt, or Pearson-VII provides improved peak position for indexing. Also, use of the fundamental parameter approach, implemented in some of the programs such as TOPAS, in addition to giving more accurate peak positions, can also give a rough estimate of particle sizes.

9.2.2 *Full-Profile Fitting*

As the name indicates, fitting the complete powder diffraction profile as a function of intensities, background and a peak shape function is full-profile fitting.[34]

In addition to extracting the integrated intensities, full-profile fitting provides a useful means to establish the truthfulness of the unit cell constants, and the choice of space group of a powder pattern. Although space group determination can be done by the examination of the systematic absences, in PXRD, due to exact and accidental overlap of the peaks, a knowledge of systematic absences would lead only to the extinction symbol. More recently, methods based upon Bayesian probability theory have been successfully used to estimate the most probable space groups, by using integrated intensity covariance matrix obtained by profile fitting using one of the profile fitting methods.

There are three common methods used for full-profile fitting, namely, Le Bail method,[35] Pawley method,[36] and

fundamental parameter approach for extraction of integrated intensity data from powder diffraction patterns. These methods are also often called pattern decomposition methods.

The Pawley method is a method of least squares analysis where parameters that depend on the intensities, namely, atomic coordinates, displacement parameters, etc., are ignored and refinement is against the intensities themselves.

The Le Bail method is a clever extension of the original work of Rietveld. The key difference between the two methods is that the Le Bail method uses iteratively the values of intensities obtained from the previous least squares cycle, and assumes unit values for all the peaks to initiate the refinement. Rietveld's method, on the other hand, uses the intensities calculated based on an initial model for the structure.

Both the Pawley and Le Bail methods of intensity extraction or pattern decomposition have their own benefits and shortcomings.

The fundamental parameters approach[37] has been recently implemented in some of the current programs. It gives, to a certain extent, physical meaning to the parameters involved in pattern decomposition. This method attempts to model the contributions from various instrumental components (such as monochromators, slits) and geometry to the observed peak profile shapes. Since this is done considering the relevant physics involved from the generation, diffraction, and detection of PXRD, it leads to more physical meaning than the two methods described earlier. This method can be used not only to perform full pattern decomposition, but also effectively to do a standardless refinement of the sample effects such as crystallite size and microstrain.

9.3 Structure Solution

Structure solution in powder diffraction[27] is approached by two different methodologies. One is using the conventional reciprocal space methods. The second is by real space methods where all the known details about the sample (say, molecular details such as bond distances, angles, etc., for an organic molecule, and coordination spheres such as octahedral, tetrahedral etc., in case of inorganic compounds) in question are exploited to solve the structure.

9.3.1 *Reciprocal Space Methods*

In theory single crystal methods can be effectively used for structure solution from powder diffraction X-ray data. However, in powder diffraction the number of peaks involved are limited, and hence the data-to-parameter ratio is very small, due to the transfer of the three-dimensional data to one dimension, namely, 2θ. In spite of the inherent shortcomings, conventional crystallographic methods such as Direct, Patterson and maximum entropy methods have been successfully applied to powder diffraction data. The most popular program, which uses reciprocal space methods for structure solution is EXPO.[38]

In Direct methods, the intensities are extracted from an indexed powder diffraction pattern by profile fitting procedures such as the Le Bail method and Pawley method. Then the integrated intensities obtained are corrected for Lorentz polarization and normalized. These corrected intensity values are then subjected to routine Direct-method procedures. The structural model obtained is completed using difference Fourier maps. This method works successfully when a sufficient number of intensities could be extracted from the powder diffraction pattern.

Patterson methods have also been successfully used for structure solution from powder diffraction data. By taking advantage of the Patterson function $|F_{\vec{h}}|$, useful information about the crystal structure can be deduced. Compared to Direct methods, Patterson techniques are more suitable for powder diffraction data with lower resolution, and peak overlap causing significant difficulties. The Patterson function can be calculated by using the equation

$$P(\vec{u}) = \frac{1}{V^2} \sum_{\vec{h}} |F_{\vec{h}}|^2 \exp(2\pi i \vec{h} \cdot \vec{u}) \qquad (37)$$

where, $|F_{\vec{h}}|^2$ are the extracted intensity structure factors at the reciprocal point $\vec{h}$. The vector $\vec{u}_{ij}$ from the origin to a peak in the Patterson map corresponds to a vector $\vec{x}_i - \vec{x}_j$ between two atoms at positions $\vec{x}_i$ and $\vec{x}_j$ in the real space lattice. By this approach, usually the heavy atoms in the unit cell are located. Then by incorporating these atoms and doing several least squares cycles, and by analyzing the difference Fourier map the structural model is completed.

Modifications of the original Patterson methods have been designed to improve on the success rates for powder diffraction applications. Maximum entropy methods based on Patterson maps have also been developed.[27]

9.3.2 *Real Space Methods*

The real space methods have become possible with ever increasing computational power. In real space methods, all the known information about the compound in question is input into the unit cell. Based on the supplied information, a powder pattern is calculated. An agreement factor between the observed and the calculated pattern is estimated. Then the structural model is tuned based on the agreement factor. One of the real space methods, namely, simulated annealing (SA), which is based on a Monte Carlo approach, can be related to the physical crystallization from a melt, where at high temperatures the molecules/atoms are at higher energy and hence higher randomness. As the temperature decreases the energy of the system decreases and crystallizes into the thermodynamically stable crystal. In a similar process, several thousands of molecular configurations are tested. At higher temperatures of simulation, jumping between different configurations with larger residual differences are accepted, and as the temperature decreases the perturbations in the configurations are decreased. With every change in

the arrangement of the molecule in question, the agreement factor between the observed powder pattern and the pattern generated based on the model is calculated; in the process the configuration with lowest reliability factor is saved in. This process works well with organic, and pharmaceutical compounds. As the whole hypersurface is not examined in this process, it is possible that the SA process would end in a false minimum. For this reason, more than one SA process is carried out to confirm the minimum. In a related process, parallel tempering (PT), instead of using one SA chain with decreasing temperature, several parallel optimizations are run simultaneously, each with a different temperature. After regular intervals, exchange of configurations is allowed between the parallel chains, with the same rules of probability within a single chain. This allows any configuration caught in a local minimum to come out of it to a higher temperature and hence increases the possibility of finding the true minimum. Although PT needs exhaustive computational power compared to SA, with modern computers this becomes absolutely feasible. DASH[32] and FOX[39,40] are two programs that have implemented SA and PT, respectively. These programs have been successfully used to solve several crystal structures from powder diffraction patterns. FOX, in particular, is friendly for solving both molecular and nonmolecular structures.

Other methods such as Genetic Algorithm based on evolution principles, maximum entropy method based on Bayesian theory, and maximum likelihood methods have also been developed.[27]

The choice of whether to use the conventional reciprocal space approach or the modern real space method depends on the quality of the powder diffraction and the complexity of the problem in hand.

9.4 Structure Refinement or Rietveld Refinement

A structural model obtained either from a database (such as ICSD, CCDC, etc.) or from the ab initio structure solution method is refined with the observed powder pattern by a nonlinear least squares method to obtain accurate values of various parameters involved.[6,41] The residual, S_y, is minimized:

$$S_y = \sum_i w_i (y_{io} - y_{ic})^2 \tag{38}$$

where, $w_i = 1/y_{io}$, y_{io} is the observed intensity at the ith step, and y_{ic} is the corresponding calculated intensity. This procedure is popularly known as *Rietveld-Refinement* (also known as Rietveld-method or Rietveld-analysis). Although the method was initially developed for constant wavelength neutron diffraction data, it has been widely extended to accommodate PXRD data, and time of flight data as well.

The powder pattern (i.e. the intensity at the ith step, y_i) is calculated from the structural model by including the structure factor contributions from the Bragg reflections (taking into account the neighboring reflections, if necessary), and various factors that influence the intensity including Lorentz, polarization, and multiplicity factors, a function to define the profile, PO, absorption effects, and the background.

Several reliability factors are defined to compare the observed pattern *vs.* the pattern calculated based on the model. Most common are the weighted profile R-factor (R_{wp}), profile R-factor (R_p), Bragg R-factor (R_B), and goodness of fit (S) or its square (χ^2). These are defined as follows:

$$R_{wp} = \left\{ \frac{\sum w_i (y_{io} - y_{ic})^2}{\sum w_i (y_{io})^2} \right\}^{1/2} \tag{39}$$

$$R_p = \frac{\sum |y_{io} - y_{ic}|}{\sum y_{io}} \tag{40}$$

$$R_B = \frac{\sum |I_{Ko} - I_{Kc}|}{\sum I_{Ko}} \tag{41}$$

$$\chi^2 = \left(\frac{R_{wp}}{R_{\mathrm{exp}}} \right)^2 \tag{42}$$

where, I_{Ko} and I_{Kc} are the observed and calculated intensity of the Kth Bragg reflection at the end of refinement cycles. $R_{\mathrm{exp}} = \left[(N - P)/\sum w_i y_{io}\right]^{1/2}$ (N and P represent the number of data points and number of refined parameters, respectively).

In the presence of several minima close to the true one, it is often possible to get trapped into local false minima. This is more true when restraints and/or constraints are used in the refinement. There is no foolproof procedure that will lead to a global (true) minimum instead of a false minimum. A practical way is to test the minimization by varying the starting model and verifying that the same minimum is reached on refinement. When Rietveld refinement is carried out, it is important to understand the sequence in which the parameters could be ‘‘turned on’’ for refinement. Although, there is no simple rule for this, from experience, some of the parameters, which are known beforehand and dependent on the instrument, for example zero shift (known from instrument alignment), peak shape functions, etc., can be fixed to their known values. If accurate lattice parameters were known from a full-profile fitting, by the Pawley or Le Bail method, it can be fixed until near the end of refinement. It is also important to understand the parameters that correlate with each other, say zero shift and sample displacement errors, occupancy and thermal parameters, etc. If possible these correlating parameters should not be allowed to vary simultaneously until a stable refinement is reached.

There will always be a question of when to stop carrying out the refinement cycles. Perhaps the best way to decide on this is to make sure the variations in the parameters involved in the refinement change the model within acceptable standard deviations. Also, the model, in addition to explaining the observed powder pattern, must also make absolute chemical sense (*e.g.* bond distances, angles,

torsions) and should justify other properties observed for the sample in question.

Rietveld-analysis can be used to handle more than one phase. This ability has been exploited to perform accurate quantitative analysis. The results obtained are reasonably precise and have been used extensively, for example, in the cement industry.

METHOD SUMMARY

Acronyms, Synonyms

- Circular Dichroism (CD)
- Optical Rotatory Dispersion (ORD).

Measured physical quantities

- CD spectroscopy measures the difference in absorbance between left- and right-circularly polarized incident radiation, in the near ultraviolet to visible and infrared regions of the spectrum.
- ORD uses plane polarized light and provides the degree of rotation of plane polarized light as an angle.

Information available

When ORD can specifically provide information it is mentioned, otherwise the following information is for CD primarily:

- presence of chiral chromophores (both CD and ORD)
- relative amounts of α-helix and β-sheet secondary structure in protein molecules
- changes in all degrees of structure in biological molecules
- denaturation as a function of structure, readily determined using CD spectral data as a function of a physical (e.g., temperature) or chemical (e.g., pH, denaturant) change
- monitoring of structural and metal ion-ligand changes in metalloprotein complexes by titration experiments
- metal-ligand stoichiometry
- metal-ligand coordination geometry.

Information not available, limitations

- Chromophore must be chiral for any information to be obtained.
- Metal-ligand binding information is inferred from changes in spectral titrations, but specific bonds between a metal atom and its ligating atoms cannot be assigned.
- Metal atoms with high energy absorbance bands (that absorb in the far ultraviolet) cannot be directly probed; these include the alkali metals and alkaline earth metals.

Examples of questions that can be answered

- What are the stoichiometries of the major complexes between a metal ion M^{n+} and a protein ligand?
- How does metal substitution occur when a different metal ion with higher binding affinity to the protein is added to a solution of an existing metal-protein ligand complex?

- How does the protein morphology or secondary structure change upon metal binding?
- What are the identities of the protein atoms that bind to the metal ion (e.g., Cotton effect question, especially for Fe binding)?
- Is the compound analytically pure?
- Is the chirality opposite that of the enantiomer?

Major advantages

- The method obtains highly reproducible information on metal-ligand changes as the titration experiment proceeds.
- CD signals can be compared to the analogous absorbance spectra for distinguishing metal binding.
- Chiral chromophores are discernible in samples with multiple overlapping absorbance bands.
- Sample can be combined with other spectroscopic techniques in ‘‘real time’’.
- CD spectra in particular are immune to solvent effects and therefore can provide exceptionally good data on the chirality of a molecule with absorption bands distributed throughout the optical spectrum.

Major disadvantages

- Much of the structural information for metal-ligand binding (coordination number, stoichiometry) is inferred by the titration; confirmation of structural information is required by other techniques.
- Analytical uses cannot be estimated prior to use of a pure sample. Estimation of the rotation (in ORD) and the signal intensity (in CD) cannot be carried out.
- The absolute sign of the rotation or the CD signal cannot be calculated (+ or −) currently.

Sample constraints

- Soluble samples are the easiest.
- Scatter from frozen samples can cause significant baseline deviations in CD experiments.
- Samples must contain a chiral chromophore that absorbs in the near ultraviolet to infrared region.

1 INTRODUCTION

Circular dichroism (CD) spectroscopy is a method that measures the difference in the absorbance of left- and right-circularly polarized light as a function of the energy of the radiation (but usually reported as the wavelength of the light) by chiral chromophores. The absorbing chromophore may be a chiral center due to asymmetric coordination chemistry, as in the example of the chiral Cotton effect due to the asymmetric coordination chemistry of iron complexes. Alternatively, the chromophore may display an induced chirality brought about by the formation of three-dimensional bonding structures. This is the case in chiral structures such as the α-helix or β-sheet conformations found in peptide chains, and commonly referred to as the secondary structures of proteins and polypeptides. Similar delocalized chiral chromophores resulting from induction of the specific three-dimensional structure are also observed in metal-ligand clusters. These structures are commonly found in proteins chelating a variety of metal ions. Moreover, the variety of possible metal-binding side-chain functionalities in the amino acids within the protein chain, the changes in metal-ligand stoichiometry, variable metal coordination chemistry, and the possibility of intermolecular cross-linking all can result in changes to the three-dimensional structure of the chromophore, with concomitant profound changes in the resultant CD spectrum of the sample. These specific changes in the CD spectrum allow detailed study of metal-binding properties.

There is a formidable and varied array of metal ions that participate in biological systems, both as essential cofactors within the cells and organs of the living organism or as toxic elements deleterious to the organism. Metal ions in vivo are principally found chelated to proteins and polypeptides, owing to the wide variety of negative dipole functional groups (usually with oxygen, nitrogen, or sulfur as the ligating atom from the amino acid side chains of the protein) attracted to the positive metal ions. A great deal of research has been conducted and remains ongoing to define and elucidate the roles and unique chemistry that the various metal ions play in biological systems, specifically as metal-protein complexes.

In general, the type of information that is of greatest interest when discussing metal-protein chemistry include the following: (1) changes in stability of the protein resulting from changes in protein secondary structure; (2) identification of the ligating functional group of the protein; (3) the oxidation state of the metal ion; (4) the coordination number of the metal ion; (5) the metal-to-ligand stoichiometry; and (6) changes in metal-protein reactivity.

2 TECHNICAL BACKGROUND

2.1 Measuring CD Spectra

The easiest way to obtain a CD spectrum is to use a spectropolarimeter. In these instruments the signal is plotted as

the ellipticity of the emerging radiation after passage through a sample, $\theta = (2.303/4)(A_l - A_r)$ with units of radians as a function of the wavelength of the light, θ vs. λ in units of nm usually.

When reduced to units of degrees, $\theta = 2.303(A_l - A_r)(180/4\pi) = 32.98\Delta A_{L-R}$

The molar quantity is given by: $[\theta] = 3298(\varepsilon_L - \varepsilon_R) = 3298\Delta\varepsilon_{L-R}$, where the 3298 converts the $L\,M^{-1}\,cm^{-1}$ unit of molar absorptivity (ε) to the $0.1\ L\,M^{-1}\,cm^{-1}$ units of molar ellipticity.

It is easier, and to some extent more useful, to quote CD spectral data in terms of ΔA_{L-R} for solutions without known concentrations and $\Delta\varepsilon_{L-R}$ when concentrations are known. This then can match data from the associated magnetic CD spectroscopy (*see* ***Magnetic Circular Dichroism (MCD) Spectroscopy***).

Reporting CD spectral data as $\Delta\varepsilon_{L-R}$ vs. λ in nm is good practice.

Most CD spectropolarimeters must be calibrated. A common way is to compare the absorption and CD spectra of ammonium (+)-d10-camphorsulfonate (ACS) using a solution nominally $1\,mg\,mL^{-1}$ in a 1 mm cell. Using the absorption at 285 nm ($\varepsilon_{285\,nm} = 34.5\ M^{-1}\ cm^{-1}$) to determine the concentration, the positive CD band at 290 nm may be used for calibration $\Delta\varepsilon_{291\,nm} = 2.36$. A negative band at 190 nm can be used as well to extend the calibration into the UV region.

Of major concern in measuring CD spectra, is the absorbance of the solvent. Whereas in the electronic absorption spectrum (*see* ***Electronic Spectroscopy***) all components can be measured if the blank is simply set to be the empty cuvette or air in the double beam instrument, in the CD experiment, the nonchiral components are not ''seen'' or recorded in the CD spectrum yet they absorb light and can easily reduce the CD spectral data to useless lines. In reality, this only becomes a major problem when solvents and buffers begin to absorb below about 300 nm. Although, we should note that great care should be taken to keep the absorption low (may be less than 0.6) for the CD spectra of porphyrinoids, especially in the Q−band region from 580 to 800 nm. However, the problem is insidious in that after the measurement has been made, it is not possible to determine if the background absorbance precluded accurate measurement.

What goes wrong? The CD intensities start being nonlinear with respect to concentration of the absorbing species when the background absorbance (and instrument insensitivity) results in the controlled DC voltage of the photomultiplier tube losing its lock. Most instruments maintain this DC voltage by changing the applied dynode volts of the photomultiplier tube within its working range. The gain on the photomultiplier tube is increased by increasing the dynode voltage, which concomitantly increases the noise of the measurement. As the light striking the photomultiplier tube decreases (because of increased background absorbance), so the dynode voltage increases. When no more gain can be obtained, the signal starts being nonlinear and eventually the photomultiplier reports totally erroneous CD signals. Remembering that an absorbance of 1 allows transmission of only 10% of the incident light, and an absorbance of 2 allows transmittance of just 1% of the incident light, it is easy to see that with solvent or buffer, most of the light may be absorbed. CD spectrometers typically do not measure linearly for total sample absorbance above 1.0.

2.2 Choice of Cuvettes

Continuing with the theme of obtaining CD spectral data unaffected by the nonchiral components, including the solvent, leads us to consider the cuvette. As described above, one must be very careful to check that the cuvette, solvent, and all other components do not absorb significantly in the region of interest. This becomes a concern in the UV- and IR-regions of the spectrum. As an example, for spectra below 190 nm, fused silica windows are beneficial and the sample compartment must be purged of O_2 with N_2 gas, because O_2 has absorption lines near 178 nm (O_2 must also be purged from the lamp and monochromator to reduce the build up of O_3). Because the concentration of the solvent (including all components, notably buffers) is so high, cells with pathlengths down to 0.01 cm should be used. For all measurements below 200 nm, it would be wise to use a series of cuvettes, with pathlengths of 0.05, 0.1 and 0.2 cm to confirm linearity of the CD signal.

Strain in the cuvette (from the windows themselves, from misalignment, etc.) can result in significant distortions in the CD spectrum recorded. It is essential that a solvent blank be measured with the cuvette in *exactly* the same orientation to be used with the sample. It is good practice to mark the cuvette so it is placed with the same window facing the lamp. Many other factors can contribute to depolarizing distortion that will result in incorrect spectral data; it is wise to be very careful with cuvette choice and testing, especially below 200 nm and below room temperature.

A final word of caution extends to the quality of the lamp. Xe lamps darken quite quickly with age, so long before the lamp should be replaced (say at 1000 h), the far-UV output will have diminished. This makes the head-room for absorbing species much less. Opening the slits can help, but then spectral resolution is lost. Always using two or three cuvettes for setting up these measurements will provide confirming evidence that the measurements are real.

3 APPLICATIONS

3.1 Identification of Protein Secondary Structure

CD spectroscopy has long been used as a simple and direct technique to assess the extent of folding within the

protein structure, as well as the type of secondary structure adopted by the protein.[1] In general, proteins with α-helical structure display negative CD signals in the far-UV region at 208 and 222 nm. The second signal is typically used to estimate the α-helix content of a protein. Comparatively, the β-sheet conformation within the protein is characterized by a signal at 215 nm, which may be sinusoidal in nature.

The simplicity of performing this protein secondary structure analysis makes CD spectroscopy useful in monitoring protein conformational changes between wild-type and mutant proteins, as well as in identifying changes in the protein secondary structure upon addition of a bound cofactor such as a metal ion. Several recent examples of applying CD spectroscopy for these purposes are now described.

Yamniuk *et al.* report the use of CD spectroscopy to measure the structural changes in calcium- and integrin-binding protein upon addition of the divalent metal ions Ca^{2+} and Mg^{2+} to the metal-free apoprotein.[2] They found increases in the α-helical content of the protein of over 30% when either of the metal ions was added to the protein. Futaki *et al.* showed that the α-helical character of a model peptide could be destabilized by the addition of ferric ion.[3] This destabilization of the secondary structure was indicated by suppression of the 222 nm signal upon addition of Fe^{3+}. The authors concluded a possible ferric/ferrous redox control of the helical structure of the peptide.

Dai *et al.* reported that intermolecular associations within the γ-carboxyglutamate-rich neuroactive peptide conantokin-G could be promoted specifically by the binding of Ca^{2+} ions to the protein.[4] The binding of Ca^{2+} was found to favor an α-helical structure important for intermolecular cysteine–cysteine cross-linking. Interestingly, other divalent metal ions (Mg^{2+}, Zn^{2+}, and Mn^{2+}) bound to the protein with greater increase in α-helical content of the protein as observed in their respective CD spectra as compared to Ca^{2+} binding, but did not promote the intermolecular cross-linking.

Murphy *et al.* used CD spectroscopy to monitor the secondary structure of a novel human-derived apyrase (human soluble calcium-activated nucleotidase-1 (hSCAN)) in the presence and absence of calcium ion binding.[5] Their study indicated that although Ca^{2+} was essential for enzymatic activity, the binding of Ca^{2+} was not accompanied by any observable changes in the secondary structure, as the calcium-free protein displayed a β-sheet conformation that was not altered upon Ca^{2+} addition. By comparison, in a study by Tickler *et al.*,[6] CD spectroscopy was used to monitor changes in secondary structure of wild-type amyloid-β peptide (Aβ40) and its methylated histidine imidazole equivalents [Aβ40(HisτMe)] and [Aβ40(HisπMe)].[6] This study demonstrated that the binding of Cu^{2+} to the wild-type peptide and to the π-nitrogen methylated imidazole peptide was accompanied by a conformational shift from random coil to predominantly β-sheet structure.

The increase in β-sheet content in the peptide accelerates the peptides susceptibility to form aggregates.[7] The further indication that the modified peptide analog methylated at the τ histidine imidazole nitrogen did not change conformation upon Cu^{2+} binding supports the idea that it is these imidazole nitrogens within the amyloid-β peptide that form bridging structures leading to the oligomerization of the peptide.

The finding that metal binding by a peptide leads to preferred α-helix structure within the peptide was also indicated in a study by Wang *et al.* using CD spectroscopy to monitor the metal-peptide structure[8] (Figure 1). The authors prepared a five-residue peptide that models the metal-binding site of the olfactory receptor protein. They found that upon addition of up to one Cu^{2+} equivalent, the CD signal changes from one characteristic of a random peptide structure to one with the double minima at 209 and 222 nm characteristic of α-helix peptide structure.

Interestingly, α-helicity is very uncommon for a peptide of less than 15 residues, suggesting that binding to the metal ion is essential for creating and maintaining the peptide structure. This structure is thought to require a tetrahedrally coordinated metal ion such as Cu^{2+}, Zn^{2+}, or Ni^{2+}. Using the spectroscopic and structural data for the metal-bound peptide, the authors indicated that the ligation of the metal ion occurs with coordination to one histidinyl nitrogen atom, a cysteinyl sulfur atom, a glutamate oxygen atom, and one solvent molecule that can be replaced by an odorant molecule. This binding is consistent with the 1:1 metal ion:peptide binding ratio observed spectroscopically.

The ability of CD spectroscopy to monitor changes in protein secondary structure is also used to assess the stability

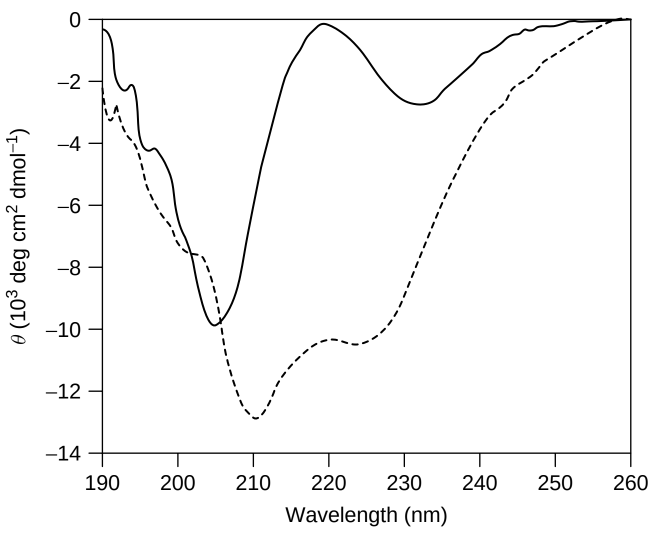

Figure 1 Far-UV CD spectrum of HAKCE peptide, in the absence of metal ions (solid line) and in the presence of 1.0 equivalent of Cu(II) added (dotted line); 20 mM peptide, pH 7.4 potassium phosphate buffer, 298 K. (Wang, J., Luthey-Schulten, Z. A., Suslick, K. S. (2003) *Proc. Natl. Acad. Sci.* USA **100**:3035–3039. © 2003 National Academy of Sciences, USA)

of the protein toward thermal or chemical denaturation. This is especially applicable when comparing the structural stability of the protein in the absence and presence of bound metal ions. A number of recent studies have employed CD spectroscopy for this purpose.

Golynskiy *et al.* used the CD signal at 222 nm characteristic of the α-helical protein conformation to monitor the thermal denaturation of the metalloregulatory protein MntR, a manganese(II)-responsive transcription factor in *Bacillus subtilis*[9] (Figure 2). In the metal-free form, the protein displayed a melting temperature of about 67 °C. Addition of Mg^{2+} or Ca^{2+} had no effect on the melting temperature of the protein. However, the *d*-group divalent metal ions Mn^{2+}, Co^{2+}, Ni^{2+}, and Cd^{2+} increased the thermal stability of the protein such that the melting temperature increased by 15 to 30 °C upon addition of these metals (Figure 2).

The thermal stability of wild-type peptides and modified analogs in the absence and presence of bound metal ions was also measured using CD spectroscopy in studies by Sissi *et al.*[10] and by Cox *et al.*[11]

In a separate study by Kovári *et al.*, the authors report the use of CD spectroscopy to study the binding of Mg^{2+} to the DNA repair enzyme dUTPase.[12] This enzyme catalyzes the hydrolysis of uracil triphosphate (UTP) to uracil monophosphate and inorganic pyrophosphate, leading to removal of excess uracil. The Mg^{2+} ion is an essential cofactor for enzyme activity. CD spectroscopy indicated that Mg^{2+} binding modulates the conformation of the enzyme allowing for enhanced formation of the enzyme-substrate complex. Binding of the Mg^{2+} ion and the subsequent binding of the UTP substrate also lead to increased stability of the enzyme toward proteolytic digestion by trypsin.

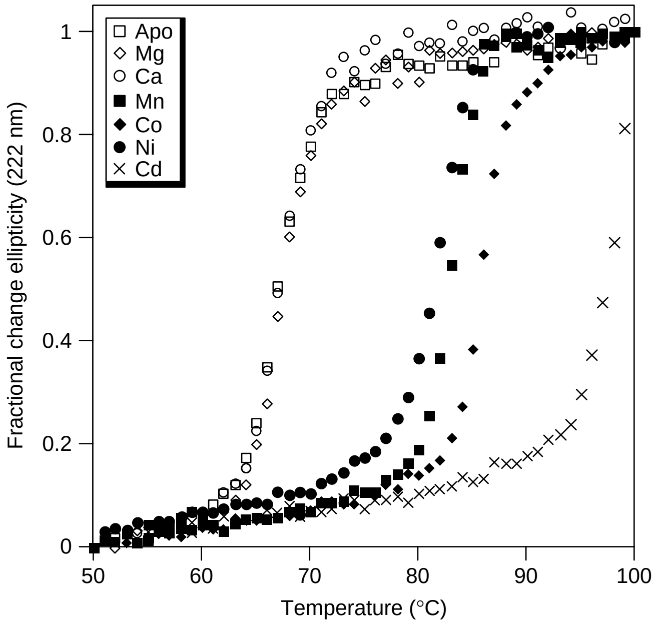

Figure 2 Thermal denaturation curves for wild-type MntR (8 µM) monitored by CD spectroscopy at 222 nm: unfolding of apo MntR (open squares) and of MntR in the presence of 1.0 mM Mg^{2+}, Ca^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, and Cd^{2+}. Buffer 20 mM HEPES, pH 7.2 at 4 °C, 200 mM NaCl, 5% (v/v) glycerol. Pathlength 2 mm. (Reprinted with permission from Golynskiy, Davis, Helmann and Cohen.[9] © 2005 American Chemical Society)

CD spectroscopy has also provided valuable insight into the chemical stability and chemical denaturation of proteins. A recent study by Rumfeldt *et al.*[13] examines the guanidinium-chloride induced denaturation of mutant copper-zinc superoxide dismutases (SODs).[13] These mutant forms of the Cu, Zn-SOD enzyme are associated with toxic protein aggregation responsible for the pathology of amyotrophic lateral sclerosis. In this study, CD spectroscopy was used in conjunction with tryptophan fluorescence, enzyme activity, and sedimentation experiments to study the mechanism by which the mutated enzyme undergoes chemical denaturation. The authors found that the mutations in the enzyme structure increased the susceptibility of the enzyme to form partially unfolded destabilized monomers, rather than the stable metallated monomer intermediate or native metallated dimer.

Ghosh *et al.* also used CD spectroscopy to assess the association affinities of peptide coils in the absence and presence of bound Hg^{2+} or Cd^{2+}.[14] These authors constructed a family of peptides having secondary structures that bind metal ions in a trigonal thiolate coordination environment, even metal ions like Hg^{2+} and Cd^{2+} that prefer tetrahedral coordination geometries. Their results indicate increased stability of coiled-coil peptide structures upon addition and binding of the metal ions, and support the hypothesis that favorable tertiary interactions within the protein systems allow for stabilizing the non-preferred coordination geometry of the bound metal ions.

While the study by Ghosh *et al.*[14] examined the use of CD spectroscopy to elucidate metal ion coordination chemistry as a result of the stabilization of specific secondary structures within the peptide, CD spectroscopy can also directly probe the binding environment and coordination chemistry of metal ions bound to protein ligands. This is the case when functional groups on the peptide chain bind metal ions with the formation of asymmetric metal-ligand clusters due to bond constraints within the peptide structure. This asymmetry in the metal ion environment leads to chiral chromophores centered at the metal ion. This is especially the case when clusters of metal ions are bound within a protein structure by bridging peptide ligands between the metal ions. The chiral electronic transitions that are most often observed in these instances are ligand-to-metal charge transfer (LMCT) transitions most common with *d*-shell metal ions.

Many *d*-block metals (Groups 3–12) have important roles in biological systems, both as essential cofactors within a variety of cellular processes, and as interfering species that are toxic to the cell and organism. These metals exist in biological systems as ions that are often bound to proteins and peptides with the exhibition of unique coordination geometries, such

that these species become of interest to the inorganic chemist as well as the biological scientist. Because of the ubiquitous nature of the interaction of *d*-shell metal ions with biological molecules and the inherent sophistication of the metal ion chemistry when bound to the biological molecules, tools that have sought to explain the character of metal-protein binding, including CD spectroscopy, have mainly been applied to the binding of the following metal ions by protein or peptide ligands: Fe^{2+} and Fe^{3+}, Cu^{+} and Cu^{2+}, and the Group 12 triad of Zn^{2+}, Cd^{2+}, and Hg^{2+}. The applications of CD spectroscopy to the understanding of metal-protein binding, structure, and reactivity are herein presented with focus on these metal ions, followed by brief descriptions of CD spectral studies of protein molecules binding other metal ions less common to biological environments. Finally, we highlight the use of CD spectroscopy in the determination of speciation in the protein metallothionein.

3.2 CD Spectra of: Complexes of the Group 8–10 Transition Metals

The formation of metal-protein complexes of the transition metals has been an area of intense research, with CD spectroscopy providing essential insights into the structural, electronic and stoichiometric properties of the complexes. The binding of iron ions to proteins has provided the greatest amount of results. As with copper ions, iron complexation with biological ligands is of interest due to iron being both an essential element and a potentially toxic element, as well as the wide range of complexes that iron ions form because of two different stable oxidation states (Fe^{2+} and Fe^{3+}) and the variety of protein ligands and structural motifs that the iron cations may adopt.

The binding of iron to a model miniaturized protein has been reported by Lombardi *et al.*[15] The miniaturized protein was constructed based on the tetrahedral tetrathiolate $[S\text{-}Cys]_4$ iron-binding site of the rubredoxin protein, and named miniaturized electron transfer protein (METP). The far-UV CD spectrum of the apoprotein and of the Fe^{3+} complex indicate that the protein structure changes from an unordered peptide chain in the metal-free state to an ordered α-helical structure with negative CD bands at 204 nm and 222 nm upon addition of Fe^{3+}. In the near-UV and visible regions of the spectrum, the Fe^{3+}-METP complex displays a strong Cotton effect with signals at 580 nm (+), 500 nm (−), 440 nm (+), 370 nm (+), and 315 nm (−). In the metal-reduced complex of Fe^{2+}-METP, CD signals are observed at 280 nm (+), 305 nm (−), and 320 nm (+). These spectral characteristics, as well as those for the Co^{2+}-METP complex, are similar to the CD spectra of natural and reconstituted rubredoxin, confirming that the same metal-binding environment was maintained in the model system relative to the natural protein.

Multi-thiolate iron-protein clusters are also found in the ferredoxin family of electron transport proteins. In particular, the interconversion between ferredoxin clusters containing three iron atoms and other clusters containing four iron atoms was the subject of research by Jung *et al.*[16] It was found that the replacement of one cysteine residue central to the metal-binding site with an aspartate residue allowed for the conversion of the redox active site from $[4Fe\text{-}4S]^{2+/+}$ to the $[3Fe\text{-}4S]^{+/0}$ cluster. CD spectroscopy is very sensitive to the type of iron-sulfur cluster that is formed within the protein. Native ferredoxin has CD spectra with signals at 310 nm (+), 395 nm (+), 470 nm (+), and 580 nm (+) for the ferric protein, and 360 nm (+), 405 nm (+), 450 nm (−), 510 nm (+), and 580 nm (+) for the ferrous protein. The mutated protein with substitution of a central cysteine → aspartate displayed CD spectra for both the oxidized and reduced forms that were very similar to those for the native ferredoxin protein. This indicates that the mutated protein has iron atoms ligated by only three thiolate cysteine residues, without a distant cysteine providing a fourth thiolate ligand to the cluster. Supporting crystallography data indicate that the aspartate residue itself provides the fourth ligand to the Fe-S cluster through a carboxyl oxygen atom.

CD spectroscopy has also been used to study the metal-binding and reactivity properties of iron- and manganese-containing SODs. These enzymes metabolize the superoxide ion radical $O_2^{\bullet-}$ into molecular oxygen and hydrogen peroxide. The Fe- and Mn-SOD enzymes are strictly metal specific. Jackson and Brunold[17] show that, despite the fact that Fe replacement of Mn in the Mn-SOD enzyme [(Mn → Fe)-SOD] results in an inactive enzyme, the CD spectrum of wild-type Fe-SOD and (Mn → Fe)-SOD are remarkably similar. This suggests that the destroyed enzyme activity, upon replacement of the metal, does not occur via distortion of the enzyme active site.

CD spectroscopy of the Fe-heme binding site of a protein has also been used to monitor the binding of other metal ions to a protein. Hemopexin is a plasma protein that binds free heme, reducing the extent of iron loss and preventing possible oxidative damage that would be catalyzed by free heme. Hemopexin has also been shown to bind other metal ions. Mauk *et al.* indirectly studied the binding of Cu^{2+} and Zn^{2+} to hemopexin by monitoring the CD Soret signal of the heme iron group within this protein[18] (Figure 3). Addition of up to 18 equivalents of either Cu^{2+} or Zn^{2+} altered the CD signal from a bisignate Soret with maximum at 415 nm and minimum at 430 nm, to a positive Cotton signal centered at 420 nm.

These changes were reversed upon addition of excess EDTA. The changes in the CD spectrum caused by Cu^{2+} or Zn^{2+} addition to hemopexin suggest structural or electrostatic perturbations in the vicinity of the heme group by the added metal ions. The authors indicate that binding of Cu^{2+} or Zn^{2+} to hemopexin may play a role in exchanging ligands to the bound heme group, possibly leading to dissociation of the heme complex from the protein.

In comparison to the large amount of research that has been conducted on copper and iron complexes of biological

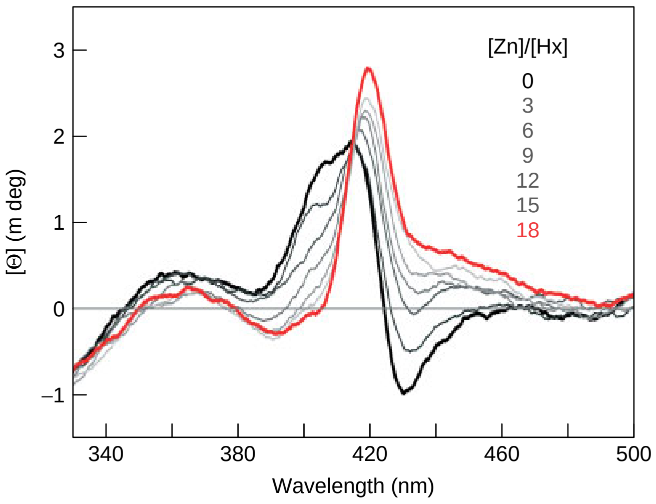

Figure 3 Effect of Zn^{2+} binding on the CD spectrum of the hemopexin (Hx)-heme complex: the Hx-heme complex (thick black curve), additions of 3–15 equiv of Zn^{2+} (thin black curve), and addition of 18 equiv of Zn^{2+} (red curve). The Hx-heme concentration is 8 µM, with 50 mM bisTris buffer and 50 mM sodium chloride (pH 7.0, 25 °C). (Reprinted with permission from Mauk, Rosell, Lelj-Garolla, Moore and Mauk.[18] © 2005 American Chemical Society)

ligands, similar information with other metal ions is relatively sparse. Vanadium is an essential trace element with a very complex inorganic chemistry, owing to its multiple stable oxidation states and its chelation by a variety of ligand donors. Tasiopolous *et al*. synthesized and characterized dipeptide complexes of V^{3+} and oxovanadium(IV) (VO^{2+}) as possible models of vanadium-protein interactions.[19] The dipeptides used in this study all contained glycine as one residue, with alanine, valine, or phenylalanine as the second amino acid. 1,10−phenanthroline was also present as an additional ligand. Part of the characterization of these complexes included CD spectroscopic analysis of the complexes in solution and in the solid state. The authors report that the V^{3+}–dipeptide complexes with phenanthroline had CD spectral signals that were too weak to be measured in solution. However, in the solid state the V^{3+} complexes displayed visible CD signals at about 740 to 780 nm (+), 480 to 550 nm (−), and 420 to 490 nm (+). By contrast, the VO^{2+} analogues of these dipeptide complexes had much stronger CD spectral signals that could be measured in solution. CD signals were observed at 725 to 735 nm (+), 470 to 480 nm (−), and 395 to 410 nm (+). In the solid state, the VO^{2+}-dipeptide phenanthroline complexes were characterized by strong signals at 770 to 800 nm (+), 550 to 570 nm (+), and 465 to 485 nm (−). The two lower wavelength signals are inverted in sign relative to the V^{3+} complexes. These CD signals may be used as a spectral fingerprint of octahedral VO^{2+} complexes with $N_{amine}–N_{peptide}–O_{carboxylate}$ ligation.

The chemistry of cobalt with biological ligands has been an area of increasing research owing to the role of this metal as an essential trace element, for example, as a cofactor in the vitamin B_{12} molecule, and as a possible mimic of the biological chemistry of other metal ions. Cobalt binds to biological ligands predominantly as the divalent ion, such that its bioinorganic chemistry is expected to be similar to other *d*-shell divalent metal ions like Zn^{2+}, Cu^{2+}, or Fe^{2+}. The Co^{2+} ion also displays *d*–*d* electronic transitions in the visible region of the spectrum which can be easily monitored by CD spectroscopy during a binding experiment.

Zhu *et al*. studied the metal-binding properties of copper chaperone proteins using CD spectroscopy by addition of Co^{2+} as a mimic of copper binding.[20] The authors of this study compared the binding of Co^{2+} to two different copper chaperone proteins, from Tomato copper chaperone for superoxide dismutase (tCCS) and human copper chaperone for superoxide dismutase (hCCS) sources. Both of these proteins are comprised of three structural domains. The tomato protein sequence includes four cysteine residues, two cysteines in each of domains 1 and 3, which were expected to be responsible for metal ion ligation. The human protein has nine cysteine residues with 3, 4, and 2 cysteines in the three respective domains of the protein. The main structural difference between the copper chaperone homologs is that the tomato protein has no cysteine residues in its second domain while the human protein has four cysteines in this domain. Moreover, this domain in hCCS has a great extent of sequence homology with the Zn^{2+} binding site of Cu,Zn-superoxide dismutases. Thus it is expected that divalent metal ions bind to domain 2 of hCCS with high affinity in a tetrahedral M^{2+}-$Scys_4$ geometry.

Addition of Co^{2+} to metal-free hCCS initially leads to minimal changes in the CD spectrum, up to addition of one equivalent of the metal ion. Further, addition of a second equivalent of Co^{2+} results in significant alterations to the CD spectrum, with strong signals appearing at 380 nm (+), 505 nm (−), and 610 nm (+). From these results the authors conclude that the binding of Co^{2+} to hCCS occurs first with one equivalent binding to the tetra-cysteinyl domain 2 with a symmetric tetrahedral binding geometry, followed by the binding of a second Co^{2+} to four of the remaining cysteine residues of domains 1 and 3 in a chiral distorted tetrahedral structure.[20]

Addition of Co^{2+} to tomato CCS resulted in the immediate formation of strong CD signals at 395 nm (+), 520 nm (−), and 620 nm (+). The spectrum reached saturation after addition of one Co^{2+} equivalent, at which point the spectrum was almost superimposable to the CD spectrum resulting from addition of two Co^{2+} equivalents to hCCS. Removal of the domain 1 cysteine residues resulted in much weaker CD signals. These data further indicate that the binding of Co^{2+} to cysteine residues across domains 1 and 3 of the CCS proteins results in a highly optically active distorted tetrahedral structure with Co^{2+} bound to four cysteine ligands.

3.3 CD Spectra of Group 11 Metals

Most of the research that has examined the binding of Group 11 metal ions to biological molecules has focused on the binding of copper ions. There are a number of reasons for this, including the range of biological molecules that bind copper ions, the fact that copper is both an essential element acting as a cofactor in numerous enzymatic processes while being potentially toxic at elevated concentrations, the various coordination geometries that copper can adopt, and different binding characteristics between the monovalent and divalent oxidation states of copper ions.

As a general rule, monovalent copper ions bind exclusively to cysteine thiolate ligands of proteins and peptides. The bound Cu^{+} ions usually adopt the trigonal planar coordination geometry, although digonal binding geometries are sometimes observed, especially with bridging thiolate ligands. As with the Group 12 metal ions, the use of CD spectroscopy to probe the binding of Cu^{+} to metallothioneins has been a very rich area of research in terms of the biological and inorganic chemistry of the Cu^{+}-thiolate cluster formation. Studies that have examined Cu^{+} binding to metallothioneins using CD spectroscopy are also discussed within the separate Section (3.6) on metal binding to the metallothioneins.

CD spectroscopy has also been used to monitor Cu^{+} binding to a copper-transporting protein, the P-type ATPase ATP7B found to be involved in Wilson's disease, a disorder characterized by over-accumulation of copper in liver cells and other sites[21] (Figure 4). It was found that the addition of Cu^{+} (by reduction of added Cu^{2+} with dithiothreitol) had the most dramatic effect on a peptide derived from the ATPase that contained three cysteine residues, two of which were separated by a single proline residue to give a −CPC−motif. Moreover, the authors of this study examined the nature of the CD spectral bands in order to formulate a hypothesis regarding the speciation of the Cu^{+}-peptide complexes. In this study, four well-resolved signals were detected including a maximum at 270 nm, a double minimum at 290 nm and 320 nm, and another maximum signal centered at 354 nm.

The CD signals in the near-UV to visible region are typically LMCT transitions. The authors also suggest that the higher wavelength signal at 354 nm may be assigned to a spin-forbidden $3d \rightarrow 4s$ metal cluster-centered transition that is favored by d^{10}–d^{10} interactions of adjacent Cu^{+} ions. These transitions would require multiple Cu^{+} ions binding in close proximity to each other, with bridging thiolate ligation necessary for the assembly of these clusters. The presence of these bridged Cu^{+}-thiolate clusters is also associated

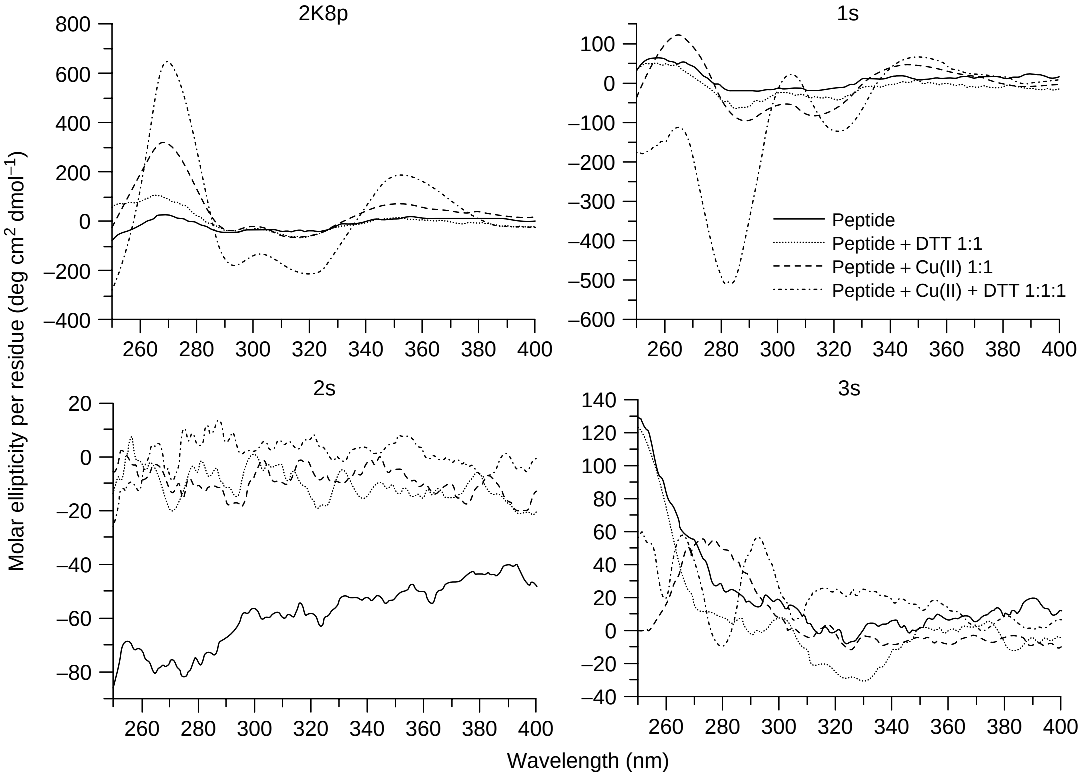

Figure 4 Changes in the CD spectra of variants of ATP7B, 2K8p and the mutants 1s, 2s and 3s in the region 250–400 nm induced by the addition of Cu(II) and DTT (peptide, solid line; peptide + DTT, dot; peptide + Cu(II) 1:1, dash; peptide + Cu(II) + DTT, dash dot). (Reprinted from Myari, Hadjiliadis, Fatemi and Sarkar.[21] © Elsevier 2004)

with the formation of oligomeric species. The equilibrium between the formation of the monomeric Cu^+-thiolate species with only terminal thiolate ligation and formation of the oligomeric bridged Cu^+-thiolate clusters is dependent on the stoichiometric ratio of added Cu^+ to peptide concentration.

Another class of copper transport proteins that have been studied using CD spectroscopy are the copper chaperone proteins. Two copper chaperones, one from *B. subtilis*[22] and another from *Enterococcus hirae*,[22] have recently been examined. The work of Kihlken *et al.* demonstrated that Cu^+ binds to the *B. subtilis* chaperone protein CopZ in three phases.[21] The first phase lasts up to a Cu^+: protein ratio of 0.5:1, and is characterized by the growth of CD signals at 265 nm (+) and 287 nm (−). The second phase of Cu^+ binding to the CopZ protein extends from 0.5 up to 1.0 Cu^+ equivalent per protein. This second phase is characterized by a shift and weakening of the 265 nm signal to about 275 nm, and the growth of a broad negative band that is centered at about 335 nm. The final phase of Cu^+ binding to the CopZ protein lasts up to a Cu^+: protein ratio of 1.5:1. This final phase is characterized by the formation of a derivative-shaped CD signal with a minimum at 265 nm, a maximum at 287 nm, and a sharp isodichroic point at 280 nm. Carrying out the titration in the presence of dithiothreitol, a small molecule-reducing agent that may also act as a sulfur donor ligand, limits the Cu^+-CopZ binding mechanism to the first phase only. Along with results from analytical ultracentrifugation and gel-filtration experiments, this CD study for Cu^+ binding to CopZ concluded that the binding of Cu^+ initially results in the assembly of a dimeric complex with a single metal center. Further addition of Cu^+ leads to formation of a second dimeric species with two Cu^+ ions bound by four cysteine thiolate sulfur atoms. In this species, two of the cysteine sulfur ligands (one from each peptide subunit) are bridging ligands, leading to closer $Cu^+{-}Cu^+$ interactions. These metal-centered interactions may be responsible for the higher wavelength CD signal that is observed during the second phase of the Cu^+ titration. In the third phase of the titration, the dimeric structure is thought to be conserved with an additional Cu^+ center within the metal-thiolate cluster.

For Cu^+ binding to the CopZ protein from *E. hirae*, Urvoas *et al.* also observed the formation of a dimeric species with a stoichiometric ratio of two protein subunits to one Cu^+ ion.[23] These authors also report that the dimeric species can be changed to a monomeric complex by the addition of the copper-coordinating molecule glutathione.

As we have seen, the electronic spectra of Cu^+ complexes are dominated by LMCT and metal-ligand charge transfer (MLCT) transitions in the near-UV and UV regions only under specific conditions of metal loading and bridging ligation within the metal-protein cluster. No $d{-}d$ transitions are possible. By comparison, the loss of a d-shell electron to give the Cu^{2+} ion results in the formation of complexes in which the electronic spectra are dominated by transitions in the visible region.

Ganadu *et al.* have presented CD spectroscopic evidence for complex formation between Cu^{2+} and the $\alpha\beta$-crystallin protein.[24] This protein is a structural protein of the eye lens that functions as a stress response protein, presumably as a molecular chaperone involved in protecting denatured proteins from aggregation. The chaperone-like activity of $\alpha\beta$-crystallin is enhanced in the presence of the Cu^{2+} ion, indicating that the protein contains a binding site for this metal ion. The CD spectrum of the $\alpha\beta$-crystallin protein with Cu^{2+} added is composed of a band at 343 nm, which becomes more enhanced with increased pH. This signal is ascribed to an imidazole N $\rightarrow$ Cu charge transfer (CT) transition, suggesting that a histidine residue is one of the ligands of the Cu^{2+} ion. The CD spectrum of the Cu^{2+}-protein complex also shows a strong derivative-shaped signal in the visible region, with a negative band at 550 nm and positive band at about 650 nm. This signal is consistent with a Cotton effect typical for the chiral $d{-}d$ electronic transitions of optically active Cu^{2+} complexes.

A further example of the use of CD spectroscopy to monitor Cu^{2+}-protein complex formation is the binding of this ion to the amyloid β-peptide. This peptide is composed of 40 to 43 amino acids residues and is the principal component of the aggregates or plaques associated with neurodegenerative disorders such as Alzheimer's disease. The ability of this peptide to bind metal ions has been well documented. In fact, it has been shown that Cu^{2+} and Fe^{3+} induce the formation of β-amyloid aggregates.[25] A study by Kowalik-Jankoska *et al.*[26] sought to elucidate the binding of Cu^{2+} to the amyloid β-peptide from human and mouse sources. The authors used CD spectroscopy and EPR spectroscopy (*see* ***Electron Paramagnetic Resonance (EPR) Spectroscopy***) to elucidate Cu^{2+}-peptide complex formation with different fragments of the peptide under a variety of solution conditions. The authors showed that in all cases of Cu^{2+} binding to the various peptide fragments, the CD spectrum is composed of $d{-}d$ transitions in the visible region from 480 nm to 670 nm, and LMCT transitions assigned to (i) imidazole N $\rightarrow$ Cu transitions in the near-UV region from 320 nm to 370 nm, (ii) amide N $\rightarrow$ Cu transitions at wavelengths from 310 nm to 320 nm, and (iii) amino N $\rightarrow$ Cu transitions in the region below 300 nm. The intensities and signs of the CD bands, along with complementary data from EPR spectroscopic experiments, are used to arrive at a distribution of Cu^{2+}-amyloid β-peptide species under different conditions of pH and Cu^{2+} loading.

In a similar way, the binding of Cu^{2+} to another protein involved in neurodegenerative disease has also been studied using CD spectroscopy. The prion protein is a membrane-associated glycoprotein that undergoes an alteration from a monomeric form to an oligomeric protease-resistant form leading to its toxic effects. It has been suggested that the prion protein plays a role in copper metabolism.[27,28] The amino-terminal end of the prion protein is rich in histidine and glycine residues, and is believed to be the metal-binding site of the protein. Specifically, the mammalian prion protein

contains a highly conserved region of four repeats of the eight residue sequence –PHGGGWGQ–, the so-called octarepeat sequence. Separate studies by Aronoff-Spencer *et al.*[29] and La Mendola *et al.*[30] have examined the speciation of Cu^{2+}-prion protein complexes using CD spectroscopy, in addition to other spectroscopic techniques. The CD spectra demonstrate the visible region *d–d* transitions and imidazole N → Cu CT transitions observed in other Cu^{2+}-protein complexes with imidazole and amide ligation. Specifically, in the study by Aronoff-Spencer *et al.*, the data are indicative of a 1:1 stoichiometry between Cu^{2+} and the aforementioned octarepeat, such that the histidine imidazole provides one ligand to the Cu^{2+} ion and glycine amide groups provide additional ligation of the metal ion.[29]

In addition to studying the binding of Cu^{2+} to known metal-binding proteins, CD spectroscopy has also been used to characterize a novel putative metal-binding protein. Barney *et al.* report on the isolation of a small (9.9 kiloDalton) protein (SmbP) from the periplasm of the ammonia-oxidizing bacterium *Nitrosomonas europaea*[31] (Figure 5). The authors found that this protein was expressed in the bacterium in response to Cu^{2+} addition to the growth medium, suggesting that this novel protein plays a role in cellular copper metabolism. To characterize the protein, they prepared the metal-free protein and titrated with increasing equivalents of Cu^{2+}.

In the far-UV region, the apoprotein displayed the CD signal characteristic of α-helix secondary structure with double minima at 209 nm and 222 nm. This region of the CD spectrum was unchanged with addition of Cu^{2+}. However, the visible region of the CD spectrum showed dramatic changes during titration of the protein with Cu^{2+}. A positive band was observed at about 490 nm with addition of the first equivalent of the Cu^{2+} ion, which remained unchanged with further Cu^{2+} addition. This band is ascribed to a histidine imidazole N → Cu CT transition. Further addition of Cu^{2+} was accompanied by the formation of a derivative-shaped CD signal with minimum at 580 nm and maximum at 760 nm. These transitions are Cu^{2+}-centered *d–d* transitions, and their relative energies are suggestive of mixed ligation by nitrogen and oxygen donor ligands. The sequence of this novel protein indicates the absence of any cysteine residues and a large proportion of histidine, aspartate, and glutamate residues, consistent with the suggested ligation of the Cu^{2+} ions. With further addition of Cu^{2+} equivalents, the visible region CD signals increase in intensity in a relatively linear manner up to 5 to 6 equivalents of Cu^{2+} being added. This stoichiometry is further supported by comparable titration experiments monitored by absorbance spectroscopy and EPR spectroscopy. Moreover, a similar titration of the protein with Fe^{3+} revealed absorbance and CD spectral changes up to a stoichiometry of six Fe^{3+} equivalents per protein molecule. From these experiments, the authors propose that the novel protein isolated from *Nitrosomonas europaea* in response to Cu^{2+} is a metal ion scavenger induced to sequester high concentrations of free Cu^{2+}, and possibly other free metal ions as well.

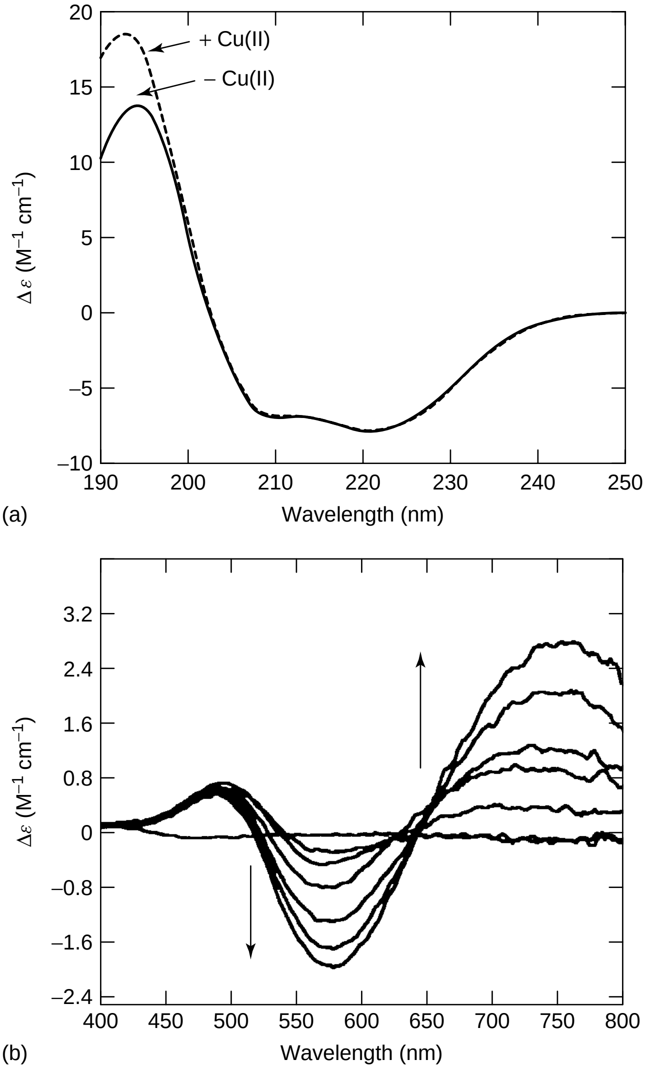

Figure 5 Panel (a) shows the UV CD spectra (190–250 nm) of apo-SmbP and SmbP (25 μM, pH 7.5, no buffer) with 1 equiv of Cu(II) bound. Spectra for 2 and 5 mol equiv of Cu(II) are not shown because they are virtually identical to the 1 mol equiv of Cu(II). Panel (b) shows the visible CD spectra (400–800 nm) of SmbP (250 μM, pH 7.5, no buffer) titrated with increasing equivalents of Cu(II) (0, 0.8, 1.4, 2.7, 3.7, 4.6, and 5.3) from an aqueous solution of $CuCl_2$. Additional mole equivalents of Cu(II) did not result in further changes in the CD spectra. (Reprinted with permission from Barney, LoBrutto and Francisco.[31] © 2004 American Chemical Society)

In addition to the protein complexes of copper ions, CD spectroscopy has also been used to study metal-protein complex formation of the other Group 11 metals, silver, and gold. The Ag^{+} ion has been used extensively in metal-protein experiments to act as an analog of Cu^{+} complex formation. Ag^{+} is comparable to Cu^{+} in oxidation state, the types of ligands to which it binds, and often displays equivalent binding geometries to these ligands. Moreover, Ag^{+} is easier

to work with because of its oxidative stability, as it does not have a higher stable oxidation state to which it can be oxidized, as is the case with Cu^{+}. However, the structural properties of Ag^{+} complexes are not identical to those of Cu^{+}, likely due to the larger ionic radius of Ag^{+} leading to other preferred binding geometries under certain ligand and stoichiometric conditions. For example, the binding of Ag^{+} to the metallothioneins results in both similarities and differences in comparison to Cu^{+} binding to this family of proteins. These specific results will be discussed in the section on applications of CD spectroscopy with metallothioneins (Section 3.6).

Gold complexes with biological ligands present further structural possibilities because of a different preferred oxidation state, the +3 oxidation state. Marcon *et al.* have employed CD spectroscopy to study complex formation between Au^{3+} and the abundant serum protein albumin.[32] This protein is believed to play a role in extracellular metal ion transport, and may be involved in the exhibited anticancer activity of Au^{3+}-based drugs. The authors determined that bovine serum albumin (BSA) forms very stable complexes with the Au^{3+} compounds $[Au(diethylenetriamine)Cl]^{2+}$ and $[Au(6\text{-}(1,1\text{-dimethylbenzyl})\text{-}2,2'\text{-bipyridine})OH]^{+}$, such that the metal ion could only be removed from the protein complex by treatment with excess potassium cyanide. The CD spectrum of the BSA complex with the latter of the two Au^{3+} compounds results in the appearance of visible spectrum signals characteristic of Au^{3+} complexes bound within a chiral protein environment. These signals include two negative bands, a strong signal at 405 nm and a weaker band at about 340 nm.

3.4 CD Spectra of Complexes involving Group 12 metals

This group consists of the elements zinc, cadmium, and mercury. Each of these metals binds to ligands as divalent metal ions, and usually adopt the tetrahedral binding geometry. These metal ions often bind to thiolate ligands, such as the cysteine sulfur atoms of proteins and polypeptides, although Zn^{2+} may also bind to the imidazole nitrogen atom of histidine residues. These metal ions are also known to form clusters of multiple metal ions within one protein unit through the chelation by both bridging and terminal peptide residue ligands.

The spectral characteristics of the Group 12 metal ions binding to biological ligands are dominated by the LMCT transitions from the electron-donating ligand atom to the *d*-shell of the metal atom. These transitions occur in the near-UV region of the spectrum, from 230 nm to 360 nm.

We have previously mentioned that Ghosh *et al.* have examined the binding of Cd^{2+} and Hg^{2+} to peptide coils[14] (Figure 6). They found that the metal ions adopted the unusual trigonal planar binding geometry in order to stabilize the coiled-coil structure of the peptides. This group had previously elucidated the binding geometry of the metal ions to these peptides.[33] In this earlier study, the authors found

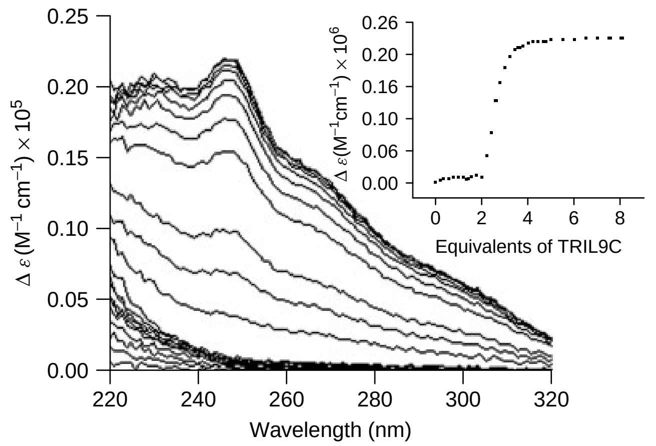

Figure 6 UV-visible titration of TRI L9C into a solution of $Hg^{II}Cl_2$ at pH 8.5. The data are plotted versus wavelength. The inset shows the titration curve following $\Delta\varepsilon$ at 247 nm plotted versus equivalents of peptide added at 247 nm. that the placement of the cysteine ligand along the peptide chain had a profound effect on the metal-protein structure as evidenced by complete inversions of the CD spectra.

The identical energies of the electronic transitions indicate that the coordination geometry of the metal ions, essentially trigonal planar with some trigonal pyramidal character in the Cd^{2+}-bound peptide structure, remained the same regardless of the position of the cysteine ligand. However, the peptide folding around the metal ion was drastically altered upon changing the placement of the cysteine residue, resulting in significant modifications in the constraints placed on the metal-thiolate cluster and different interaction of the chiral center with polarized light accompanied by inversion of the CD spectrum.

The formation of cadmium-protein complexes has also been observed in a protein model of the metal-binding domain of rubredoxin.[34] This protein model contains one Cys–X–X–Cys metal-binding motif. CD spectroscopy indicated that addition of the Cd^{2+} ion to the metal-free protein model resulted in binding of the metal ion with assembly of the protein into a coiled-coil secondary structure. The CD spectrum of the apoprotein model indicated a disordered random structure in the absence of bound metal ions, as evidenced by a major signal at 205 nm and a weak broad band centered at about 220 nm. Binding of Cd^{2+} led to a far-UV CD signal representative of a coiled α-helix structure in the protein model, with strong negative bands centered at 209 nm and 222 nm, and a thiolate S → Cd charge transfer transition at about 240 nm. Both the LMCT signal and the CD bands representing the α-helix structure of the protein were destroyed upon oxidation of the cysteine thiolate residues, indicating that the reduced thiolate was required to bind the Cd^{2+} ion leading to stabilization of the α-helix secondary structure of the protein model surrounding the Cd^{2+}-thiolate

cluster. Moreover, both CD spectroscopy and UV-visible absorbance spectroscopy were used to monitor the titration of the protein model with increasing relative amounts of Cd^{2+} ions. It was found that the respective changes in the spectral signals occurred up to a Cd^{2+}: protein stoichiometry of 1:2, suggesting that four chelating cysteine thiolates are required to bind one Cd^{2+} ion having a tetrahedral binding geometry, such that the Cd^{2+} ion acts as a bridging atom between two α-helix coiled protein ligands.

Like cadmium, mercury is the subject of significant research owing to its toxicity to living things. Bacterial resistance to mercury poisoning involves a specific periplasmic mercury-binding protein, MerP, and the mercuric reductase enzyme, MerA. Rossy *et al.* have studied the amino-terminal extension of a mercuric reductase that resembles the Hg^{2+}-binding motif of a MerP protein.[35] Using CD spectroscopy to monitor Hg^{2+} addition to the MerA amino-terminal extension, the authors noted that Hg^{2+} ion binding occurs with three main characteristics: an increased intensity and blue-shifting of a signal at 265 nm in the metal-free peptide to about 260 nm upon Hg^{2+} addition, the development of a negative CD signal centered at about 290 nm, and a sharp isodichroic point at 270 nm. Changes in the CD spectrum were observed for Hg^{2+} addition up to one mole equivalent with respect to the MerA amino-terminal model peptide, indicating only one metal-binding site within the peptide. The isodichroic point indicates the existence of only two possible states for the peptide, these being the metal-free and Hg^{2+}-bound forms. Moreover, the authors report that the far-UV CD signal did not change upon Hg^{2+} addition, indicating no change in the secondary structure of the peptide with metal binding. The authors propose that the metal-free peptide adopts a structure such that it is poised to bind the metal ion. This may be a critical property of a protein conferring mercury resistance to an organism.

Modeling of the metal-binding characteristics of the mercury-resistance proteins was also the subject of a study by DeSilva *et al.*[36] The authors constructed 18-residue peptides with metal-binding sites consisting of two cysteine residues and two alanine residues, with metal-binding site sequences as –CCAA–, –CACA–, or –CAAC–. The binding of each of the Group 12 metal ions, as well as Group 11 metal ions Cu^{+} and Ag^{+}, were monitored by CD spectroscopy. The authors found that Hg^{2+} bound the strongest of any of the metal ions to the peptide containing the –CAAC–motif, and was the only metal ion to bind to the –CCAA–containing peptide. It is thought that the fact that Hg^{2+} can adopt a range of geometries, specifically the linear digonal coordination, allows it to bind to the peptide with the neighboring cysteine residues.

Similar metal-binding motifs are common in various proteins and peptides with metal-binding capabilities. Suzuki *et al.* examined the metal-binding characteristics of one such protein, the heavy metal-binding protein Cdl19 from *Arabidopsis*.[37] The authors prepared the 225 amino acid residue amino-terminal peptide containing the –CXXC–metal-binding motif. Addition of Cd^{2+} to the cysteine-containing peptide was accompanied by significant changes in the CD spectrum. These changes were not observed if the cysteine residues were replaced with glycine. Similar spectral changes were also observed upon addition of Cu^{2+} and Hg^{2+}, consistent with chelation of the metal ions by the cysteine thiolate groups of the peptide, but not upon addition of Mn^{2+}, Co^{2+}, or Ca^{2+}.

The formation of metal-protein complexes and clusters containing Group 12 metal ions is further exemplified in the metallothionein class of proteins. Metallothioneins are a ubiquitous class of cysteine-rich polypeptides (approximately one-third of the residues are cysteines) that are known to bind a variety of metal ions as poly-metal thiolate clusters, containing both bridging and terminal thiolate ligation. The binding of the Group 12 metal ions to metallothioneins is discussed in a separate section devoted to the use of CD spectroscopy in monitoring metal-binding within this class of proteins (Section 3.6).

3.5 CD Spectral Data from other Metal Complexes

As we have seen, CD spectroscopy is uniquely sensitive in its ability to monitor both the binding environment of a metal ion within a biological molecule and the structural environment of the entire biological molecule. Determining the predominant secondary structure motifs of a protein or polypeptide is achieved by measuring far-UV CD signals that are characteristic of α-helix or β-sheet conformations. By comparison, the environment of a bound metal ion is monitored through visible to near-UV signals that may originate either from d–d, MLCT or LMCT electronic transitions. For this reason the binding of transition metal ions or of the Group 12 metal ions to protein ligands are most applicably studied by CD spectroscopy via the electronic transitions to their d-shells of specific LMCT bands. Only a few of the heavier main group metal ions display electronic transitions in a range applicable for CD spectroscopy, and of these Pb^{2+} is of significant biological significance due to its known toxicity.

In many ways, metal-ligand complexes containing Pb^{2+} are very similar to the analogous complexes of Hg^{2+}. Both of these ions are large, predominantly divalent, and can adopt a range of binding geometries with various donor ligands, although Hg^{2+} typically binds with higher affinity than Pb^{2+}. Mehra *et al.* used CD spectroscopy to study the binding of Pb^{2+} to the phytochelatins,[38] a glutathione-derived class of polypeptides commonly found in plants. These polypeptides have the general structure $(\gamma\text{-Glu–Cys})_n$–Gly, in which n determines the length of the polypeptide chain. As with many of the cysteine-containing polypeptides and proteins that have been discussed, metal ligation by the phytochelatins is almost exclusively via the cysteine S atoms either as terminal or bridging ligands.

Addition of Pb^{2+} to the $n = 2$ phytochelatin (containing two cysteine residues) induced changes in the

CD spectrum including formation of a band at 255 nm (+), a shoulder at about 270 nm (+), a weaker signal at 300 nm (−), and a broad signal centered at 330 nm (+). The CD spectrum became saturated after addition of one equivalent of Pb^{2+} per phytochelatin molecule. The authors concluded from these spectral data that the bound Pb^{2+} adopts a two-coordinate binding geometry when bound to this phytochelatin.[38]

For the $n = 3$ phytochelatin, Pb^{2+} addition resulted in a CD spectrum very different from that for the $n = 2$ phytochelatin. A CD spectrum was formed comprised of a peak at 225 nm (+), a shoulder at 255 nm (+), a broad negative signal in the 270 to 310 nm region, and a slight positive signal at 335 nm. This CD spectrum was again saturated with addition of one Pb^{2+} equivalent to the polypeptide. The spectroscopic and stoichiometric evidences indicate a distinct binding geometry for Pb^{2+} with this phytochelatin, either in a three-coordinate geometry or possibly adopting a distorted tetrahedral geometry with bridging cysteine thiolate ligands to form a multi-metal thiolate cluster.

Titration of the $n = 4$ phytochelatin with Pb^{2+} produced even more interesting results. Up to the addition of 0.75 equivalents of Pb^{2+}, CD bands were formed at 250 nm (+), 300 nm (−), and 325 nm (+). Further addition of Pb^{2+} up to two equivalents resulted in a new CD signal developing at 360 nm (+) and a red-shift of the main positive CD signal from 250 nm to 260 nm. These CD results indicate a shift in the binding geometry adopted by Pb^{2+} bound to the longer phytochelatin. Up to about the first equivalent, the Pb^{2+} binds in a three-coordinate or four-coordinate geometry comparable to that observed with the $n = 3$ phytochelatin. With further Pb^{2+} addition, the binding geometry shifts to two-coordinate. These results are very similar to the binding pattern of Hg^{2+} to the metallothioneins, with lowering of the metal ion coordination number, as more equivalents of the metal ion are added to the polypeptide ligands.

3.6 Metallothioneins: a Special Case of a Metalloprotein with Highly Sensitive Metal-dependent CD Spectral Properties

The protein metallothionein provides an example of a very special metal-induced CD spectrum. The spectrum to the red of 220 nm is entirely due to the presence of LMCT bands. These bands are measured at a range of wavelengths depending on the metal ion bound to the protein.[39] Metallothioneins have been isolated from an extremely wide range of organisms, suggesting that this protein exists throughout biology. Quite a remarkable range of elements bind to the protein both in vivo and in vitro, with As(III) being a recent addition to the list of those elements with detailed stoichiometric data available.[40] Key to the mammalian proteins is a high fraction of cysteines (up to 20 out of approximately 60 residues in total), a lack of aromatic amino acids, a two-domain metal-binding structure, the formation of clustered metal-cysteine binding sites and a metal-to-protein stoichiometry of 7 for divalent metals, 12 for monovalent metals and up to 18 for Hg(II) and Ag(I). The metal-binding properties have been very well studied using UV-visible absorption and CD spectroscopies,[39–47] with confirmation of the metal speciation available recently from electrospray ionization mass spectrometry. The typical divalent metal-binding structure for the α and β domains involves the peptide wrapping around both metal-binding sites providing the thiolate sulfurs from the cysteine residues (Figure 7).[41] This wrapping generates the chiral field that results in distinctive CD spectral patterns under the LMCT absorption due to the Cys → M.

The CD spectrum of rabbit liver Cd_7-MT 2a shows a characteristic spectrum of mammalian metallothioneins, with a derivative band centered at 250 nm (cross-over), positive at 260 nm, and a negative at 240 nm.[43–45] This band envelope was first characterized as due mainly to the filled α domain, arising from exciton splitting of pairs of Cd(II) atoms in this domain. The CD spectrum of the isolated Cd_3-β domain is weak and broad.[39] While the CD spectrum of Cd(II)-containing proteins has been used as a marker for cadmium binding detailed information can be obtained by titrating out the Cd(II) with metals of higher binding affinity. Metal binding to the cysteinyl sulfurs in metallothioneins follows the same trend as to organic thiolates: K_B Zn(II) < Cd(II) < Cu(I) < Hg(II). The changes in the CD spectrum as an incoming metal binds follow the trends: (i) the band maxima are dependent solely on the LMCT energies, so as the metal changes, so the band maxima change, (ii) LMCT energies are dependent on the coordination geometry, so as the geometry changes from tetrahedral, to trigonal to digonal, so the band maxima changes, and, finally, (iii) the CD spectral envelope measured is determined directly by the route the peptide chain takes in wrapping the 20 cysteine residues around the metal ions.

In total then, the CD spectrum provides a direct view of the changes in the coordination geometry in the

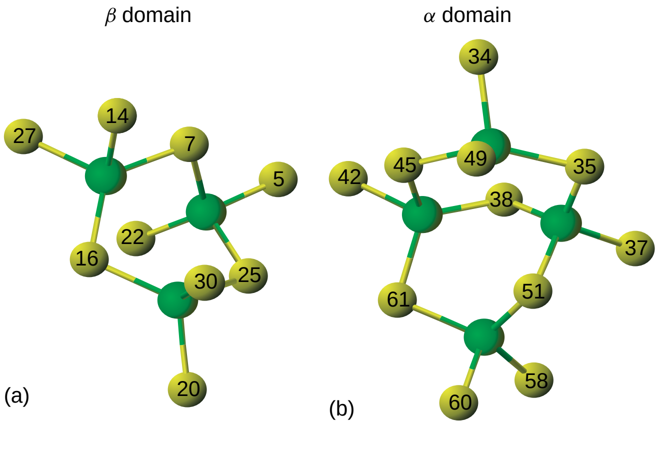

Figure 7 The β (a) and α (b) cadmium-thiolate domain structures in mammalian metallothionein. Yellow spheres represent Cys-sulfurs and Green spheres represent Cd(II) atoms. Based on models developed in our laboratory, for example, Ref. 41

metal-binding site, unobscured by the usual, strong chiral signals of aromatic amino acids. We illustrate this with the spectral changes when Cu(I) is added in mole equivalent aliquots to Zn_7-MT 2a[45] (Figure 8). At the elevated 52 °C temperature used in this experiment, the peptide chain is able to realign to accommodate the trigonally directing Cu(I).[45] Interestingly, because the folding is metal-directed, there is no ''melting'' or other typical denaturing effects observed. The 3D-representation in Figure 8 clearly shows a number of steps. Initially, the bands from the S → Zn(II) CT are replaced by new bands arising from the Cu(I). The maximum at Cu_9Zn_2-MT can be seen to exist in the same or similar peptide wrapping because the CD spectral intensities do not change between the Zn_7 and this species. However, immediately after this, a new species dominates the spectrum. Cu_{15}-MT exhibits bands at 340 nm—very much red-shifted. We interpret this as being due to a change to digonal $Cu(S^-)_2$ geometry.

It may be expected that Hg(II) would replace other group 12 metals isomorphously in a tetrahedral geometry. The CD spectral changes measured during a titration of Zn_7-MT with Hg(II) shown in Figures 9 and 10 provide evidence once again that, in fact, the geometry changes from the initial tetrahedral coordination to trigonal coordination.[46] The tetrahedral geometry adopted at 7 Hg(II) gives way to a possible trigonal geometry at 11 Hg(II), which collapses at >11 Hg(II), presumably because the Hg-S_n clusters are too large to sustain with the restrictive core size offered by the 11 cysteines in the α domain and the 9 cysteines in the β domain. Further support that the 11 Hg(II):20 cys represents a specific and well-defined structure is obtained from a titration in which

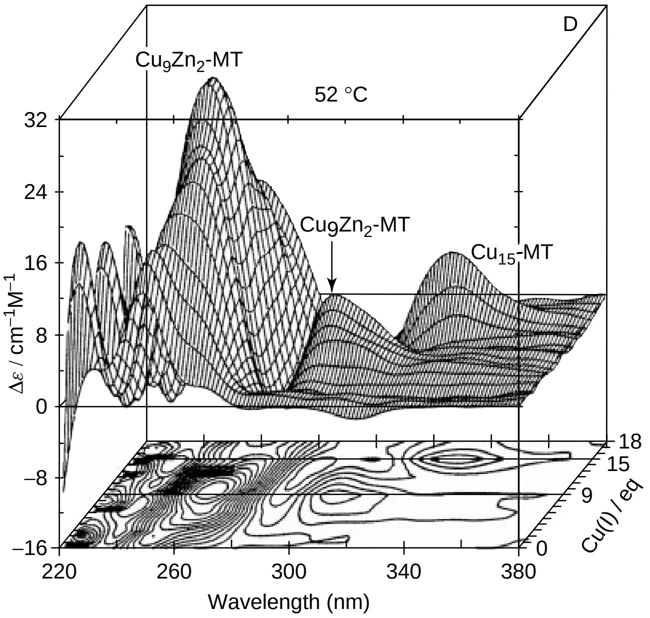

Figure 8 CD spectral changes as Cu(I) is added stepwise to Zn_2-MT 2A. (Reprinted with permission from Presta, Green, Zelazowski and Stillman.[45] © 1995 Wiley-Blackwell)

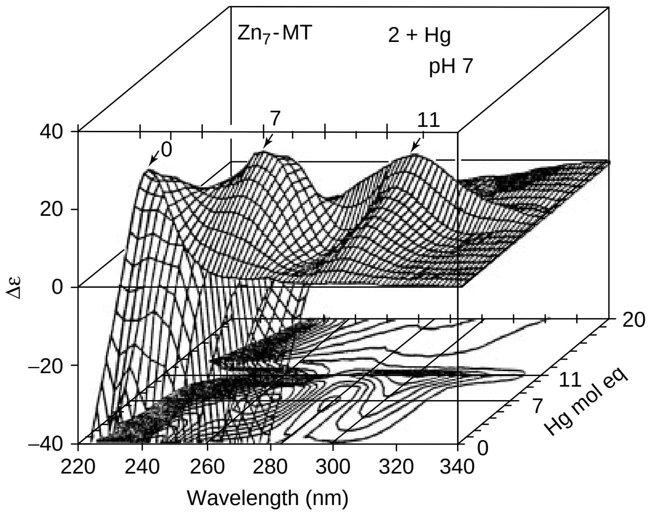

Figure 9 CD spectral changes recorded as Hg(II) was added to rabbit liver Zn_7-MT 2A at pH 7. Hg-dependent species form at the 7 and 11 Hg:MT points. (Reprinted with permission from Lu and Stillman.[46] © 1993 American Chemical Society)

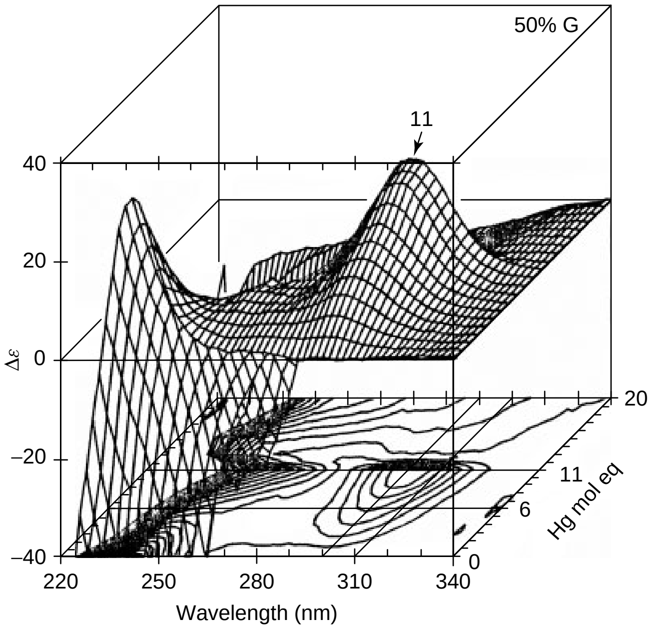

Figure 10 CD spectral changes recorded as Hg(II) was added in mole equivalent aliquots to a solution of rabbit liver Zn_7-MT 2A in a solution 50% v/v ethylene glycol showing the formation of Hg_{11}-MT as the major species. the solvent includes 50% by volume of ethylene glycol.[46] Now only the Hg_{11}-MT forms (Figure 10); that more Hg(II) can bind is evident in the spectral changes when Hg(II) is added at low pH (pH < 5 in the presence of Cl^-). Figure 11 shows the development of a signal at 18 Hg:20 cys.[44] The strong

METHOD SUMMARY

Acronyms, Synonyms

- Linear Sweep, Cyclic and Square Wave Voltammetry (LSV, CV, SWV)
- Bulk Electrolysis (BE)
- Differential Pulse Polarography (DPP)

Measured physical quantities

- potential or current response of an electrochemical system typically containing electrodes, an analyte, solvent, and electrolyte;
- coupled to other techniques in spectroelectrochemistry, additional information about alternative redox states of analytes explored.

Information available

- potential ($E°$) at which the analyte is oxidized or reduced
- number of electrons for a given oxidative or reductive process
- reversibility of an oxidation or reduction of an analyte
- the kinetics of chemical reactions that follow electrochemical reactions
- information about catalysis by electrogenerated species
- coupled with other techniques in spectroelectrochemistry. Study of the properties of oxidized and reduced forms of complexes.

Information not available, limitations

- Only electroactive materials give signals.
- The analyte must have redox activity at the potentials studied to provide a signal.
- Compatibility and solubility with a suitable solvent is needed when studying typical solution phase properties.
- Redox active sites of complex molecules must have electronic communication with the electrode surface to facilitate electron transfer.
- Resolution of overlapping processes can be difficult.
- Redox reactions can vary with the solvent, especially for irreversible reactions.

Examples of questions that can be answered

- What are the oxidation and reduction potentials, $E°$, of new materials?
- What are the electronic properties of new materials as a result of tuning orbital energetics?
- What are the properties of oxidized and/or reduced form of analytes?
- What are the kinetics and nature of chemical reactions following electrochemical reactions?
- What degree of electronic coupling of subunits within complex assemblies exist?
- What are the approximate properties of electronic excited states?

Major advantages

- Electrochemistry allows for quick and easy determination of redox properties of relatively small samples of new materials, with very small samples analyzed with microelectrodes.
- The methods are nondestructive when used for analysis with many methods not changing the bulk sample.
- Many solvent, electrode, electrolyte systems are known to provide convenient potential windows for a variety of analytes.
- Preparative methods are available for bulk transformations that are free from side reactions in chemical oxidations and reductions.
- The methods provide a clean means to provide alternative redox states of analytes, to probe with other characterization methods.

Major disadvantages

- The analyte signal response requires the presence of a redox process within the solvent, electrolyte window.
- Good signal to noise ratios are not always possible with low solubility of analyte, high solvent electrolyte background signal, or overlapping redox processes.
- To recover the sample, separation from solvent and electrolyte is necessary.
- Irreversible redox reactions result in unrecoverable samples in bulk methods.
- Nonelectroactive impurities often go undetected.

Sample constraints

- The sample is typically dissolved in a suitable solvent electrolyte system that limits the potential window.
- Milligram level samples in milliliter solvent can be analyzed by typical methods with smaller samples analyzed using microelectrodes.

1 INTRODUCTION

Over the past 25 years the field of electrochemistry has shifted from the development of techniques to applications in the laboratory, not only useful to the analytical chemist, but to a wide array of scientists. The materials presented herein are designed primarily to be of practical use for the intended audience, inorganic chemists who are students and research level professionals, with an introduction of the technical background covering basic theory at the fundamental level. The electrochemical techniques covered herein are from an inorganic chemist's perspective, and are thus a reflection of the authors' interests. For a more detailed discussion of the theory of electrochemistry, see Bard and Faulkner's *Electrochemical Methods*[1] and *Laboratory Techniques in Electroanalytical Chemistry* by Peter Kissinger.[2] Another useful electrochemistry book with an inorganic perspective is *Inorganic Electrochemistry* by Zanello,[3] which also contains information designed specifically for students and research level inorganic chemists.

This article will focus on experimental electrochemistry with an inorganic perspective. The fundamentals of electrode reactions and other electrochemical processes, as well as a discussion of electrochemical cells and electrodes/solvent/electrolyte systems will be covered. The topics presented here cover several current electrochemical methods including potential sweep techniques like linear and cyclic voltammetry (CV), potential step techniques such as square wave voltammetry (SWV), differential pulse polarography (DPP), and bulk electrolysis (BE). Coupled techniques, like spectroelectrochemistry, have emerged recently as valuable analytical techniques capable of providing unique information, and will be discussed. The technical background will be covered for the various electroanalytical techniques, followed by applications to inorganic systems, including practical concerns and data interpretation.

2 TECHNICAL BACKGROUND

2.1 Electrode Reaction Fundamentals

To evaluate reactions that take place at the electrode at a fundamental level, we first consider a thermodynamic perspective. Any thermodynamic analysis of a chemical reaction begins with the Gibbs free energy equation (1),[1] which relates cell potentials directly to free energy

$$\Delta G^\circ = -n\mathrm{F}E^\circ \qquad (1)$$

where ΔG° is the standard free energy change, n is the number of electrons, F is Faraday's constant (96 485 C mol^{-1})[4] the total charge of 1 mole of electrons, and E° is the standard potential. The application of thermodynamics to electrochemistry considers systems that are at equilibrium. As such reversibility, specifically thermodynamic reversibility, is integral in evaluating cell potentials mathematically. If a process is thermodynamically reversible, or nernstian, the Nernst equation (2)[1] can be used to relate the concentrations of two species, O (oxidized species) and R (reduced species) (equation 3), to potential, E

$$E = E^\circ + \left(\frac{RT}{n\mathrm{F}}\right) \cdot \ln\left(\frac{[\mathrm{O}]}{[\mathrm{R}]}\right) \qquad (2)$$

where E is the potential at nonstandard conditions, R is the gas constant (8.314 J K^{-1} mol^{-1}),[4] and T is temperature in K. The units on the second term yield J C^{-1} or V.

$$\mathrm{O} + n\mathrm{e}^- \longrightarrow R \qquad (3)$$

The reaction in equation (3), the addition of electrons, is a reduction, and the opposite reaction, the removal of electrons, is an oxidation, and the concentration of species O and R are that of the bulk. When examining an electrochemical reaction of an analyte in solution at the surface of an electrode, mass transport and the kinetics of electron transfer at a solid/liquid interface become important considerations.

The study of electrochemistry involves the addition and removal of electrons. In inorganic molecules this process can result in bond making/breaking, typically involving a ligand covalently bound to a metal. The consequence of adding or removing electrons is directly influenced by the molecule's orbital structure. The highest occupied molecular orbital (HOMO) is of particular importance when an oxidation is involved, and the lowest unoccupied molecular orbital (LUMO) when a reduction is involved. Illustrated in Figure 1 is the molecular orbital diagram for ferrocene, a stable 18 electron organometallic complex, often used as a potential reference (Figure 2a; $E_{1/2} = 0.43$ V vs. saturated calomel electrode (SCE)).[5] The enclosed box contains the frontier orbitals, HOMO and LUMO, the orbitals involved if one electron is removed or added respectively, as well as the lower

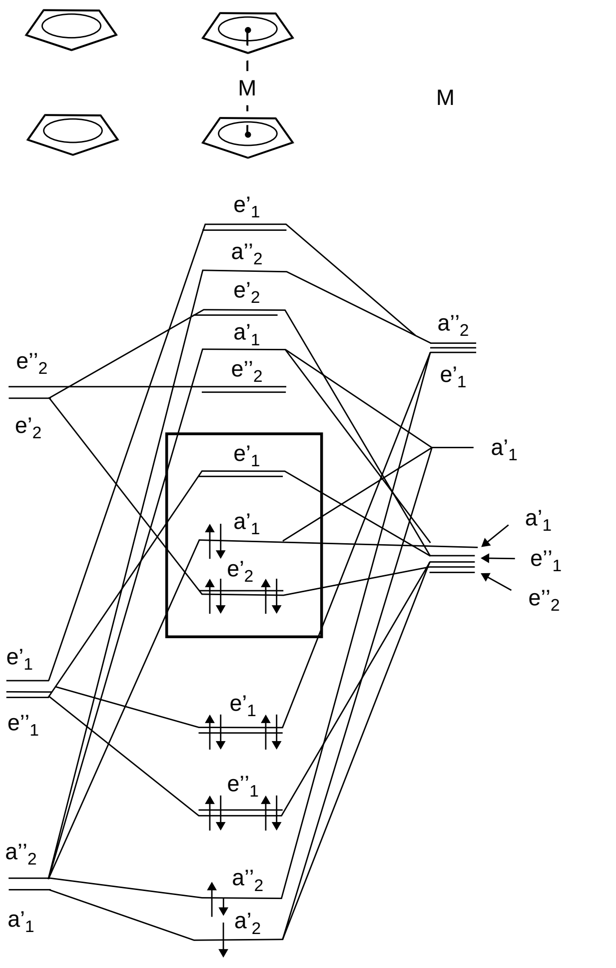

Figure 1 Molecular orbital diagram for ferrocene (M = Fe).[3] (Reprinted from Zanello[3] © 2003 Royal Society of Chemistry)

energy e'_2 orbital. The HOMO (a'_1) of ferrocene is nonbonding, therefore if one electron is removed, there will be no net change in the degree of bonding, that is no bond breaking. CV for ferrocene shows a reversible oxidation at ~0.46 V with a corresponding symmetric reduction at ~0.40 V consistent with its orbital structure, Figure 2(a). If a chemical step, like bond breaking, follows an electrochemical step the cyclic voltammogram would be irreversible and $i_p^{\mathrm{a}}/i_p^{\mathrm{c}} \neq 1$ and/or $\Delta E_p \neq 59/n$ mV, where i_p^{a} is the anodic peak current, i_p^{c} is the cathodic peak current, and ΔE_p ($E_p^{\mathrm{c}} - E_p^{\mathrm{a}}$), is the potential peak separation for the anodic (E_p^{a}) and cathodic (E_p^{c}) peak maxima. Figure 2(b) shows a cyclic voltammogram for the reductive region of $[\mathrm{Rh^{III}(bpy)_3}]^{3+}$ (bpy = 2,2′-bipyridine).[6] An irreversible reduction is observed at ~−0.9 V versus SCE identified as a $\mathrm{Rh^{III/II/I}}$ couple, followed by two reversible $\mathrm{bpy}^{0/-}$ reductions. The wave with $i_p^{\mathrm{a}}/i_p^{\mathrm{c}} > 1$ for the $\mathrm{Rh^{III/II/I}}$ couple at −0.9 V is characteristic of an irreversible redox process in which the electrogenerated complex reacts to form a species that does not undergo reoxidation at the same potential. For $[\mathrm{Rh^{III}(bpy)_3}]^{3+}$, the rhodium reduction is followed by a

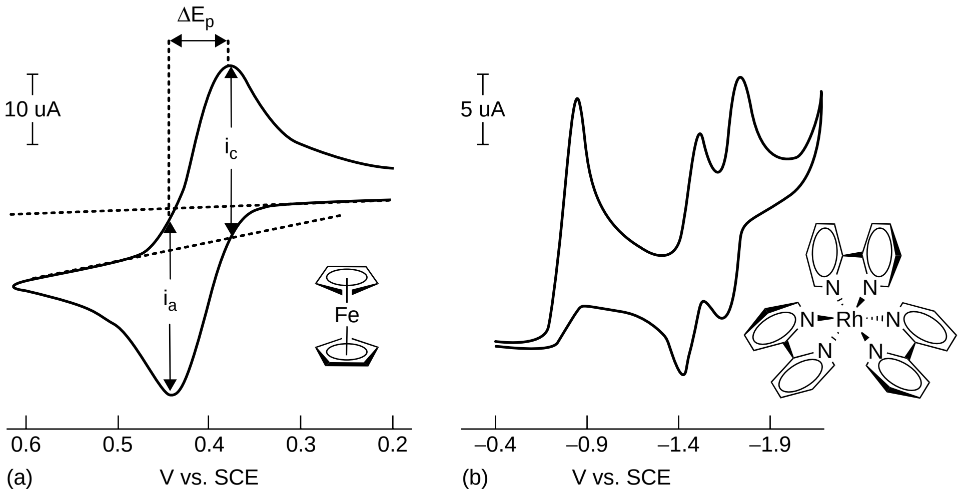

Figure 2 Cyclic voltamograms for: (a) ferrocene $[Fe(Cp)_2]$ (Cp = cyclopentadienyl anion, $C_5H_5^-$) measured in CH_3CN with 0.1 M Bu_4NPF_6 displaying a reversible oxidation at 0.43 V versus SCE;[5] and (b) $[Rh^{III}(bpy)_3]^{3+}$ (bpy = 2,2′-bipyridine), an example of an irreversible reduction followed by two reversible reductions measured in CH_3CN with 0.1 M Et_4NClO_4 versus SCE.[6] (Reprinted with permission from Kew, DeArmond, and Hanck[6] © 1974 American Chemical Society)

chemical step, bond breaking, whereby one of the bipyridines is lost to form $[Rh^I(bpy)_2]^+$.

2.2 Potentials of Electrochemical Reactions, E°

The potential of an electrochemical reaction is a measure of the thermodynamic driving force for the transfer of electrons as $\Delta G° = -nFE°$. Typical electrochemical methods measure the potential of half reactions, either oxidations or reductions. The potential of electrochemical reactions are related to electronic effects or structural changes in related series of complexes. For example the $Ru^{II/III}$ couple occurs at 1.51 V versus normal hydrogen electrode (NHE) for $[Ru(bpy)_3]^{2+}$ and at 0.18 V for $[Ru(en)_3]^{2+}$ (en = ethylenediamine) indicative of the more electron rich metal center in the en complex.[7] Similarly variation of the metal center to give $[Os(bpy)_3]^{2+}$ leads, to an oxidation at 1.06 V versus NHE, indicative of the higher energy 5d orbitals on Os versus the 4d orbitals on Ru.[7] The variation of electrochemical potentials for related series of complexes has led to the development of electrochemical parameterization of metal complex redox potentials through the development of ligand electrochemical series by Lever *et al.*[7–11] The use of measured data allows for the prediction of metal $M^{n/n-1}$ redox potentials for unstudied complexes, assuming all ligand contributions are additive

$$E_{\text{redox}} = S_{\text{m}}(\Sigma E_L(L)) + I_{\text{m}} \quad (4)$$

where E_{redox} is the potential of the $M^{n/n-1}$ couple, S_{m} and I_{m} are derived from the slope and intercept of the plot of available data for each metal and are specific to the spin and redox state

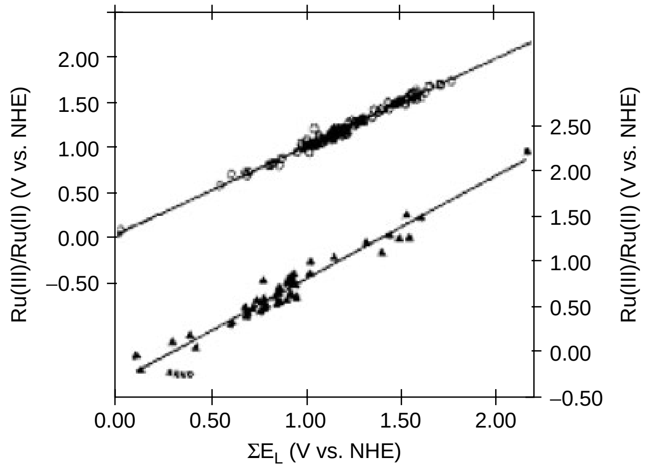

Figure 3 Plot of observed Ru(III)/Ru(II) potentials for ruthenium complexes against ΣE_L (sum of ligand parameters) measured in organic phase solvent and referred to left-hand *y* axis (circles) and measured in water and referred to right-hand *y* axis (triangles). All data are versus NHE.[7] (Reprinted with permission from Lever.[7] © 1990 American Chemical Society)

of each metal. The E_L parameters are related to the σ donation and π donation or acceptance ability of the ligands. The $Ru^{II/III}$ S_{m} in water was found to be 1.14 with I_{m} of −0.35 versus S_{m} of 1.61 and I_{m} of −1.30 for $Os^{II/III}$ in water. E_L values of bpy of 0.26 and en of 0.06 for each N bound to a metal allow for the reasonable prediction of E_{redox}. For example, E_{redox} ($[Ru(bpy)_3]^{2+}$) = 1.14(6(0.26)) + (−0.35) = 1.43 V versus NHE. These methods have been applied to a large series of complexes.[12–18] An illustrative example is shown in Figure 3.

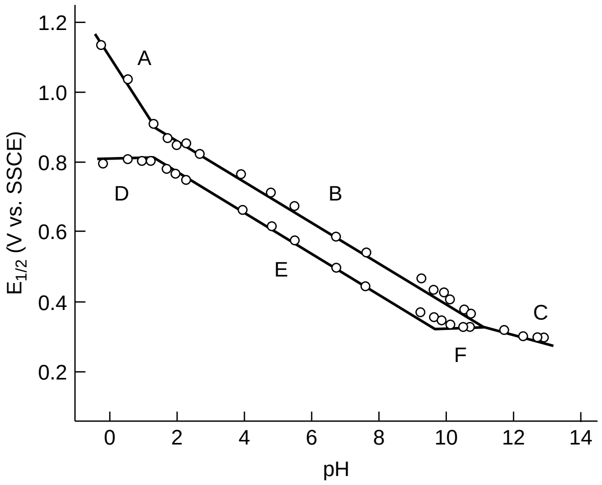

Figure 4 Pourbaix diagram plotting potential versus pH for the $Ru^{IV/III}$ and $Ru^{III/II}$ redox couples of the complex $[(tpy)(bpy)Ru^{II}OH]^{2+}$. A) $Ru^{IV} = O^{2+}/Ru^{III}-OH_2{}^{3+}$; B) $Ru^{IV} = O^{2+}/Ru^{III}-OH^{2+}$; C) $Ru^{IV} = O^{2+}/Ru^{II}-OH^{+}$; D) $Ru^{III}-OH_2{}^{3+}/Ru^{II}-OH_2{}^{2+}$; E) $Ru^{III}-OH^{2+}/Ru^{II}-OH_2{}^{2+}$; F) $Ru^{III}-OH^{2+}/Ru^{II}-OH^{+}$.[19] (Reprinted with permission from Takeuchi, Thompson, Pipes, and Meyer[19] © 1984 American Chemical Society)

Many analytes that have basic sites prone to protonation, display pH-dependent electrochemistry. The redox properties of metal complexes of H_2O, OH, and O^{2-} often display pH-dependent electrochemistry as demonstrated by Meyer *et al*. for the complex $[M(tpy)(bpy)O]^{2+}$ (M = Ru or Os; tpy = 2,2′,2″-terpyridine). These complexes have been studied probing their electrochemistry over a wide range of pH.[19] CV and DPP were used to determine $E_{1/2}$ for the $Ru^{IV/III}$ and $Ru^{III/II}$ redox couples of the complex $[Ru(tpy)(bpy)O]^{2+}$ from pH 0 to 13 (Figure 4) and the Nernst equation (2) was used to fit the data.

2.3 Electrochemical Cells and Practical Considerations

An electrochemical cell is typically composed of the working, auxiliary, and reference electrodes illustrated in Figure 5. Current flows between the working electrode, where the reaction to be monitored takes place, and the auxiliary electrode while the potential is controlled between the working electrode and the reference electrode. A potentiostat is also needed to supply the current at the desired potential to drive the redox reactions to be monitored. Table 1 is a listing of several sources of electrochemical equipment, glassware, and electrodes.

2.3.1 Solvent/Electrolyte for Electrochemistry

The solvent, solvent purity, and electrolyte are important factors in electrochemistry. The potential window available is controlled by solvent. Solvent purity is a factor to consider. Water, an impurity commonly found in many solvents, often displays an oxidation or reduction in the desired potential window, necessitating drying of the solvent.[20] Even ‘‘dry’’ solvents can contain mM H_2O which is often similar to the concentration of the analyte. Additional drying of organic solvents like acetonitrile can be achieved by passing over alumina activated in a vacuum oven, followed by solvent filtering with a syringe filter. Particles of alumina or analyte can lead to poor quality electrochemical data. The presence of H_2O limits the accessible potential window. The standard oxidation and reduction potentials for water are 1.23 V ($O_2(g) + 4H^+(aq) + 4e^- \rightarrow 2H_2O$) and −0.83 V ($2H_2O + 2e^- \rightarrow H_2(g) + 2OH^-(aq)$) versus NHE,[21] which are pH-dependent. Solutions should also be sufficiently deoxygenated to remove O_2 or the oxygen couple will appear as an irreversible couple at approximately −0.8 V versus Ag/AgCl, or O_2 could react with the reduced analyte.

Dimethylsulfoxide	$[NEt_4][ClO_4]$, $[NBu_4][PF_6]$	-2.3 to $+1.0$[3]
Tetrahydrofuran	$[NBu_4][PF_6]$, $LiClO_4$, $NaClO_4$	-2.4 to $+1.3$[3]
Water	$NaClO_4$, KNO_3	~ -0.8 to $+1.2$[(b)]

[(a)]Potential for platinum working electrode with $[NBu_4][PF_6]$ as supporting electrolyte.
[(b)]pH dependent.[21]

Acetonitrile and methylene chloride are typically good solvents for extending the window for anodic scans, while tetrahydrofuran (THF), N,N-dimethylformamide (DMF), and dimethyl sulfoxide (DMSO) are typically good solvents for extending the potential window for cathodic scans (Table 2).

2.3.2 Working Electrodes

The working electrode is the electrode surface at which the electrochemical reaction involving the analyte takes place. Working electrodes are typically composed of redox inert materials such as carbon, platinum, gold, or mercury and are typically small surface area electrodes for analysis methods, and large surface area for BE methods. A working electrode is chosen based on the needed potential window and the type of electrochemical technique. Often minor water impurities can limit potential windows unless a working electrode material is chosen with a high overpotential for water oxidation or reduction. Mercury, for example, does not have a very wide window into the anodic region, so in the case where one wants to investigate a highly positive oxidation, an alternative electrode like carbon or platinum would be required. Platinum working electrodes limit the reductive window in the presence of water. Techniques dependent on mercury working electrodes, like the dropping mercury electrode (DME), static mercury electrode, and hanging mercury drop electrode, will be discussed in detail later.

The solvent chosen must be of sufficient purity to be chemically inert in the potential window to be studied and be able to dissolve the analyte in high enough concentration. The supporting electrolyte must also be soluble in the chosen solvent to provide for the electrical conductivity of the solution reducing solution resistance, and limiting analyte motion by electromotive force. It is important that the electrolyte not be redox active in the potential window studied. Table 2 lists commonly used organic solvents and their corresponding supporting electrolytes. Electrochemistry can also be performed at reduced temperature to extend the accessible potential window as demonstrated by DeArmond and Hanck where the cathodic region for DMF at $-54\,°C$ was extended to -3.0 V versus NHE.[22]

The microelectrode is a class of working electrodes that has increased in popularity since the 1980s and is used mainly by electroanalytical chemists.[1] These electrodes have improved time resolution for electrochemical reactions, and can function in higher resistance solutions. Diffusion is treated as hemispherical as the electrode surface area is more like a point than a plane as is the case with macroelectrodes. Typically microelectrodes are difficult to construct and have cross sections on the order of 5 μm.

The working electrode is typically stationary; however, there is a class of electrodes, the rotating disk

electrodes (RDE) and the rotating ring disk electrodes (RRDE), that are in continuous motion. These electrodes spin at a controlled speed resulting in forced convection, one type of mass transport, whereas the stationary working electrode typically undergoes diffusional mass transport. The various types of mass transport will be discussed in detail later. The rotating disk and RRDE are designed to make measurements independent of time. This allows one to make steady state measurements without considering electrolysis time, and is particularly useful in that transients can sometimes be observed, allowing for elucidation of the electrochemical mechanism. RDEs can also be used in electrocatalysis, discussed in detail in section 3.3.

2.3.3 Reference Electrodes

A reference electrode is needed to provide a potential scale for E° values as all voltages are relative. Any electrochemical reaction with a stable, well known potential can be used as a reference electrode. The NHE or standard hydrogen electrode (SHE) (Pt/H_2, 1.0 M H^+) was the first well known reference electrode and is used as a reference in most tables of redox potentials.[23] An NHE is difficult to construct and operate and therefore, is not typically used experimentally. Since the NHE is widely accepted, potentials are still often referenced to the NHE, converted from other reference electrodes. For aqueous solvents the SCE (Hg/Hg_2Cl_2 (KCl)) and the silver/silver chloride (Ag/AgCl) electrode are now commonly used as reference electrodes. To convert from the SCE to the NHE, E (vs. NHE) $=E$ (vs. SCE) $+ 0.24$ V. For nonaqueous solvents the silver/silver nitrate ($Ag/AgNO_3$) reference electrode is often used. A pseudo-reference electrode can also serve as a reference point for aqueous or nonaqueous solutions. A silver or platinum wire can be used as a pseudo-reference electrode after being calibrated by adding a stable reversible redox species like ferrocene (0.43 V vs. SCE)[5] or ferricyanide (0.194 V vs. SCE),[24] for nonaqueous and aqueous solutions respectively. In addition, any measurement can use ferrocene as an internal reference (added to the analyte, solvent, electrolyte solution), provided that the analyte redox couples do not overlap with the ferrocene$^{0/+}$ couple. Reference electrode potentials can deviate from the established values by up to 100 mV. This should be corrected by measuring the potential of a known redox couple. If in calibrating a reference electrode, ferrocene is measured to be 0.36 V versus an Ag/AgCl (3 M NaCl) reference electrode (ferrocene$^{0/+}$ $E_{1/2}$ is 0.38 V vs. Ag/AgCl), the reference electrode can be corrected using equation (5).

$$\Delta E = E_{\text{theoretical}} - E_{\text{measured}} \tag{5}$$

Where ΔE is the correction factor, $E_{\text{theoretical}}$ is the potential of ferrocene, and E_{measured} is the measured potential for ferrocene. In the above case, $\Delta E = 0.38\,\text{V} - 0.36,\ \text{V} = 0.02\,\text{V}$, and 0.02 V should be added to every measurement using that specific reference electrode to correct for its deviation from established values. Table 3 provides potentials for commonly used reference electrodes.

2.3.4 Auxiliary Electrodes

The auxiliary electrode is used to complete the electrochemical circuit allowing current to flow between the working and auxiliary electrodes so that E is more accurately measured between the working and reference electrodes. Auxiliary electrodes have small surface areas, like a wire, for analysis methods and large surface areas for BE methods. While the redox reaction of the analyte takes

place at the working electrode, the counterreaction takes place at the auxiliary electrode, typically involving the oxidation or reduction of solvent. Depending on the electrochemical technique used, a platinum wire, mesh, or coil is most often used as the auxiliary electrode, but other stable electrode materials like carbon cloth and reticulated vitreous carbon (RVC) are sometimes employed.

2.4 Electrochemical Processes

Typical electrochemistry occurs in solution at a solution-electrode surface interface. An electrochemical reaction, $O + e^- \rightarrow R$, involving the addition of an electron to the oxidized species O, to generate the reduced species R, in a solution at the surface of an electrode involves a number of processes. The potential of the electrode is set providing the driving force for electron transfer. The species O must approach the electrode surface within a critical distance to allow transfer of an electron from the electrode surface to the analyte, O, generating R. As species O is reduced at the electrode surface, additional O molecules can undergo mass transport to the electrode surface to continue the reduction. As this is taking place, species O is reduced to generate the species R, which can take place via an inner sphere or outer sphere mechanism. The electrogenerated R then undergoes mass transport back into the bulk solution. Mass transport can take place by diffusion, convection, and migration. Diffusion takes place when the concentration of a species in a solution is not constant, resulting in the random movement of molecules, eventually resulting in a constant concentration throughout the solution. Convection takes place when a mechanical force like stirring or a gradient of pressure is applied to a solution, resulting in the movement of molecules. Migration takes place in the presence of an electric field where ions are attracted to an oppositely charged electrode or repelled from an electrode with the same charge.

3 APPLICATIONS

3.1 Potential Sweep Methods

Potential sweep methods which vary potential and measure current are widely used as they are easy techniques to employ. The methods include linear sweep voltammetry (LSV) and CV which can yield a large amount of electrochemical data in a short amount of time. These potential sweep methods are commonly used by inorganic chemists due to their ease of use and the information obtained. CV has appeared in the literature as the most popular electrochemical technique among inorganic chemists over the past three decades. Another advantage to potential sweep methods is that instrumentation is widely available at relatively low cost. Potential sweep methods usually involve varying the potential linearly with time, and monitoring the cell current. The rate of the potential change is called *the scan rate* and it typically ranges from $100\,\mathrm{V\,s^{-1}}$ to $10\,\mathrm{mV\,s^{-1}}$. Potential sweep methods plot the current response versus the applied potential.

3.1.1 Linear Sweep Voltammetry (LSV)

Linear sweep voltammetry (LSV), also known as linear sweep chronoamperometry, is a potential sweep method where the applied potential (E) is ramped in a linear fashion while measuring current (i). LSV is the simplest technique that uses this waveform. The potential range that is scanned begins at an initial or start potential and ends at a final potential. It is best to start the scan at rest potential, the potential of zero current. For a reversible couple, the peak potential can be calculated using equation (6).[1]

$$E_p = E_{1/2} + \frac{1.109\,\mathrm{RT}}{nF} \tag{6}$$

Where E_p is the peak potential and $E_{1/2}$ is the half wave potential. The forward peak current, i_p, for a reversible process can be related to the analyte concentration, C_o, by the Cottrell equation (7).[2]

$$\mathrm{i}_p = 2.6910^5 n^{3/2} A D_o^{1/2} C_o \nu^{1/2} \tag{7}$$

where A is the electrode area ($\mathrm{m^2}$), D_o is the diffusion coefficient ($\mathrm{m^2\,s^{-1}}$), C_o is the concentration of analyte ($\mathrm{mol\,L^{-1}}$), and ν is the scan rate ($\mathrm{V\,s^{-1}}$). Figure 6 shows the potential wave form for LSV and a corresponding example of a voltammogram for this electrochemical technique.

3.1.2 Cyclic Voltammetry (CV)

CV is in all practical regards a continuation of LSV, where the potential ramp is reversed at the end of the first sweep and the current is measured a second time in the reverse direction. It is best to start at the rest potential, the potential of zero current, to avoid electrochemical change prior to starting the scan. Figure 6 illustrates the potential ramp for LSV and CV and a typical current response for the methods. The second sweep for a cyclic voltammetric measurement can be continued past the original starting point to a more negative or positive potential to a second switching point where the potential ramp is reversed once more. The potential is then typically ramped to the original initial potential completing a cycle, hence CV. For systems with many redox couples it is beneficial to sequentially vary the switching potential after the first, second, ... redox couples to isolate each reductive or oxidative couple so that reversibility of each couple can be ascertained. In some cases running multiple cycles can be beneficial in revealing mechanistic information. Variation of scan rate can impact reversibility as faster scan rates limit the time that an electrogenerated redox state has to react.

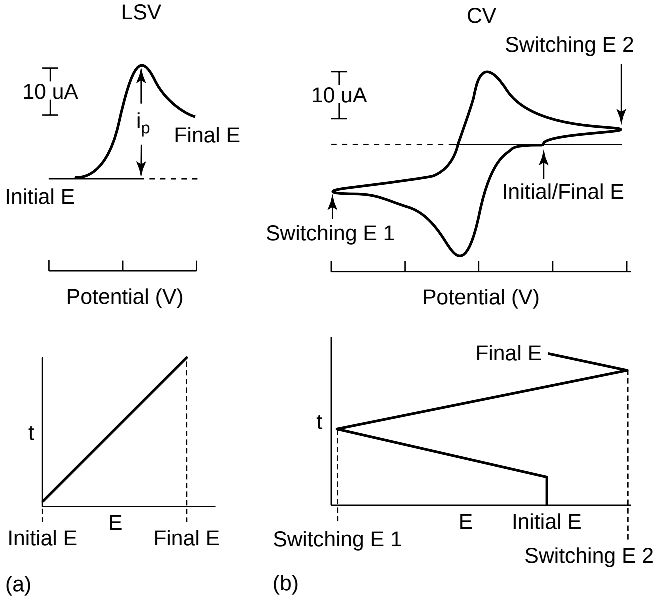

Figure 6 Potential waveforms for linear sweep (LSV; (a) and cyclic voltammetry (CV); (b) displaying potential versus time including the initial and final potentials, and a typical linear sweep voltammogram and cyclic voltammogram plotting current versus potential

The ultimate goal for all of the electrochemical techniques for the inorganic chemist is to provide information about the electron transfer processes especially those involving the frontier orbitals. Analysis of peak shapes and positions for CV can elucidate the potential for and reversibility of the redox processes. The redox couple reversibility is a probe into any following chemical reactions that can occur after the redox step. If the redox couple is reversible, it indicates no following chemical reaction. Irreversible or quasireversible peaks in CV, indicate a following chemical reaction for that given redox couple. The ratio of the anodic peak current, i_p^a, and the cathodic peak current, i_p^c, $i_p^a/i_p^c = 1$, indicates reversibility (Figure 6). This i_p^a/i_p^c ratio indicates whether a redox process is reversible, irreversible, or quasireversible. The peak to peak separation, ΔE_p ($\Delta E_p = E_p^c - E_p^a$), where the anodic peak potential, E_p^a, the cathodic peak potential, E_p^c, are all independent of the scan rate. ΔE_p is dependent on temperature (equation 8), with ΔE_p (at 25 °C) = 59/n mV (n = number of electrons transferred in the redox reaction) for a reversible redox couple.[1]

$$\Delta E_p = \frac{2.3\,\mathrm{RT}}{(nF)} \tag{8}$$

Some deviation of ΔE_p is typically observed experimentally due to solution resistance, especially at higher scan rates. Many potentiostats can compensate for this phenomenon with internal resistance compensation. When $i_p^a/i_p^c \neq 1$ and/or when $\Delta E_p > 59/n$ mV, the electrochemical process is quasireversible. If no return wave is observed in the cyclic voltammogram, the electrochemical process is considered irreversible.

3.1.3 Practical Considerations for Potential Sweep Methods

There are several disadvantages to potential sweep methods. First, it is difficult to measure multiple, closely spaced redox couples. This lack of resolution is due to the broad asymmetric nature of the oxidation/reduction waves. In addition, the analyte must be relatively concentrated as compared to other electrochemical techniques to obtain measurable data with good signal to noise. This decreased sensitivity is due to a relatively high capacitance current which is a result of ramping the potential linearly with time. Potential sweep methods are easy to perform and provide valuable insight into the electron transfer processes. They are excellent for providing a preliminary evaluation, but are best combined with other complementary electrochemical techniques.

There are many practical considerations important to any experimental technique and important considerations other than the previously delineated solvent, electrolyte, and electrode selection are summarized below. As with any experimental technique, a background scan is necessary and should be conducted on the solvent/electrolyte system. The absence of sufficient electrolyte can lead to increased internal resistance which is displayed as large $\Delta E_p > 59/n$. Electrochemical irreversibility can also result from not having a clean working electrode or adsorption of the analyte onto the electrode surface. Adsorbed analyte generated during an electrochemical scan often leads to the presence of adsorption and/or desorption spikes which appear as intense sharp peaks in LSV, CV, and many other techniques. Changing the solvent and/or working electrode material can often eliminate analyte adsorption with DMF typically providing improved solubility limiting adsorption. Electrode contamination, resulting in electrochemical irreversibility, can be removed by cleaning the working electrodes with very fine alumina, or electrochemically, by holding the potential at very positive or very negative potentials in clean solvent/electrolyte. The purity of the solvent is the key to electrochemical reversibility and the accessible potential window and high purity dry solvents should always be used. Typical dry solvents, dried over molecular sieves, include millimolar water which is similar in concentration to most analytes in electrochemical experiments. Additional drying is sometimes needed and can be accomplished with many organic solvents using alumina that has been activated at high temperatures in a vacuum oven and dried in an inert atmosphere. The solvent should be syringe filtered to remove any small particles. The solvent, electrolyte, and analyte solution must not contain undissolved materials as this can lead to adsorption issues that give rise to reversibility problems. As already mentioned, the presence of H_2O limits the accessible potential window. The

standard oxidation and reduction potentials for water however, are 1.23 V ($O_2(g) + 4H^+(aq) + 4e^- \rightarrow 2H_2O$) and −0.83 V ($2H_2O + 2e^- \rightarrow H_2(g) + 2OH^-(aq)$) versus NHE,[21] which are pH dependent. Solutions should also be sufficiently deoxygenated to remove O_2 or the oxygen couple will appear as an irreversible couple at approximately −0.8 V versus Ag/AgCl and O_2 could react with the reduced analyte. Bubbling argon prior to taking the measurement is typical but once data collection begins, bubbling must be discontinued to prevent a turbulent solution from affecting mass transport leading to a very noisy signal. To obtain a proper signal, the electrochemical circuit must be complete or the electrochemical signal will display significant noise or zero current. If there is not enough electrolyte added to the solution, resistance could be too high resulting in poor current flow, often reflected by very high ΔE_p and/or a ramp-like signal in CV. Typically 0.1 M electrolyte is sufficient. Air bubbles can sometimes form within a reference electrode which can block the solvent interface resulting in issues with the signal or potential measurement. These bubbles can be dislodged by tapping the electrode. Bubbles under the working electrode can also lead to similar issues.

3.1.4 Example of Application of CV to Study Rh Complexes

DeArmond used CV to probe reaction sequences for $[Rh^{III}(bpy)_3]^{3+}$ and $[Rh^{III}(bpy)_2Cl_2]^+$ F.[6] First, cyclic voltammograms were recorded at two different sweep rates, 0.10 and 31 V s^{-1} (Figure 7a). The slower sweep rate shows an irreversible two-electron rhodium reduction followed by two one-electron bpy reductions. The fast sweep rate reveals that the two-electron rhodium reduction is actually two one-electron reductions with little separation. Figure 7(b) shows the initial part of the first reduction at a very fast scan rate, 46 V s^{-1}. Reversing the potential after the very first part of the rhodium reduction (at ca. −0.85 V) isolates the $Rh^{III/II}$ couple from the $Rh^{II/I}$ couple. Isolating couples can provide information about peak reversibility. At the fast 46 V s^{-1} scan rate, the first part of the reduction has a corresponding oxidation indicating reversibility for the first one-electron reduction of $[Rh^{III}(bpy)_3]^{3+}$. These data, suggest that the irreversible nature of the $Rh^{III/II/I}$ couple at slower scan rates are due to the $Rh^{II/I}$ couple, indicating that a chemical reaction takes place upon generation of Rh^I, that is, loss of a bipyridine. The related complex, $[Rh^{III}(bpy)_2Cl_2]^+$, displays an irreversible reduction even when attempting to isolate the first couple. This indicates a reaction following the first one-electron reduction to generate Rh^{II} that is loss of chloride. Finally the complex $[Rh^I(bpy)_2]^+$ shows no reduction corresponding to the $Rh^{III/II/I}$ couple confirming the rhodium-based identity of the first reduction in $[Rh^{III}(bpy)_3]^{3+}$ and $[Rh^{III}(bpy)_2Cl_2]^+$ (Figure 7c).

3.1.5 Surface-Attached Analytes in CV

Analytes can also be bound to the electrode surface resulting in unique nondiffusion controlled electrochemistry. Meyer used 4-vinyl-4′-methyl-2,2′-bipyridine (vbpy) bound

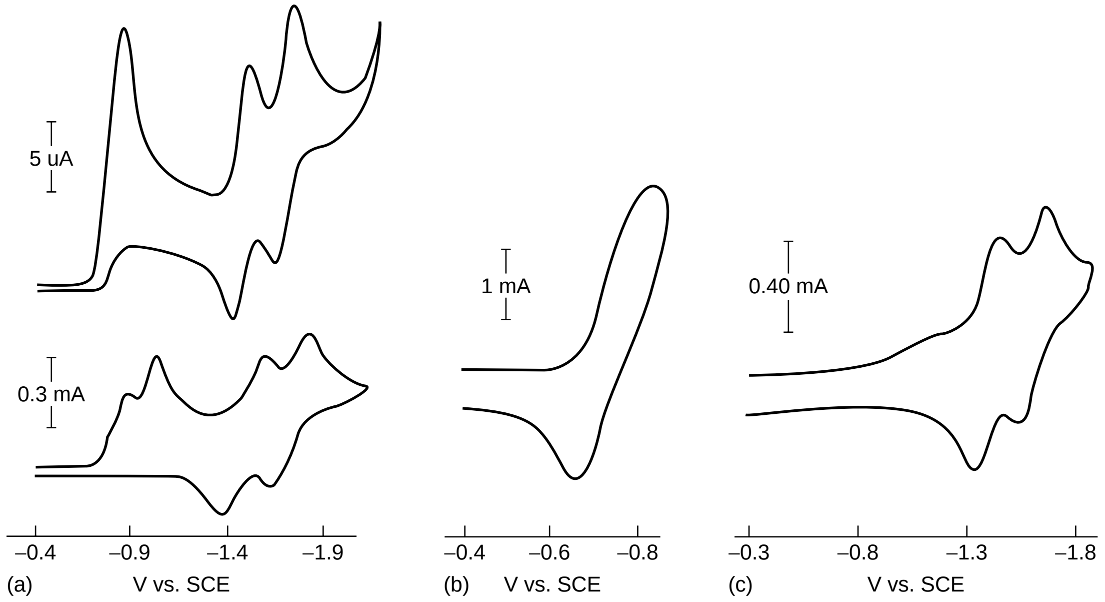

Figure 7 Cyclic voltammetry for $[Rh^{III}(bpy)_3]^{3+}$ (bpy = 2,2′-bipyridine) measured in CH_3CN with 0.1 M Et_4NClO_4 versus SCE showing: (a) the reductive region at two different scan rates, 0.10 V s^{-1} and 31 V s^{-1} (see also Figure 2b); (b) the initial part of the first reduction at a high scan rate, 46 V s^{-1}, showing some reversibility, and (c) reduction of the reduced complex $[Rh^I(bpy)_2]^+$ showing the absence of the rhodium reduction as its already in a reduced state, followed by two reversible bpy$^{0/-}$ reductions.[6] (Reprinted with permission from Kew, DeArmond and Hanck[6] © 1974 American Chemical Society)

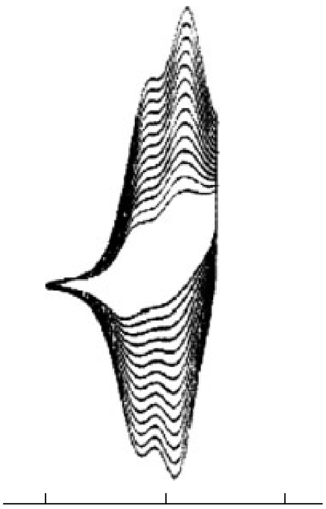

Figure 8 Cyclic voltammogram showing the reductive region of the electropolymerization of $[Ru(vbpy)_3]^{2+}$ (vbpy = 4-vinyl-4′-methyl-2,2′-bipyridine) versus SSCE with 0.1 M Et_4NClO_4 as the supporting electrolyte in CH_3CN on a platinum electrode.[25] (Reprinted with permission from Denisevich, Abrura, Leidner, Meyer, and Murray[25] © 1982 American Chemical Society)

to metal complexes to electropolymerize and thereby attach ruthenium, osmium, and cobalt complexes to the electrode surface.[25] Electrode attachment via an electropolymerization reaction results in a thin film of transition metal complexes bound to the platinum working electrode. Once the analyte is surface bound, diffusion is not needed in electrochemical measurements. Figure 8 shows the electropolymerization in progress as initiated and monitored by CV. The peak current increases as more analyte is attached to the electrode via the electropolymerization process, initiated by reduction of the vbpy ligand. The CV of the surface-attached analyte shows no peak to peak separation (ΔE_p) as diffusion is not needed when the analyte is attached to the electrode surface.

Alkyl thiols have also been used to covalently attach inorganic complexes to electrode surfaces.[26] Ferrocene terminated thiols have been shown to form self-assembled monolayers as a mixture with alkane thiols on the surface of a gold electrode. These systems can be used to study interfacial electron transfer or can be employed in the biosensor field. Figure 9 shows a cyclic voltammogram of a ferrocene thiol attached to a gold electrode surface. These thiol-modified electrodes have monolayer coverage. The electrochemical signal is characteristic of a surface-attached species showing low background current and little to no peak to peak separation, ΔE_p. Thiol-modified electrodes with redox active sites are also used as electron relays to catalyze a redox process in a solution. The analyte in the solution does not undergo oxidation or reduction until the surface-bound redox active site is oxidized or reduced since the analyte cannot approach the

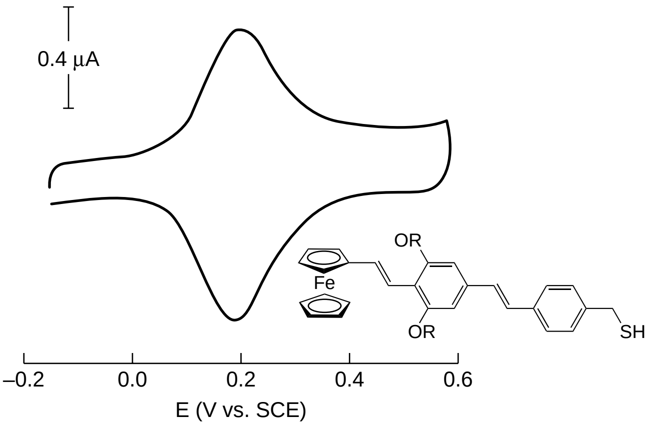

Figure 9 Cyclic voltammogram of a ferrocene terminated thiol bound to the surface of a gold electrode.[26] (Reprinted with permission from Dudek, Sikes, and Chidsey[26] © 2001 American Chemical Society)

electrode surface. The typical signal for such a measurement is a large increase in current for the surface bound redox active site dependent on analyte concentration, with a reduction in the return couple current for the surface bound redox site.

3.2 Potential Step/Pulsed Methods

Potential step methods have emerged as valuable electrochemical methods due to the highly sensitive nature of the technique. The waveform employed in potential step methods, also referred to as pulsed methods, have some advantages over potential sweep methods. The main advantage is that the steplike waveform can discriminate and separate the capacitive current versus the faradaic current, the current due to the reduction or oxidation undergone by the analyte, increasing signal to noise. Capacitive versus faradaic current discrimination is the basis for all of the pulsed techniques. The rate of decay of the capacitive current and the faradaic current is not the same. The capacitive current has an exponential decay whereas the faradaic current decays as a function of $t^{-1/2}$. Since the rate of decay of the capacitive current is much faster than that of the faradaic current, the potential is stepped up after which it remains constant for a time delay; the current is measured just before the next step up. This delay in the measurement allows for the capacitive current to fall off to a larger extent than the faradaic current. Due to the decreased capacitive current, the potential step/pulsed techniques result in a larger accessible potential window, a higher signal-to-noise ratio, and a lower limit of detection. Scan rates for this method are typically slow, $50\,mV\,s^{-1}$, due to the delay that is necessary to minimize the capacitive current. Faster scan rates are possible, but increasing the scan rate results in a decreased signal-to-noise ratio. The potential step methods that will be discussed include voltammetric techniques (use of a solid working electrode) like normal pulse voltammetry

(NPV), differential pulse voltammetry (DPV) and SWV, and polarography methods (use of a mercury drop electrode) like normal (normal and pulse polarography (NPP)) and DPP, although sometimes these polarographic versus voltammetric terms are used interchangeably. These step methods do not typically use return scans and therefore often do not provide information about reversibility of the redox process and can sometimes give data that, unknown to the researcher, are characteristic of decomposition products.

3.2.1 Voltammetric Techniques

Normal Pulse Voltammetry (NPV). Normal pulse voltammetry (NPV) has the waveform shown in Figure 10(b), and uses a steplike waveform to minimize the capacitive current. Again it is best to start at rest potential. The pulse is comprised of an initial potential step up, followed by holding the potential steady for a length of time which defines the pulsed width. The current measurement takes place at the end of the pulse, followed by the potential stepped back down to the initial potential, usually zero or the rest potential. This is the simplest waveform of the pulsed methods. An example of a current signal response is shown in Figure 10(a).

Differential Pulse Voltammetry (DPV). There are two main differences between differential pulse and NPV. The waveform for DPV, Figure 10(b), involves a pulse of amplitude ΔE_{pulse} like that of the normal pulse sequence but the step back down is not to the initial potential, instead it is to a specific differential that is used during the measurement. Also, there are two sampling periods for each pulse, once at the end of the potential step up, like in NPV, and an additional sampling period at the end of the step down in potential, after which the difference in the two signals is recorded; hence the name DPV. This pulse sequence results in a current signal response different from that of NPV, shown in Figure 10(b). If the electrochemical process is reversible, the peak half width, $\Delta E_{p/2}$, is determined by equation (9),[1]

$$\Delta E_{p/2} = \frac{(3.52\,\mathrm{RT})}{(nF)} \tag{9}$$

and the current at time t, i_t, is determined by equation (10) where $(t-t')$ is the time of the pulse width.[1]

$$i_t = \frac{(n\mathrm{FAD}_{\mathrm{o}}^{1/2}C_{\mathrm{o}})}{(\pi^{1/2}(t-t')^{1/2})} \tag{10}$$

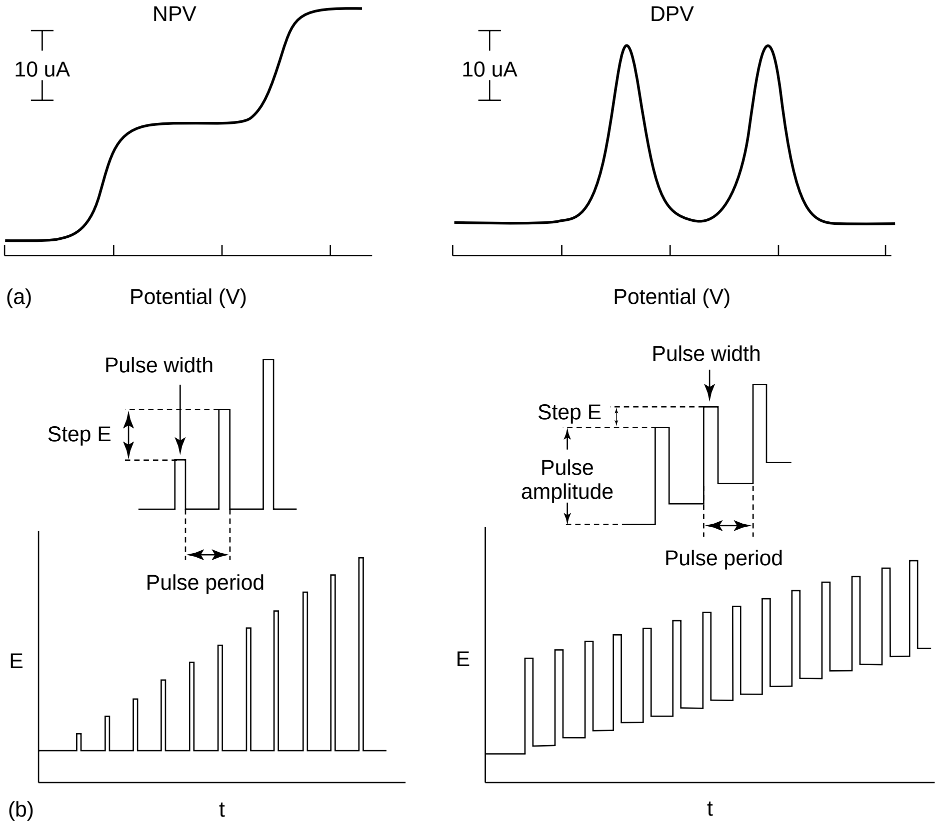

Figure 10 Potential waveforms for normal pulse (NPV) and differential pulse voltammetry (DPV) displaying potential versus time (b), and a typical normal pulse and differential pulse voltammogram plotting current versus potential (a)

Square Wave Voltammetry (SWV). SWV, the third potential step method discussed here, has recently found widespread use. It was developed by Ramaley and Krause during the 1960s[27] and popularized by Janet and Robert Osteryoung in the 1980s[28,29] and is sometimes referred to as Osteryoung squarewave voltammetry (OSV). This technique is an especially useful method for investigating electrochemical reactions with overlapping redox waves. The pulse sequence is very similar to DPV, shown in Figure 10(b), but typically can be conducted at faster scan rates. There is a potential step up, which could be anodic (or cathodic), where the potential is held steady and the first current measurement is taken. This potential step is followed by a reversal of the potential opposite of the initial potential change. This cathodic (or anodic) potential step is exactly double the original anodic (or cathodic) potential step. This is followed by the potential held steady for the same period as the first potential step, at the end of which the second current measurement is taken. The next potential step up is equal to the step down plus a small potential increment. The waveform then repeats. Both the anodic and cathodic potential changes are proportional to the pulse widths forming a squared appearance. The current signal response in Figure 11 is also similar to DPV but typically higher scan rates are possible. The increased tolerance of faster scan rates is due to measuring the difference current. Some of the capacitive current is subtracted out so the long delay to decrease the capacitive current is not as necessary as with the other stepped techniques. The difference current, Δi, for SWV is given by equation (11).[1]

$$\Delta i = \Delta\psi \frac{(n\mathrm{FAD}_o^{1/2}C_o)}{(\pi^{1/2}t^{1/2})} \tag{11}$$

where $\Delta\psi$ is a dimensionless peak current that depends on potential variables.

Practical Considerations for Potential Step Techniques. Potential step techniques have many advantages that result from the pulse sequence. One disadvantage of the pulsed techniques is that the relatively slow scan rates employed can sometimes make interpreting the results difficult if the electrogenerated species is not particularly stable. This may lead to observed data being unknowingly characteristic of a decomposition product and not the analyte. Coupling to other electrochemical techniques like CV can help uncover decomposition. The application of SWV has improved the scan rate limitation. Given that reverse scans are not typically available with most commercial instruments, information about reversibility present in CV may be unavailable in these pulsed methods. Cyclic SWV has been developed by Osteryoung[30] but this pulse sequence is not typically available on most commercial instruments. The same practical considerations are necessary with the potential step methods as the potential sweep methods. Solutions must be dry and deoxygenated, and a sufficient amount of electrolyte and analyte are required for optimal signal-to-noise ratio, although generally a lower concentration of analyte can be used, given the higher signal-to-noise ratio of these pulsed techniques.

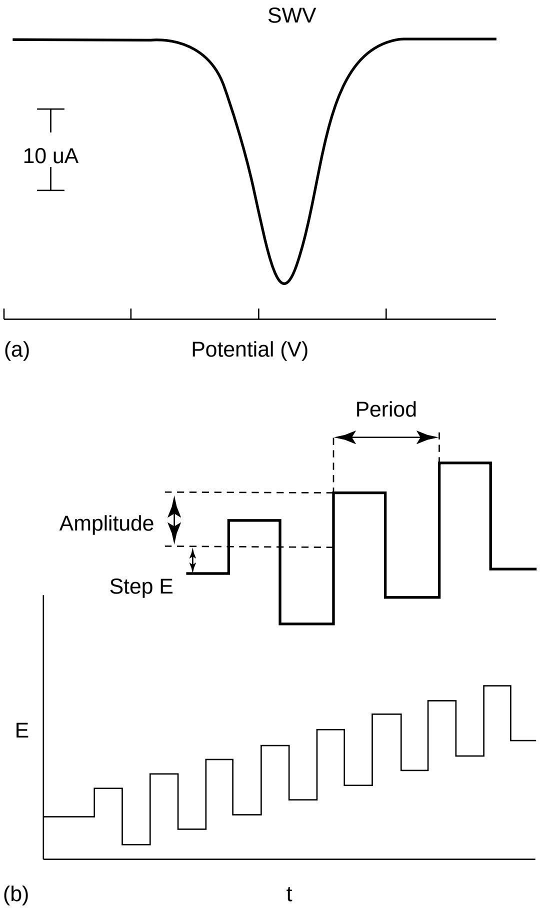

Figure 11 Potential waveform for square wave voltammetry (SWV) displaying potential versus time (b), and a typical square wave voltammogram plotting current versus potential (a)

Application of Square Wave Voltammetry to Analysis of Hydrogen Peroxide. Stevenson used SWV in a method developed for detection of ultralow concentrations of H_2O_2, designed for biodiagnostic applications.[31] For biosensors, typically enzymes are employed to catalytically generate a redox active species like H_2O_2 which can be detected electrochemically. Stevenson's approach utilized a microelectrode in conjunction with a chemically activated mediator, Amplex Red, which is chemically oxidized by H_2O_2 in the presence of horseradish peroxidase. SWV is used because of its background suppression and intrinsic low limit of detection. For this application SWV was more sensitive than CV by a factor of five (Figure 12). This combined SWV method with the mediator and peroxidase, results in a significant increase in analytical sensitivity for H_2O_2 detection, resulting in detection limits as low as 8 pM.

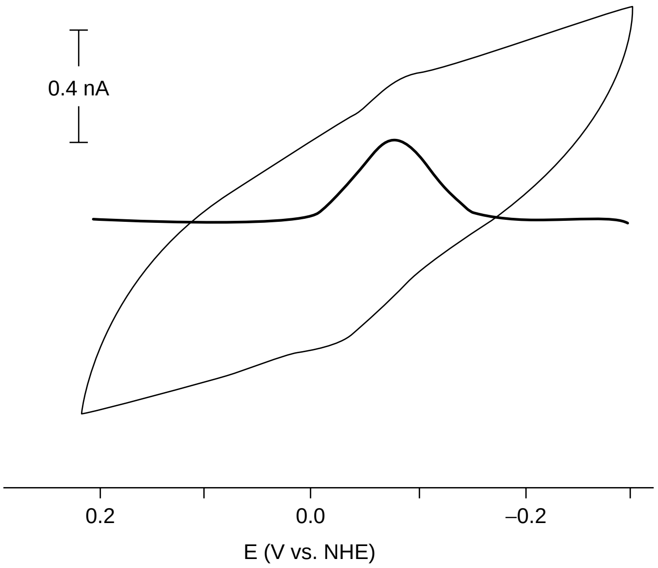

Figure 12 A 300 nM H_2O_2 standard is shown for both cyclic voltammetry (CV) (light line) and square wave voltammetry (SWV) (heavy trace) comparing the signal-to-noise ratio of the two techniques.[31] (Reprinted with permission from Lyon and Stevenson[31] © 2006 American Chemical Society)

3.2.2 Polarography Techniques

The nature of the waveform for potential step/pulsed techniques lends itself well to polarographic techniques. Polarography techniques use a mercury drop electrode like a DME, historically the most commonly employed mercury electrode, a static drop mercury electrode (SDME), or a hanging drop mercury electrode (HDME). With the DME, each pulse can coincide with each drop of mercury. Using an electrode that is constantly replenished can be beneficial if the redox process leads to analyte adsorption, as replenished electrodes do not need to be cleaned. Since the 1980s, the SDME has become the primary electrode for polarographic techniques. The voltammetric techniques discussed in the previous section, NPV and DPV, were originally developed as polarography techniques and used in analytical chemistry. The waveforms for NPP are the same as those of the voltammetric methods discussed previously. There are however, a number of differences between the techniques, all of which are due to the nature of the electrodes.

The DME, invented by Heyrovsky[32] is a historically important technique which forms the basis for many of the electrochemical techniques discussed here. This electrode is composed of a capillary through which mercury flows forming a spherical drop of approximately 1 mm, at which point its weight surpasses the surface tension and the drop falls into solution. There are a few drawbacks to this technique. The mercury drop has a finite lifetime, typically 2 to 6 s, and with the drop moving through solution, the area can continuously change which makes accounting for mass transport difficult.

The SDME, also referred to as a HDME, was developed by Princeton Applied Research Corporation in 1980[1] to overcome some of the disadvantages of the DME. This electrode also employs a capillary to allow mercury to form a drop; however, in the case of the SDME, the mercury drop can remain attached to the surface indefinitely. The drop can be dislodged and a new one formed as needed. The drop remains stationary for as long as is needed and is stable in size, making it easier to account for mass transport mathematically. One major difference between polarographic techniques and voltammetric techniques is mass transport by diffusion. Polarography relates to how the working electrode operates using polar coordinates to deal with electrode processes like radial diffusion. NPP and DPP utilize the same waveforms as their voltammetric counterparts, however, with radial diffusion, the current response changes from a peak shape to a sigmoidal shape. A typical current response can be seen in Figure 13 using a normal pulse waveform, the same waveform as in Figure 10(a).

3.3 Hydrodynamic Methods

A few electrochemical techniques make use of working electrodes that are nonstationary. The rotating disk (RDE) and RRDE, as their names suggest, rotate as a means to affect mass transport. Rotations make the diffusion layer thinner which increases the concentration gradient. The thinning of the diffusion layer and the increase in the concentration gradient can be controlled as they are both proportional to the spinning speed of the electrode. Increasing

the concentration gradient leads to an increase in the faradaic current relative to the capacitive current assisting with the signal to noise ratio and a steady state is achieved quickly. Under nernstian conditions the concentration of the species to be oxidized or reduced is essentially zero which can be achieved by setting the potential negative or positive enough respectively. Construction of RDE and RRDE is more difficult than stationary electrodes as the mass transport conditions under laminar flow must be reproducible. The mass transfer limited current, i_l (A), is given by the Levich equation,[2] equation (12),[1]

$$i_l = 0.620\, n\, \mathrm{FAD}_o^{2/3} C_o \cdot \nu^{-1/6} \omega^{1/2} \tag{12}$$

where n is the number of electrons, F is Faraday's constant, A is the electrode surface area (m^2), D_o is the diffusion coefficient (m^2 s^{-1}), C_o is the concentration of analyte (mol L^{-1}), ν is the kinematic viscosity of the solution and ω is the angular velocity of the disk.[2]

Meyer used a RDE to study the diffusion of ferrocene through a thin film of poly(x)[Ru(Me$_4$bpy)$_2$(vpy)$_2$](PF$_6$)$_{2x}$ (1−x)[Ru(vbpy)$_3$](PF$_6$)$_{2-2x}$ (Me$_4$bpy = 4,4′,5,5′-tetramethyl-2,2′-bipyridine), to analyze the porosity of different films.[33,34] Section 3.1.5 also discusses complexes bound to electrode surfaces. Photolysis of these films leads to photocleavage of the Ru^{II}–vpy bonds resulting in loss of [–Ru(Me$_4$bpy)$_2$](PF$_6$)$_2$ fragments. This results in a more porous film with less crosslinking. Diffusion studies using a RRDE show that the thin films act as a size selective barrier to the electrode.

3.4 Bulk Electrolysis (BE)

All of the techniques discussed thus far represent oxidations or reductions taking place at the electrode surface resulting in a diffusion layer where the species to be oxidized or reduced is depleted and a bulk solution where no net redox process takes place. BE techniques differ in that the redox process takes place on a large scale and through forced convection the entire solution will undergo electrolysis. These methods use convection by stirring or bubbling and large surface area working and auxiliary electrodes. The potential is set slightly more positive or negative of the oxidation or reduction that is going to take place and remains at that level for the duration of the experiment. The current is plotted versus time and the electrolysis is considered complete when the change in current overtime is minimal (Figure 14). Typically the current is measured and integrated and the number of electrons for the redox process can be determined since the concentration of the analyte is known and the total charge passed, Q, is determined. BE is governed by Faraday's Law, equation (13).[1]

$$Q = nFE \tag{13}$$

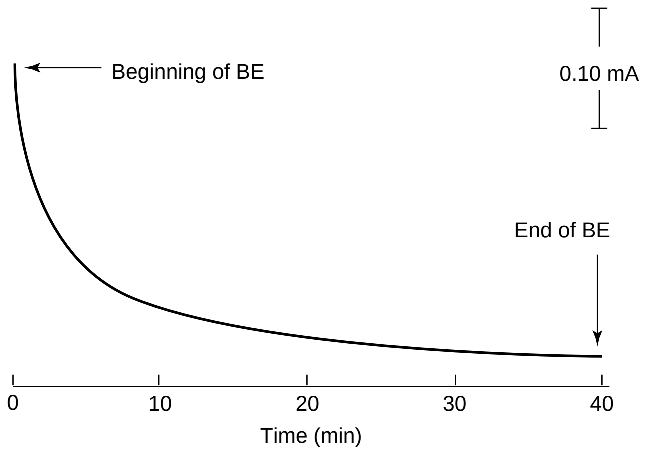

Figure 14 Bulk electrolysis (BE) displaying current versus time

Q is the total charge passed, n is the number of electrons passed, F is Faraday's constant (96 485 C mol^{-1}),[4] and E is the potential of the electrolysis. This technique, the most common BE method, is also referred to as potentiostatic coulometry. Another BE method used is amperostatic coulometry, whereby the current is kept constant. This technique requires the use of an amperostat instead of a potentiostat which limits its use.

3.4.1 Electrosynthesis

Another type of BE is electrosynthesis, a synthetic technique that takes place in an electrochemical cell. The potential is set to drive the intended redox reaction and electrolysis continues until all the analyte has been reduced or oxidized. Electrosynthesis is often useful in industrial applications and is desirable, as side reactions are often minimal compared to conventional synthetic techniques.

Electrocatalysis is a type of electrosynthesis that uses surface modified electrodes, or mediators/electrocatalysts to facilitate the redox reaction. Meyer reported the design and synthesis of a chemically modified electrode that consists of a thin polymer film with covalently attached redox sites,[35] designed to facilitate rapid electron transport for electrocatalysis. Complexes of Fe, Ru, Os, Re, and Co were synthesized in such a way that when electrochemically reduced, they reacted to form smooth electroactive polymer films that adhered well to the working electrode to form a chemically modified electrode designed for electrocatalysis.

3.4.2 Electrocatalysis of CO_2 Reduction by [Ni(cyclam)]$^{2+}$

The conversion of CO_2 to CO is a valuable commercial process. Reductive electrocatalysis of CO_2 to CO can be performed on a mercury electrode with [Ni(cyclam)]$^{2+}$ (cyclam = 1,4,8,11-tetraazacyclotetradecane) present as the electrocatalyst.[36] Sauvage has shown that [Ni(cyclam)]$^{2+}$

can act as an efficient and selective electrocatalyst for this reaction which can function in pure water at potentials 0.5 V more negative than the thermodynamic value (E (CO_2/CO) = −0.41 V vs. NHE at pH = 5). No electroreduction is observed at this potential without $[Ni(cyclam)]^{2+}$ as the overpotential for direct CO_2 electroreduction is high.

3.4.3 Electrocrystallization

Electrocrystallization is another synthetic method similar to BE. Electrocrystallization is unique in that certain higher oxidation states are obtainable that would otherwise not be accessible through normal synthetic procedures. The silver oxides AgO and Ag_2O_3 were originally synthesized using this approach[37] and the highly oxidized Ag_3O_4 is the only example of a binary silver compound in the Ag^{II} oxidation state.[38] There are many parameters to consider when performing electrocrystallization. In addition to the electrolysis parameters, voltage, current, concentration, and temperature, the electrode material and structure also can have a large impact on products. The complexity of electrocrystallization makes it difficult and time consuming to fully explore all avenues for a particular synthesis. The products obtained through electrocrystallization are very pure and crystalline in nature.

3.4.4 Bulk Electrolysis Cell Design

BE techniques take place in a cell of a design different from the techniques discussed previously. These ‘‘bulk’’ methods require electrolyzing much larger samples, necessitating several design changes including the electrodes and the cell. There are two different cell designs both of which are designed to separate the auxiliary electrode from the working electrode.

The single cell design employs an outer compartment which contains the working and reference electrodes and an inner compartment which contains the auxiliary electrode. The secondary compartment hangs into the working compartment and makes solution contact through a porous glass frit.

The second cell design is referred to as an H-cell, which is composed of two cells connected via a porous glass frit. This separation allows the flow of supporting electrolyte ions to provide current flow but inhibit the flow of analyte (Figure 15). The analyte is contained in the working compartment along with the working electrode and reference electrode, while the auxiliary electrode is placed in the secondary compartment. Deoxygenation is necessary as is stirring to ensure efficient mass transport to the working electrode surface.

The electrodes for BE methods are important for efficient electrolysis. The working and auxiliary electrodes are required to electrolyze much more of the sample in these BE techniques. The working and auxiliary electrodes

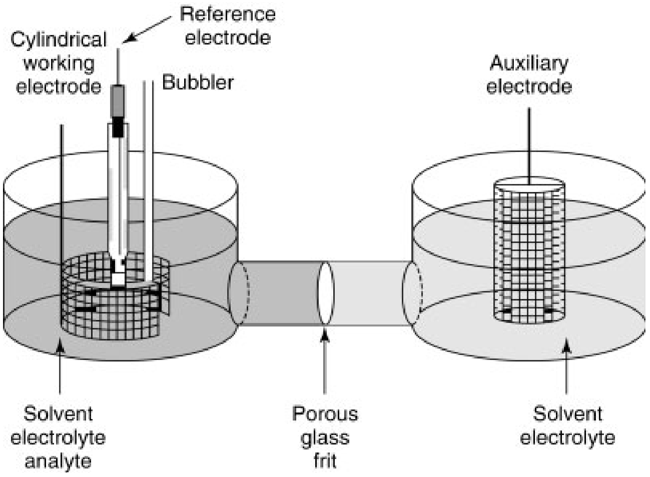

Figure 15 H-cell for bulk electrolysis showing the working and auxiliary electrodes, reference electrode, bubbler, porous glass frit, solvent, electrolyte, and analyte

discussed previously are typically replaced by a large surface area electrode like a platinum mesh or a carbon cloth in order to facilitate the electrolysis of a large amount of sample. Typically the working electrode is cylindrical with the reference electrode located in the center of the working electrode to provide accurate voltage control. Sometimes an isolation chamber is employed for the reference electrode to prevent leaking of the reference electrode solution into the analyte solution. The auxiliary electrode must be isolated from the working electrode compartment to allow for bulk conversion of the analyte. Mixing of the auxiliary and working compartment solutions will result in incomplete electrolysis and/or decomposition. Stirring or bubbling of the analyte solution during electrolysis provides good mass transport.

3.5 Electrochemical Simulations

A number of programs, like DigiSim, are capable of performing a variety of simulations. The first electrochemical simulations were designed to simulate mass transfer at different temperatures. Later programs were designed to perform general electrochemical simulations and fit experimental data. Electrochemical simulations have also been designed to evaluate the redox behavior of samples. Some software can simulate CV and other electrochemical techniques under various solution conditions like mass transport (convection, diffusion, migration), solution resistance, and pH, and various analyte factors like concentration, temperature, standard redox potentials, number of electrons transferred, and reaction rate constants.

Salimi used the DigiSim program to analyze the electrochemical properties of an aqueous dye, thionin, at a range of pH values.[39] When thionin is electrochemically reduced it can act as a catalyst for Cr(VI) reduction. DigiSim

was used to determine the standard potential and kinetic parameters for thionin by fitting cyclic voltammograms measured experimentally to the DigiSim generated CV.

3.6 Correlation of Electrochemistry to Electronic Spectroscopy

The orbitals involved in electrochemical processes are often the same orbitals involved in electronic transitions. The first electrochemical oxidative process corresponds to the removal of an electron from the HOMO and the first reduction corresponds to the addition of an electron into the LUMO. The energy gap between these two processes is indicative of the gap between the HOMO and LUMO. Although there exists a correlation between HOMO–LUMO gaps and the energy gap of the first oxidation and the first reduction, equation (14), energy gaps involving subsequent redox processes are not directly correlated as the second reductive or oxidative process is taking place on the already reduced or oxidized complex, respectively. This HOMO-LUMO electrochemical energy gap has been correlated to the spectroscopic energy gap:

$$E_{\text{optical}} = \Delta E_{\text{redox}} + \Sigma_i a_i \qquad (14)$$

Where E_{optical} is the energy of an optical transition (absorption or emission), ΔE_{redox} is an electrochemical potential, an $E_{1/2}$, and $\Sigma_i a_i$ is a collection of factors based on differences between the two process which have inequivalent orbital energies.[40] Approximations for $\Sigma_i a_i$ typically utilize the E_{00}, the energy between the ground vibrational state of the first electronic excited state to the ground vibrational, ground electronic state, often measured by emission spectroscopy. Figure 16 shows the correlation between ΔE_{redox} and E_{00} for a series of ruthenium complexes.[40] When spectroscopy and electrochemistry are combined together they become a powerful coupled technique capable of providing otherwise unobtainable redox and spectroscopic information.

3.7 Coupled Techniques

Coupled techniques have increased in popularity in recent years. Electrochemical techniques can be coupled to another characterization method to provide unique information. Many electrochemical techniques lend themselves well to coupling with other electrochemical or nonelectrochemical techniques. With these methods, cell design is often complex to allow simultaneous execution of both techniques. For example, optically transparent indium tin oxide is used as the working electrode with an optically transparent mesh electrode to allow for simultaneous electrochemical conversion and electronic absorption spectroscopy. For some techniques the sample is electrolyzed and then transferred under inert atmosphere for analysis.

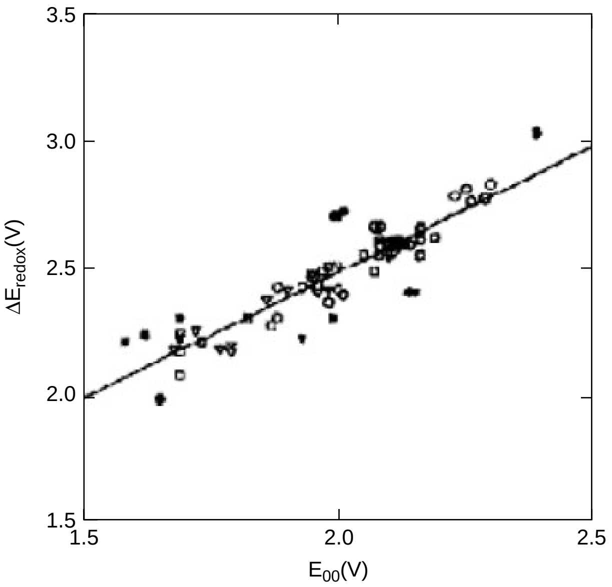

Figure 16 Correlation between ΔE_{redox} and E_{00} for a series of ruthenium complexes where the open symbols are complexes that have ''bipyridinelike'' ligands and the filled symbols have ''non–bipyridinelike'' ligands. Squares are representative of trisubstituted complexes, circles are bipyridine complexes, and triangles are other ruthenium complexes.[40] (Reprinted with permission from Vlcek, Dodsworth, Pietro, and Lever[40] © 1995 American Chemical Society)

3.7.1 *Spectroelectrochemistry*

Spectroelectrochemistry has become a valued technique coupling spectroscopy and electrochemistry. Spectroelectrochemistry is a bulk electrochemical technique and as such many of the cell requirements discussed above that pertain to BE apply for spectroelectrochemistry. Often concentrations for spectroelectrochemistry are much lower than most electrochemical techniques due to the spectroscopic absorbance requirements. The bulk solution must still be oxidized/reduced in spectroelectrochemistry. Large surface area working and auxiliary electrodes are employed as in the bulk methods described above. Cells designed with optically transparent electrodes like thin films of SnO_2 or In_2O_3 or optically transparent mesh electrodes are employed, otherwise the electrode must be manually removed to record spectra.[1] Optically transparent electrodes can be constructed such that the solution volume to electrode surface area ratio is very small making the BE occur rapidly.

Many types of spectroscopy have been coupled with electrochemistry including electronic absorption spectroscopy, X ray (*see* ***X-Ray Absorption Spectroscopy***), infrared (IR) (*see* ***Vibrational Spectroscopy***), or Raman spectroscopy, ellipsometry, specular reflectance, and electron spin resonance (ESR). Electronic absorption spectroscopy, one of the most prominent electrochemistry coupled with spectroelectrochemical techniques, will be discussed here as will

the vibrational spectroscopy techniques, IR and Raman spectroelectrochemistry, and the ESR spectroscopic technique (ESR).

Electronic Absorption Spectroelectrochemistry. Electronic absorption spectroscopy with UV and visible light is a form of spectroelectrochemistry typically employed as a transmission experiment to investigate changes in absorbance due to a species being oxidized or reduced. Typically the potential is scanned while the absorbance at a particular wavelength is recorded or the potential is stepped while a full spectrum is collected. Spectroelectrochemistry of this type can be used to establish spectroscopic signatures of reduced or oxidized forms of a compound that can be correlated to excited state transient absorbance spectroscopy.

Spectroelectrochemical measurements can be used to identify the absorption characteristics of reduced or oxidized species that can be useful in understanding excited state properties of a complex. This technique can be used in conjunction with transient absorption spectroscopy which can also provide information on excited state properties. Together, these techniques can provide a better understanding of complex excited state behavior. McCusker used these two techniques to study the excited state properties of $[Ru(dmb)_3]^{2+}$ and $[Ru(dpb)_3]^{2+}$ (dmb = 4,4′-dimethyl-2,2′-bipyridine and dpb is 4,4′-diphenyl-2,2′-bipyridine).[41] Nanosecond time resolved transient absorption spectroscopy was used in conjunction with spectroelectrochemistry to assign the excited state spectroscopy. Figure 17 shows the transient spectrum of $[Ru(dpb)_3]^{2+}$ which is correlated to the spectroscopy of the electrogenerated oxidized Ru and reduced dpb forms of the complex.

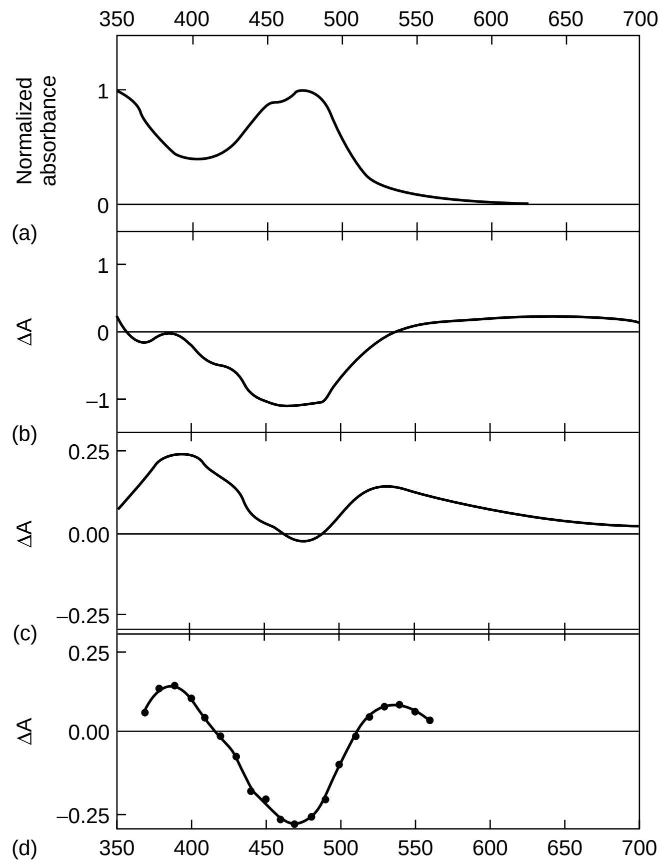

Figure 17 (a) Electronic absorption spectrum for $[Ru(dpb)_3]^{2+}$ in CH_3CN; (b) change in absorbance spectrum for $[Ru(dpb)_3]^{2+}$ after electrochemical oxidation at +1100 mV versus $Ag/AgNO_3$ for 20 min in CH_3CN with 0.1 M Bu_4NPF_6 electrolyte; (c) change in absorbance spectrum for $[Ru(dpb)_3]^{2+}$ after electrochemical reduction at −1600 mV versus $Ag/AgNO_3$ for 10 min in CH_3CN with 0.1 M Bu_4NPF_6 electrolyte (d) difference absorption spectrum of (b) and (c).[41] (Reprinted with permission from Damrauer and McCusker[41] © 1999 American Chemical Society)

Brewer and Elvington used spectroelectrochemistry to investigate a photochemical problem involving a transition metal complex.[42] Spectroelectrochemistry was used to help elucidate a complex sequence of excited state reductions in the supramolecular complex $[\{(bpy)_2Ru(dpp)\}_2RhCl_2]^{5+}$ (dpp = 2,3-bis-2-pyridylpyrazine). The spectroelectrochemical experiment involved the bulk reduction of the complex at −0.4 V vs. Ag/AgCl, just after the two-electron $Rh^{III/II/I}$ irreversible couple. The complex is monitored by Ultra violet visible absorption spectroscopy as the reduction is taking place (Figure 18). The electrochemical reduction and the resultant spectroscopy are correlated with a photochemical experiment, establishing that this complex is reduced by multiple electrons photochemically.

Electronic coupling can be probed using electrochemistry. Brewer and Richter investigated bimetallic complexes of the form $[(bpy)_2Os(BL)Os(bpy)_2]^{4+}$ (BL = 2,3-bis(2-pyridyl)pyrazine (dpp), 2,3-bis(2-pyridyl)quinoxaline (dpq) or 2,3-bis(2-pyridyl)benzoquinoxaline (dpb), and bpy = 2,2′-bipyridine) by electronic absorption spectroscopy and spectroelectrochemistry.[43] When BL = dpb, the $E_{1/2}$

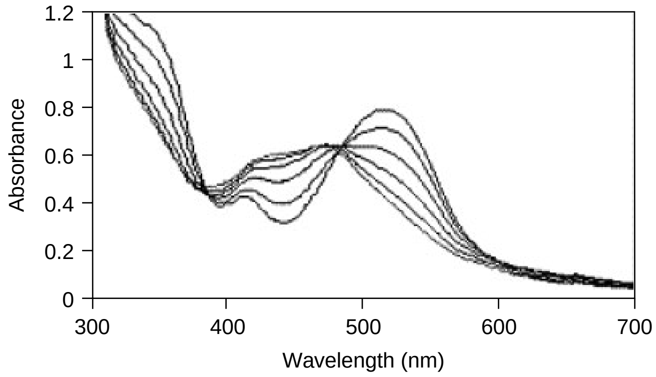

Figure 18 Electronic absorption spectrum for the electrolysis of $[\{(bpy)_2Ru(dpp)\}_2Rh^{III}Cl_2]^{5+}$ (bpy = 2,2′-bipyridine, dpp = 2,3-bis-2-pyridylpyrazine) in CH_3CN with 0.1 M Bu_4NPF_6 at −0.4 V versus Ag/AgCl.[42] (Reprinted with permission from Elvington and Brewer[42] © 2006 American Chemical Society)

for the $Os^{II}Os^{II}/Os^{III}Os^{II}$ couple is at 0.98 V and the $Os^{III}Os^{II}/Os^{III}Os^{III}$ couple is 1.30 V vs. Ag/AgCl. The $\Delta E_{1/2} = 0.32$ V allows one to calculate the comproportionation equilibrium constant, K_{com}.

$$Os^{III}, Os^{III} + Os^{II}, Os^{II} \xrightleftharpoons{K_{com}} 2Os^{III}, Os^{II}$$

K_{com} can be calculated from electrochemical data using equation (15) for $T = 298$ K.

$$K_{com} = e^{\Delta E_{1/2}/25.69} \tag{15}$$

From the $\Delta E_{1/2} = 320$ mV, K_{com} is 1.6×10^5, indicating this complex is a Robin and Day class II mixed-valence complex. Electronic absorption spectroelectrochemistry in the near infrared (NIR) shows an osmium-based intervalence charge transfer (IVCT) at 2440 cm^{-1}. The extent of electronic delocalization, α^2, can be calculated using equation (16).

$$\alpha^2 = \frac{(4.2\ 10^{-4}\ E_{max}\Delta v_{1/2})}{(d^2 E_{op})} \tag{16}$$

E_{max} is the extinction coefficient of the IVCT transition ($M^{-1}\ cm^{-1}$), $\Delta v_{1/2}$ is the bandwidth at half intensity, d is the distance between the two metals, and E_{op} is the energy of the IVCT transition (cm^{-l}). α^2 for the dpb bridged complex was calculated to be 8.6×10^{-3} which is indicative of a relatively weakly coupled class II mixed-valence complex.

Vibrational Spectroelectrochemistry. Vibrational spectroscopy experiments involve the excitation of a sample with light in the IR region of the spectrum leading to population of vibrational excited states. Oxidized or reduced species often have a change to their bond order which can be detected by IR or Raman spectroscopy. Most electrochemical techniques require a solution with electrolyte which presents a challenge in coupling these techniques as most solvents are strong IR absorbers. The key to effectively probing a sample that has undergone a redox reaction at an electrode by IR or Raman spectroscopy is to minimize the solvent signal. Reducing the solution depth to less than 100 µm helps minimize solvent signal as does utilizing an Fourier transform infrared (FTIR) spectrometer, for which IR spectroelectrochemistry is called subtractively normalized interfacial Fourier transform infrared spectroscopy (SNIFTIRS) (subtractively normalized interfacial FTIR spectroscopy).[1] Since FTIR can record a spectrum in a fraction of a second, many can be recorded and signal averaged. Spectra are also recorded at two potentials before and after an electrochemical change using a difference signal to limit most of the solvent background. Raman spectroscopy involves the detection of visible photons that scatter after striking the sample which can gain or lose small amounts of energy providing vibrational information complimentary to IR spectroscopy. Raman spectroscopy, however, can utilize visible excitation and detection. This allows for the use of aqueous solutions which absorb strongly in the IR region but do not absorb in the visible.

Wertz provides a good inorganic example of Raman spectroelectrochemistry in which a series of ruthenium–polyazine complexes were studied in varying redox states.[44] The series of complexes and redox states studied were $[Ru(bpm)_3]^{2-n}$ ($n = 0$–4), $[Ru(bpz)(bpy)_2]^{2-n}$ ($n = 0$–3), $[Ru(bpy)_2(bpz)]^{2-n}$ ($n = 0$–3), $[Ru(bpz)_3]^{2-n}$ ($n = 0$–3), (bpm = 2,2′-bipyrimidine, bpz = 2,2′-bipyrazine, bpy = 2,2′-bipyridine) where n is the number of electrons added to the complex. Resonance Raman spectra are recorded at each redox state to investigate the identity of the redox orbital for the series of complexes. Figure 19 shows a

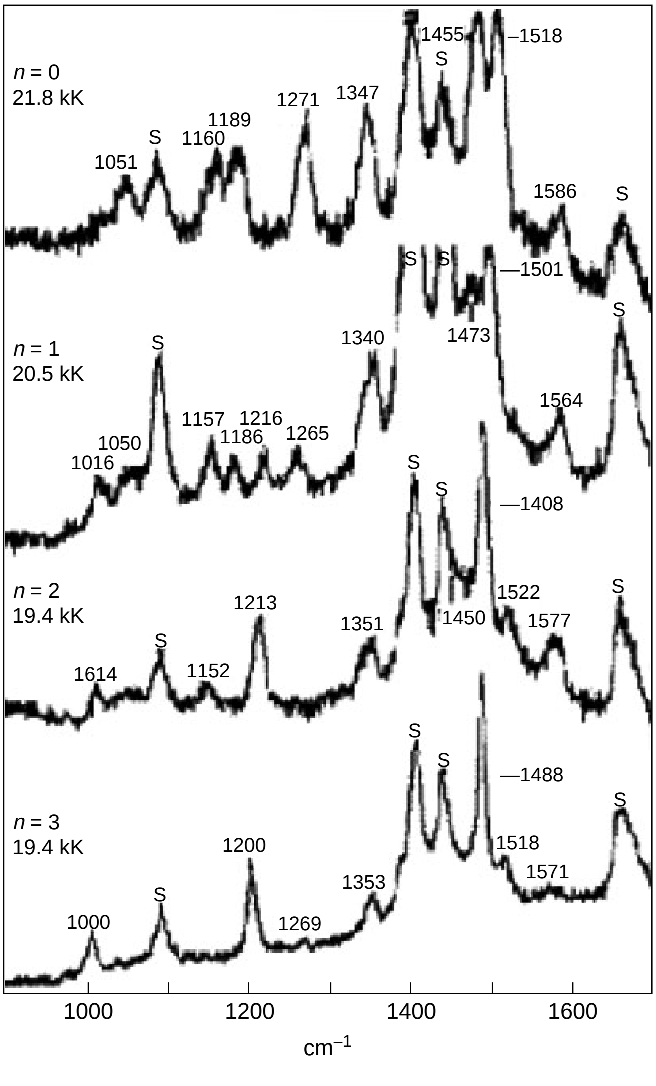

Figure 19 Resonance Raman spectra for the complex $[Ru(bpz)_3]^{2-n}$ (bpz = 2,2′-bipyrazine) where n is 0, 1, 2, and 3, show a shift in the vibrational frequencies as electrons are added indicating bpz localized redox orbitals.[44] (Reprinted with permission from Tait, Donohoe, DeArmond, and Wertz[44] © 1987 American Chemical Society)

resonance Raman spectra for $[Ru(bpz)_3]^{2-n}$ illustrating the bpz localized nature of the acceptor orbitals.

3.7.2 Electron Spin Resonance (ESR)

ESR spectroscopy is a sensitive detection method designed to provide information on radicals. This method, also known as electron paramagnetic resonance (EPR) spectroscopy, is naturally a good choice for coupling to electrochemistry as radicals can easily be electrogenerated. ESR involves the detection of unpaired electrons which are affected by nearby nuclei. Radical spin states are modified by interaction with a magnetic field, equation (17).[1]

$$\Delta E_{\text{field}} = g\mu_{\text{B}}H \tag{17}$$

Where ΔE_{field} is the splitting of electron spin states by the magnetic field, g is the spectroscopic splitting factor, μ_{B} is the Bohr magneton ($5.788 \times 10^{-5}\,\text{eV}\,T^{-1}$),[1] and H is the magnetic field strength. The interaction of the spins with nuclei produces hyperfine structure which can provide information useful in identifying the nature of the electrogenerated radical.

Wertz used low temperature ESR ($T = 90\,\text{K}$) to investigate the electrochemically reduced complex $[Ru(bpz)_3]^0$. The two-electron reduction product (Figure 20) shows typical ruthenium diimine characteristics for ligand based radicals. Temperature dependent line broadening was observed which is characteristic of electron hopping from a reduced ligand to an unreduced ligand. These data indicate that the ligand orbitals are localized in nature.[44]

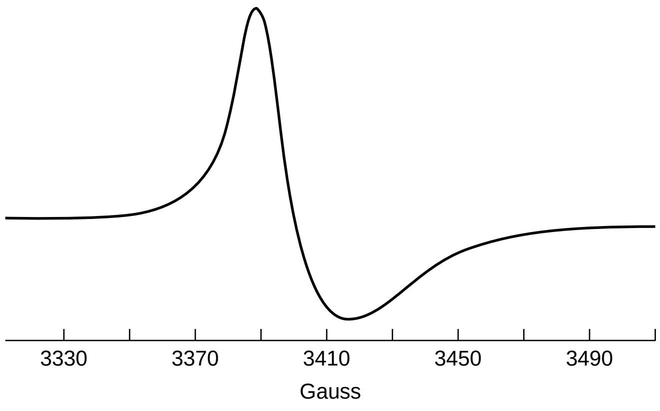

Figure 20 Low temperature ESR spectrum of the complex $[Ru(bpz)_3]^0$ (bpz = 2,2′-bipyrazine), electrochemically reduced by two electrons in DMF showing the ligand localized nature of the orbitals involved in the reductions. Microwave frequency = 9.55 GHz.[44] (Reprinted with permission from Tait, Donohoe, DeArmond, and Wertz[44] © 1987 American Chemical Society)

3.7.3 Electrochemiluminescence (ECL)

Electrochemiluminescence (ECL) is a coupled electrochemical/photochemical technique involving the electrochemical generation of excited state with subsequent detection by observation of fluorescence or phosphorescence (*see* ***Photoluminescence and Electroluminescence, Solid State***). Electrochemistry is a natural technique to couple to chemiluminescence as radical ions can easily be electrogenerated which can react to generate electronic excited states. For a detailed description, see Bard and Faulkner's electrochemical methods.[1] ECL involves the electrogeneration of reactive species, often radical ions of the analyte where $2A \rightarrow A^{+\bullet} + A^{-\bullet}$ which can then undergo an energetically favorable electron transfer reaction to generate an excited state species, $A^{+\bullet} + A^{-\bullet} \rightarrow {}^1A^* + A$, or $A^{+\bullet} + A^{-\bullet} \rightarrow {}^3A^* + A$, which can then be detected by fluorescence, ${}^1A^* \rightarrow A + h\nu$, or phosphorescence, ${}^3A^* \rightarrow A + h\nu$, respectively.

Bard employed electrogenerated chemiluminescence in a study of $[Ru(bpy)_3]^{2+}$.[45] A highly oriented pyrolytic graphite electrode was immersed in a solution containing $[Ru(bpy)_3]^{2+}$ which strongly adsorbs to the electrode surface creating a monolayer. CV was conducted on the complex coated electrode as emission intensity was recorded concurrently. Figure 21 shows a plot of emission intensity versus potential during a cyclic voltammogram for the $[Ru(bpy)_3]^{2+}$ coated electrode and the uncoated electrode.

Electrochemistry is a valuable tool for modern inorganic chemistry. A variety of methods can be used to provide information as simple as E° for a particular

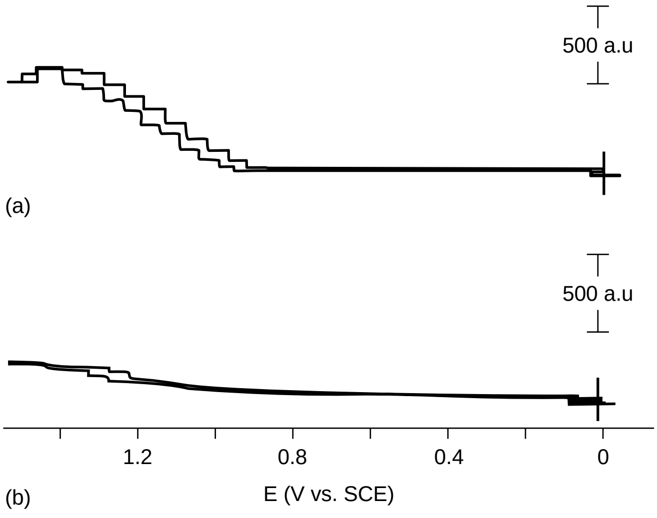

Figure 21 Emission intensity (A.U.) versus potential (V vs. SCE) for a cyclic voltammogram of: (a) $[Ru(bpy)_3]^{2+}$ (bpy = 2,2′-bipyridine) surface coated electrode; and (b) an electrode with no analyte.[45] (Reprinted with permission from Xiao-Hong and Bard[45] © 1994 American Chemical Society)

redox process to as complex as Raman signals of an electrogenerated compound. The successful application of these electrochemical methods requires a basic understanding of the factors impacting electrochemical signals, data collection and practical considerations. The widespread use of electrochemical methods in the literature today will advance the understanding of inorganic molecules.

METHOD SUMMARY

Acronyms, Synonyms

- Electron-Paramagnetic Resonance (EPR)
- Electron-Spin Resonance (ESR).

Measured physical quantities

- energy separation between different electron-spin states
- nuclear hyperfine splitting constants.

Information available

- spin state (S) of a paramagnetic center
- magnitude of hyperfine interactions
- zero-field splitting of half-integer $S > 1/2$ states
- possible identity of paramagnetic center (e.g., free radical; metals in metal clusters)
- possible identity of ligand atoms.

Information not available, limitations

- center must be paramagnetic
- integer-spin states often unobservable.

Examples of questions that can be answered

- What are the different paramagnetic centers in the sample?
- How do these centers change with changes in redox potential and pH or during substrate binding or catalysis?
- How close are the different paramagnetic centers?

Major advantages

- The technique is noninvasive.
- The volume (300 μL) and concentration (1.0–0.001 mM) are low.
- Recording spectrum can be done quickly (usually no more than 15–20 min).
- The spectrum is only of paramagnetic species.
- The spectrum is often simple to interpret.
- The spectrum often can be recorded in vivo.

Major disadvantages

- Many paramagnetic metal centers require low temperatures (20 K or lower) for detection.

Sample constraints

- Sample should be free of any adventitious paramagnetic impurities.

1 INTRODUCTION

1.1 History and Terminology

During its inception in the mid 1940s, this technique was initially described as paramagnetic resonance by the Clarendon Laboratory in Oxford, England, and was soon followed by the terms electron-paramagnetic resonance (EPR) and electron-spin resonance (ESR). This dual terminology has often been confusing to many. To avoid this confusion and come to a common ground the term electron magnetic resonance has more recently been proposed but has received little attention. Now, even after decades of debate, no consensus has been reached, and we still have the use of both terms. In general, EPR tends to be used by inorganic and bioinorganic scientists where both spin and orbital angular momentum are significant, while the term ESR is favored by those who study organic free radicals where spin angular momentum dominates. The term EPR will be used in this discussion.

EPR spectroscopy was first demonstrated in 1945. Using a 25-m wavelength spectrometer, Zavoisky recorded the broad, barely detectable spectra of several paramagnetic species[1]. The technique quickly moved into the more sensitive, high-frequency microwave spectral region in 1946 with the detection of the resolved spectrum of Mn^{2+}. It is not a coincidence that the technique rapidly evolved following the end of World War II. The vast amount of knowledge of microwave technology from radar studies that had sprung out of the war efforts laid the foundation for the construction of sensitive spectrometers. In fact, unlike its related cousin, nuclear magnetic resonance (NMR) (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Inorganic/Organometallic Molecules***, ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Metallobiomolecules***), EPR spectroscopy quickly reached its near-theoretical limit in sensitivity within two decades of its inception, due mainly to the extensive background knowledge of microwave technology. Aside from an increased range of available microwave frequencies and rapid computer-driven data handling and manipulation systems, today's spectrometers are little changed from those used decades ago.

This article will present the basics of EPR spectroscopy needed to train most scientists to understand and interpret the spectra of metals in biological systems. Researchers interested in a more detailed treatise on different aspects of the subject should consult one of the books listed under Further Reading at the end of this article.

2 RELATIONSHIP BETWEEN ''SPIN'', ANGULAR MOMENTUM, AND MAGNETIC MOMENT

An isolated electron, alone without any outside forces, still possesses an intrinsic angular momentum called ''*spin*'', ***S***. Because an electron is charged, the angular motion of this charged particle generates a magnetic field. Viewed in the classical sense the electron, due to its charge and angular momentum, acts like a little bar magnet, or magnetic dipole,

with a *magnetic moment*, $\boldsymbol{\mu_e}$

$$\text{Angular Momentum } (\boldsymbol{S}) \text{ of a Charge} \rightarrow \text{Magnetic Dipole } (\boldsymbol{\mu_e})$$

or

$$\boldsymbol{S} \propto \boldsymbol{\mu_e} \tag{1}$$

(Note : this is for a system possessing *only* spin)

For a classical bar magnet, the magnetic moment has no preferred direction in the absence of an external field in open space. The same is also true for an electron. This situation, however, changes when the electron (or bar magnet) is placed in an external magnetic field. This is analogous to the force experienced by a compass needle aligning itself with the earth's magnetic field. In the case of a quantum mechanical electron, this effect is referred to as the *Zeeman Interaction*.

3 ZEEMAN INTERACTION

A classical bar magnet, like a compass needle, orients in an external magnetic field ($\boldsymbol{B_0}$) with its magnetic moment aligned toward the south pole of the external field. Aligning the magnetic moment toward the north pole would require energy and represents the least favored (i.e., highest energy) orientation. Between these two extremes there exists an infinite number of possible orientations. This is not the case for an electron for which quantum mechanics dictates that there is an intrinsic angular momentum of 1/2 times Planck's constant (which will not be included for simplicity), or $S = 1/2$. This means that an electron can only assume two orientations in an external field oriented along the z-axis corresponding to z-axis projections $m_s = 1/2$ and $m_s = -1/2$. This Zeeman interaction has an energy (W) for each orientation that is the vector product of $\boldsymbol{\mu_e}$ and $\boldsymbol{B_0}$, for example,

$$W = -\boldsymbol{\mu}_e \cdot \boldsymbol{B_0} \tag{2}$$

For an electron the magnetic moment is proportional to the spin projection, $\boldsymbol{\mu}_e = -g_e\beta\boldsymbol{S}$, where β is a conversion constant called the *Bohr magneton* and g_e is the spectroscopic *g-factor* of the free electron and equals 2.0023192778 or about 2.00. In other words, the energies (W) for an electron in a magnetic field along the z axis ($\boldsymbol{B_0} = B_o\boldsymbol{k}$) with m_s (i.e., S_z for α and β electrons) $= 1/2$ and $-1/2$ are, respectively,

$$W_\alpha = \tfrac{1}{2} g_e \beta B_o \tag{3}$$

and

$$W_\beta = -\tfrac{1}{2} g_e \beta B_o \tag{4}$$

4 ELECTRONS IN ATOMS AND MOLECULES

Suffice it to say you will not be devoting your research career studying free electrons. Many people, however, study atoms or molecules that contain unpaired electrons, i.e., are paramagnetic. When an isolated free electron with no outside forces on it, is placed on an atom or molecule, its total angular momentum changes. In addition to the intrinsic spin angular momentum ($\boldsymbol{S}$), it may now also possess some orbital angular momentum ($\boldsymbol{L}$). Accordingly, the total magnetic moment of the electron will also change due to the vector addition of these two quantities.

Electron in space

$$\boldsymbol{\mu}_e \propto g_e\boldsymbol{S} \tag{5}$$

Electron in an atom or molecule

$$\boldsymbol{\mu}_e \propto g_e\boldsymbol{S} + \boldsymbol{L} \tag{6}$$

This last equation shows that the magnetic moment depends on the total paramagnetism, which arises from both spin *and* orbital angular momentum. This dependency on total *paramagnetism* and not just spin helps us to understand why some spectroscopists favor the term EPR over ESR.

In general, the orbital angular momentum is approximately zero for an electron in the ground state (we often say that the orbital angular momentum has been ''quenched''). This suggests that we again have a spin-only system with an effective g-factor near g_e. This would be unexciting. However, all is not lost. Mixing of the ground state with excited states by way of *spin-orbit* (*s-o*) *coupling* allows the ground state to gain back some orbital angular momentum, or

$$\boldsymbol{\mu_e} \propto g_e\boldsymbol{S} + \boldsymbol{s\text{-}o} \text{ coupling contribution} \tag{7}$$

It is common practice to assume that the s-o coupling term is proportional to $\boldsymbol{S}$, which means that we can combine both terms and just change the value of g_e to g, or

$$\boldsymbol{\mu_e} \propto g\boldsymbol{S} \tag{8}$$

This equation tells us that the electron's magnetic moment is just proportional to the electron-spin, which is why other scientists favor the term ESR over EPR.

The magnitude of the spin-orbit coupling contribution depends on the size of the nuclei interacting with the unpaired electron. Organic free radicals, with only H, O, C, and N atoms, will have a small contribution from spin-orbit coupling, producing g-factors very close to g_e while the g-factors of much larger elements, such as metals, may be significantly different from g_e.

5 THE EPR EXPERIMENT—MEASURING ''*g*''

From the above discussion we can see that one parameter we may wish to know is the g-factor. In an EPR spectrometer, a paramagnetic sample is placed in a large uniform magnetic field, which splits the W_α and W_β energy

levels of the ground state by an amount ΔW,

$$\begin{aligned}\Delta W &= W_\alpha - W_\beta \\ &= \left(\tfrac{1}{2}g\beta B_o\right) - \left(-\tfrac{1}{2}g\beta B_o\right) \\ &= g\beta B_o \end{aligned} \tag{9}$$

Since β is a constant and the magnitude of B_o can be measured, the g-factor can be easily calculated from the value of ΔW, the energy difference between the two spin levels. Irradiating the sample with energy $E = h\nu$, an absorption will occur when the condition $E = h\nu = \Delta W = g\beta B_o$ is satisfied. From this relationship, the value of g can then be calculated from ν (in GHz) and B_o (in gauss) using

$$g = \frac{h\nu}{\beta B_o} \tag{10}$$

or

$$g = \frac{714.484\ \nu}{B_o} \tag{11}$$

5.1 The EPR Spectrometer—How it Works

The energy equation ($h\nu = g\beta B_o$) describing resonance absorption suggests that we can perform our measurement in two ways. We can hold the frequency, ν, constant and vary the magnetic field strength, B_o, or hold the field constant and vary the frequency, ν, until a resonance transition occurs. In practice, the frequency is held constant while the magnetic field is linearly swept.

5.2 What Energy Is Used for Irradiation?

The most convenient energy to use in EPR spectroscopy, from an experimental point of view, is in the microwave region at around 9.4 GHz, commonly referred to as X-band. This frequency corresponds to a wavelength of about 3 cm, which approximates the internal dimension of the spectrometer's resonance cavity. In general, the larger the frequency, the larger the magnetic field, and the smaller the wavelength (hence, the smaller the resonance cavity and the sample size). X-band frequency requires a simple electromagnet yet provides high sensitivity and a workable sample size. Well over 90% of all EPR spectra are recorded at this frequency. Other frequencies commonly used are listed in Table 1. Using the relationship $g = 714.484\,\nu/B_o$, a free radical ($g = 2$) at X-band frequencies will undergo a transition at a magnetic field around 3400 gauss (G) (or 0.34 tesla (T) where 1 T = 10 000 G).

When the g anisotropy (see below) is very small, as often is the case for radicals, better resolution can be obtained by using spectrometers that operate at higher frequencies (and fields). An example is the two neighboring semiquinone anion radicals (Q_A^- and Q_B^-) in the bacterial photosynthetic reaction center recorded at X-, Q- and W-band frequencies[2] (Figure 1).

Table 1 Microwave (band) frequencies commonly used in EPR spectrometers

Band	Approximate Frequency (GHz)
L	1
S	3
X	9.4
P	15
K	18
Q	35
W	94

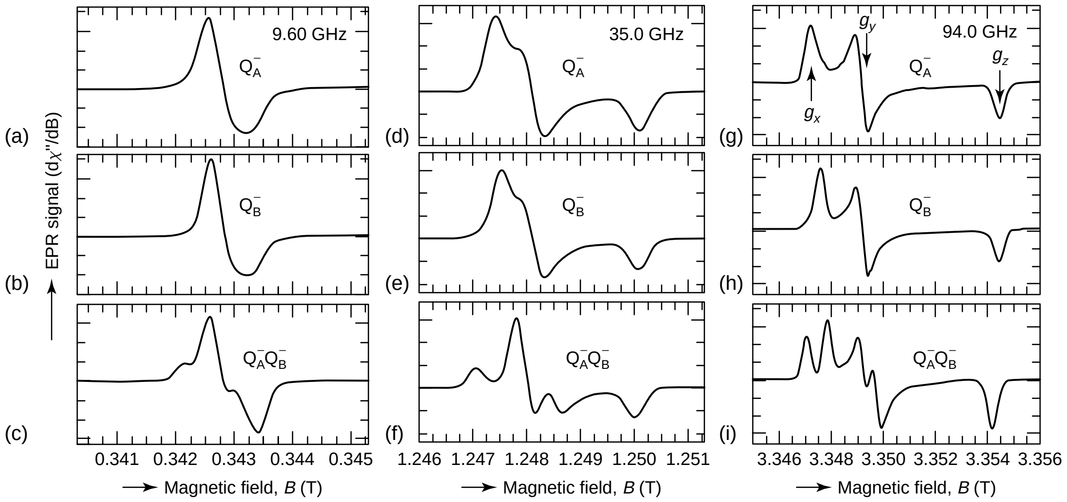

Figure 1 Comparison of the EPR spectra of two semiquinone anion radicals (Q_A^-, Q_B^-, and $Q_A^- + Q_B^-$) from the bacterial photosynthetic reaction center recorded at 9.60, 35.0 and 94.0 GHz. Note that as the spectrometer frequency increases, the overlapping spectra become better resolved. Spectra taken from Ref. 2 (Reprinted with permission from Calvo, Abresch, Bittl, Feher, Hofbauer, Isaacson, Lubitz, Okamura and Paddock.[2] © 2000 American Chemical Society)

Note how the g-factor anisotropy resolution increases with frequency.

5.3 How Much Sample Is Needed?

Most X-band EPR spectra of transition metals are recorded at low temperatures (4–100 K) using high-purity quartz tubes (no paramagnetic impurities) with a sample volume of about 300 µL. The minimum concentration of the sample depends on the broadness of its spectrum. Because EPR spectra are recorded as a first derivative (see subsequent text), the relationship between concentration, signal amplitude and spectral linewidth can be approximated as

$$\text{Conc.} \propto \text{Amp.} \times (\text{Width})^2 \tag{12}$$

To illustrate this, Figure 2 exhibits a spectrum containing two different signals representing samples of equal concentration but different linewidths. Obviously, just a small change in linewidth can induce a large change in amplitude. As such, broad spectra require a high concentration for detectable spectral amplitude. For organic free radicals, which have very narrow lines, a concentration of 10^{-7} M will usually yield a strong spectrum. On the other hand, metalloproteins often exhibit broad spectra, especially when $S > 1/2$ and, therefore, require a higher concentration (10^{-3}–10^{-5} M) for detection.

5.4 Why the First Derivative?

One of the first things one notices about an EPR spectrum is that it is a first-derivative spectrum rather than the more typical absorption presentation. This is due to an instrumental artifact. To enhance the sensitivity of the EPR spectrometer, the magnetic field is modulated. To obtain field modulation, a small set of Helmholtz coils are place about the sample in line with the external field. These coils allow the amplitude of the external field, B_o, to change by a small amount (~0.01–20 G) at a frequency of 100 kHz (smaller frequencies can also be used, but are less sensitive). Because the spectrometer is tuned to only detect signals that change amplitude with field changes at 100 kHz, the resultant signal appears as a first derivative (i.e., ΔSignal Amplitude/ΔMagnetic Field = first derivative of the absorption signal).

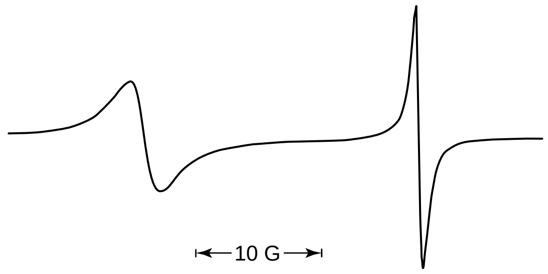

Figure 2 Spectrum illustrating the effect of spectral linewidth on amplitude. Both signals represent samples of the same concentration. The signal on the left, however, has a line width $2^{1/2}(\approx 1.4)$ greater than the signal on the right, resulting in an amplitude decrease of 1/2

5.5 Line Shape

Basic quantum mechanical calculations (i.e., the Bloch equations) show that the general EPR resonance absorption (Y) will have a Lorentzian line shape

$$Y = Y_{\max}\left[\frac{\Gamma^2}{(\Gamma^2 + \{B - B_r\}^2)}\right] \tag{13}$$

where $Y_{\max}$ is the maximum absorption, Γ equals half the absorption linewidth at half height, B is the magnetic field, and B_r is the field position at resonance (i.e., maximum absorption). Small organic radicals rapidly tumbling in solutions, where all anisotropic and inhomogeneous effects are averaged out, generally exhibit spectra with a near Lorentzian line shape associated with a homogeneous signal. This is not the case for the spectra of most transition metal ions. The presence of spectral inhomogeneities and unresolved hyperfine interactions (see subsequent text) results in a spread or ensemble of overlapping lines yielding a near Gaussian line shape,

$$Y = Y_{\max} \exp\left[\frac{-(\ln 2)(B - B_r)^2}{\Gamma^2}\right] \tag{14}$$

5.6 Saturation and Spin Relaxation

Because EPR spectrometers irradiate samples with microwaves in the X-band frequency region (Table 1), the separation between the energy levels is not large compared to kT and, correspondingly, the difference in the populations of these levels is small. For example, for an $S = 1/2$ spin system in the absence of a magnetic field, the $m_s = +1/2$ and $-1/2$ levels are degenerate. As described above, a magnetic field (B_o) will split these levels through a Zeeman interaction where the separation energy equals $g\beta B_o$. At thermal equilibrium, there will be a population difference between the split levels dictated by the Boltzmann equation. The population of the upper level (N_α) relative to that of the lower lever (N_β) will be

$$N_\alpha = N_\beta \mathrm{e}^{-g\beta B\mathrm{o}/\mathrm{kT}} \tag{15}$$

where k is the Boltzmann constant and T is the absolute temperature. At room temperature for $g = 2$ and $B_o = 3400$ G, the population of the upper level is only 0.5% less than that of the lower level. Irradiation tends to equalize their populations and, with it, decrease the observed absorption. Specifically, during a spectral scan, radiation-induced transitions occur with equal probability for both absorption and emission. In other words, the transition $\beta \rightarrow \alpha$ has the same probability of occurring as the transition $\alpha \rightarrow \beta$. Even though there is equal probability for a transition in either direction, a net absorption is observed because there is a greater population

of the lower level (equation 15) and, therefore, there are more photon-inducing absorption transitions than emission transitions. Because there are more transitions from $\beta \rightarrow \alpha$ than from $\alpha \rightarrow \beta$, the population of the upper level will increase relative to the lower level resulting in a decrease in the population difference and, with it, a decrease in the net absorption. This phenomenon is termed *saturation*. To counteract saturation and maintain the Boltzmann population difference, there are nonradiative spin relaxation processes (called *Spin-Lattice Relaxation*) that continually deplete the upper level. The Boltzmann population difference will be maintained as long as the spin-lattice relaxation rate is greater than the rate of radiation-induced transitions. As the power of the irradiating system increases, this inequality is no longer met and saturation (''power saturation'') is observed. The greater the spin-lattice relaxation rate, the greater the microwave power required for saturation. Spin-lattice relaxation rates are highly temperature dependent. The lower the temperature, the slower the rate, the easier it is to saturate the levels and, in general, the sharper the resonance line.

6 THE EPR SPECTROMETER—SETTING THE PARAMETERS

To obtain an EPR spectrum with the best signal-to-noise ratio, various spectrometer parameters must be optimized. These optimized parameters are unique for each sample and can be easily determined through a systematic approach. Let us assume that we wish to record the spectrum of an unknown paramagnetic sample containing a transition metal. Most transition metal ions are best observed at low temperature (normally 4–100 K, depending on the oxidation and spin state). The best compromise temperature for the detection of most metal ions is 10–15 K. Because we are initially only interested in detecting a signal, we are less concerned about the effects of power saturation or overmodulation (see subsequent text). Good compromise values for microwave power and modulation amplitude (MA) are 20 mW and 10 G (1.0 mT), respectively. Both of these values encourage a strong signal, albeit one that may lack resolvable detail and structure. Furthermore, most signals occur between g-factors 1.8–9. A magnetic field range that includes these values (about 1000–4000 G at X-band) should be scanned rapidly (~5 min.) using a moderate time constant (no greater than 0.1 s.). If a signal is present, it will probably be observed under these conditions.

Once a signal is observed, the spectrometer parameters can be optimized to obtain the best signal-to-noise ratio of the spectrum. Ideally, the optimum temperature for the strongest signal should also be determined. However, if a strong signal is observed using the conditions cited above, it is best to employ a temperature-dependent study later, following the optimization of the other parameters. The first parameter to be optimized is the microwave power. As stated above, signal amplitude will increase with power as long as the rate of radiation-induced transitions is less than the rate of spin-lattice relaxation. When the power becomes too large, saturation occurs and the signal amplitude lags the power, eventually decreasing with increasing power. During power saturation, the resonance line becomes distorted and broadens, concealing the true line shape and masking hyperfine structure. To determine the optimum power, a plot of the signal amplitude versus $\sqrt{(\text{power})}$ should be constructed. This plot will clearly reveal the linear dependence below saturation and the maximum amplitude as saturation is approached. Which power is finally employed depends on the signal strength. Strong signals will exhibit respectable signal-to-noise ratios well below saturation. Weak signals, however, may require the use of power levels in the near-saturation region in order to obtain respectable signal amplitude.

Following the determination of the proper power level, the dependency on MA should be investigated. Amplitude modulation is accomplished by rapidly modulating the scanning magnetic field. As long as the amplitude of this modulation is small compared to the linewidth, a near first-derivative line shape is obtained whose amplitude is proportional to the MA, the greater the MA, the larger the signal amplitude. As the MA approaches the absorption linewidth, distortions occur resulting in line broadening and a strong deviation from the true first derivative. The optimum value of the MA can be easily determined by recording the spectrum at a given MA. If the linewidth of the narrowest line in the spectrum is much greater than the MA, overmodulation effects have not occurred. However, if the measured linewidth approximately equals the MA, distortions may be present. The spectrum should be recorded at a new MA (usually half the previous MA). If the measured linewidth also decreases by one-half, overmodulation is still present and the MA should be decreased again until the measured linewidth no longer changes with decreasing MA. The measured linewidth is now the true linewidth. In general for strong signals, the MA should be set to one-fourth the width of the narrowest line. If the signal is very weak, setting the MA equal to the true linewidth is preferred. The spectrum will be slightly distorted, but a much stronger signal will be observed.

The time constant and scan time are the last parameters to be set. The time constant is set to produce the desired signal-to-noise ratio. To record a spectrum that is not distorted, the spectrometer should take 8–10 times the time constant to scan the maximum-to-minimum peak of the sharpest line. For example, suppose that the optimum time constant is 0.1 s, the sharpest line has a peak-to-peak width of 1.0 G and the full scan is 1000 G. The spectrometer should take 10 times the time constant to go 1.0 G, or 1.0 s. Therefore, to record 1000 G the spectrometer has to take 1000 s or 16.6 min, which corresponds to the minimum scan time. Scan times significantly shorter than this will result in a distorted signal.

7 RAPID PASSAGE

It has been noted that certain signals,[3] recorded in the dispersion mode at very low temperatures, actually exhibit an absorption line shape phase shifted by almost 90°. This phenomenon is due to an effect termed *Rapid Passage*. As noted above, the spin manifold has innate relaxation processes that, under low power situations, maintain the Boltzmann population distribution among all the levels. The rate of relaxation is highly temperature dependent, decreasing significantly with decreasing temperature. At low temperatures and high power, the relaxation rate can become small compared to the rate the spectrometer traverses through the signal. During such rapid-passage conditions, the spin levels saturate during the initial passage and stay saturated during the back passage resulting in a phase shift of the observed signal and the appearance of an absorption shape. This condition is very helpful when recording electron nuclear double resonance (ENDOR) spectra (*see* ***Electron-Nuclear Double Resonance (ENDOR) Spectroscopy***).

Table 2 Nuclear spin and % natural abundance of isotopes commonly encountered in biological samples

Isotope	Nuclear Spin (I)	% Abundance
^{1}H	1/2	99.9
^{2}H	1	0.02
^{12}C	0	98.9
^{13}C	1/2	1.1
^{14}N	1	99.6
^{15}N	1/2	0.37
^{16}O	0	99.8
^{17}O	5/2	0.037
^{32}S	0	95.0
^{33}S	3/2	0.76
^{51}V	7/2	99.8
^{55}Mn	5/2	100
^{56}Fe	0	91.7
^{57}Fe	1/2	2.19
^{59}Co	7/2	100

^{95}Mo & ^{97}Mo	5/2	16 & 9
^{183} W	1/2	14.4

8 HYPERFINE INTERACTION—THE EFFECT OF NUCLEAR SPIN

If all we could do was measure g-factors, EPR spectroscopy would be less interesting and not very informative. Luckily there are energy terms other than the basic Zeeman interaction. We have already said that the magnetic moment of the electron can be represented as a classical bar magnet. From basic physics, we know that a bar magnet will align itself in an external magnetic field. That is the Zeeman interaction discussed above. Physics also tells us that the energy of a bar magnet can be influenced by interaction with a neighboring bar magnet. In this latter case, the magnitude of the interaction depends on the distance of separation and the relative alignment of the two magnets. An analogous interaction occurs between an unpaired electron and a neighboring magnetic nucleus ($I > 0$). In this situation the nucleus is equivalent to the second bar magnet and the interaction is called the *hyperfine interaction*. Some of the nuclear isotopes that are important in biology and their nuclear spins are listed in Table 2.

The effect of the hyperfine interaction is to add an energy term ($\mathrm{h}Am_I$) to the Zeeman expression (equation 8) for each magnetic nucleus. For example, the energy of a single nucleus would be

$$\Delta W = \mathrm{h}\nu = g\beta B_\mathrm{o} + \mathrm{h}Am_I \quad (16)$$

where h is Planck's constant, A is called the *Hyperfine Coupling Constant* (measured in cm^{-1} or MHz), and m_I is the magnetic quantum number for the nucleus. Since there are $2I + 1$ possible values of $m_I (m_I = I, I - 1, \ldots, 0, \ldots, -I + 1, -I)$, the hyperfine interaction term splits the Zeeman transition into $2I + 1$ lines of equal intensity. Therefore, the interaction of the electron with a single proton ($I = 1/2$) will yield an EPR spectrum containing two lines ($m_I = 1/2$ and $m_I = -1/2$) while interaction with a single ^{14}N ($I = 1$) would yield three lines ($m_I = 1, 0, -1$; Figure 3). Because the spectrometer scans magnetic fields, the measured separation between these lines is in gauss (or tesla) and is called the *Hyperfine Splitting Constant* (a).

Each magnetic nucleus that interacts with the spin magnetic moment adds a hyperfine interaction term to the above energy expression and, correspondingly, splits each line in the spectrum into the appropriate number of lines. It is interesting to note that regardless of the number of hyperfine lines (and assuming no anisotropy, as defined in subsequent text), the EPR spectrum of a paramagnet in solution (i.e., rapid tumbling) is symmetrically centered about the Zeeman transition ($g\beta B_\mathrm{o}$). Therefore, g can be determined in solution spectra from the value of magnetic field (B_o) at the middle of the spectrum.

Figure 3 Solution spectrum of a typical nitroxide radical where the unpaired electron is mainly interacting (i.e., hyperfine interaction) with the nitrogen nucleus. Since nitrogen is predominantly the ^{14}N isotope, the line is equally split (hyperfine splitting constant) into three ($m_I = +1, 0, -1$) lines

9 ANISOTROPY

As already discussed, the deviation of the measured g-factor from the free electron (g_e) arises from the mixing of the orbital angular momentum through spin-orbit coupling. Because orbital angular momentum is oriented in the molecule, the magnitude of this coupling is direction dependent, or *anisotropic*. In a low-viscosity solution, the anisotropy is averaged out. This is not the situation when the paramagnetic molecules are in a fixed orientation, such as in a single crystal. The g-factor of the EPR spectrum of a single crystal changes as the crystal is rotated in the spectrometer, due to g-factor anisotropy. For every paramagnetic molecule, there exists a unique axis system called the *principal axis system*. The g-factors measured along these axes are called the *principal g-factors* and are labeled g_x, g_y and g_z.

Hyperfine coupling constants are also anisotropic (A_x, A_y, A_z), although their principal axis system is often different from that of the g-factors. Figure 4 shows the spectra of a nitroxide radical oriented in a single crystal where the external magnetic field is directed along the x, y or z principal axis (compare these with the solution spectrum in Figure 3). Note that the center of the spectrum (i.e., the g-factor) and the separation between the three transitions (hyperfine coupling constants) differ in all three orientations.

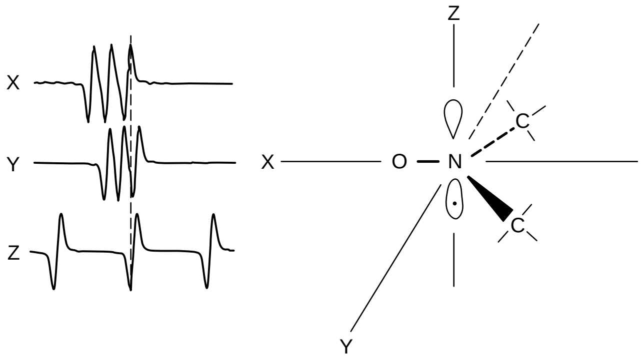

Figure 4 Spectra of oriented nitroxide radical with the external magnetic field directed along the x, y and z principal axis. Note that both the hyperfine splitting constant (separation between the lines) and center of the spectrum (g-factor) change with each orientation, illustrating the anisotropy of these terms

10 POWDER SPECTRA

Most EPR spectra of biological transition metals are recorded on frozen solution. In these samples, the paramagnets are neither aligned in a set direction, as in an oriented single crystal, nor rapidly rotating, as in a low-viscosity solution. The act of freezing fixes the molecules in all possible orientations. Therefore, the spectrum of a frozen sample represents the summation of all possible orientations and is called a *powder spectrum* (i.e., you would get the same spectrum by grinding a single crystal into a powder).

To simplify the discussion of powder spectra, we' will consider only the effect of g-factor anisotropy. Shown in Figure 5 are first-derivative spectra for three different classes of anisotropy. In the first class, called *isotropic*, all of the principal g-factors are the same ($g_x = g_y = g_z$). In this class, the g-factor is invariant with direction and, therefore, the resultant spectrum is a single symmetric line.

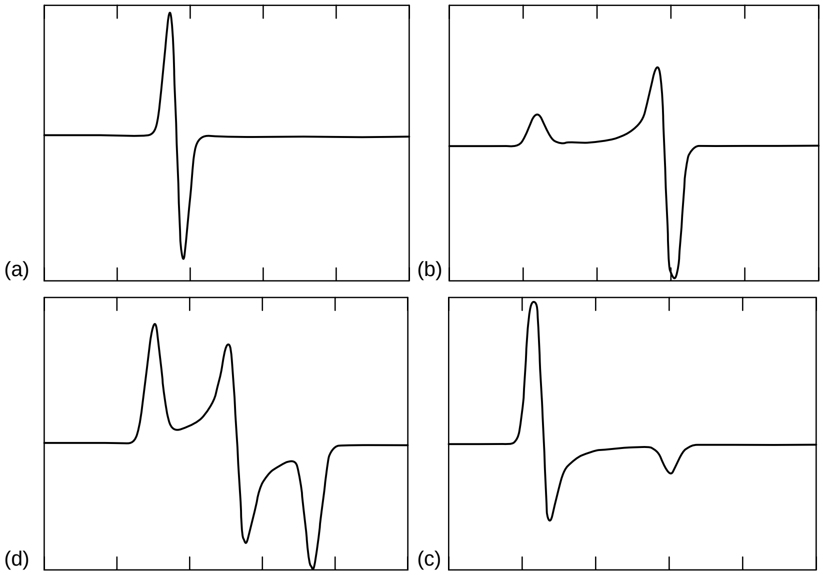

Figure 5 Line shapes of typical powder spectra, isotropic ($g_x = g_y = g_z$, a), axial ($g_x = g_y \neq g_z$, spectra b and c) with ($g_\parallel > g_\perp$, b) and ($g_\parallel < g_\perp$, c), and rhombic ($g_x \neq g_y \neq g_z$, d)

In the second class, called *axial*, there is a unique axis that differs from the other two ($g_x = g_y \neq g_z$). The g-factor along this unique axis is said to be parallel with it, $g_z = g_\parallel$ while the remaining two axis are equivalent and perpendicular to it, $g_x = g_y = g_\perp$. In this case, the powder spectrum corresponds to the summation of spectra with g-factors equal to any value between these two extremes. Because $g_\perp$ has twice the probability of occurring (i.e., because $g_x = g_y = g_\perp$) as does $g_\parallel$, the spectrum is more intense in the former region. The g-factors of the molecule can be obtained from the derivative spectrum by noting the magnetic field for the center of the minor absorption-shaped inflection ($g_\parallel$) and the midpoint of the derivative-shaped signal ($g_\perp$).

The last class, called *rhombic*, occurs when all of the g-factors differ ($g_x \neq g_y \neq g_z$). As with the axial spectrum, the principal g-factors can be determined from the derivative spectrum by noting the field positions for both the maximum and minimum absorption-shaped signals (g_z and g_x) at the extremes of the spectrum and the crossover (g_y) of the center derivative-shaped signal.

11 EXAMPLES OF $S = 1/2$ SIGNALS IN METALLOPROTEINS

11.1 Sign of the Deviation of the *g*-factor from g_e

Most of the basics have now been presented for the interpretation of the EPR spectra of transition metal ions in biological systems. Initially we will just consider $S = 1/2$ systems. The EPR spectra of mononuclear transition metals with $S = 1/2$ have g-factors close to that of the free electron with signals in the $g = 2$ region. Deviation of this g-factor from the free electron (g_e) is due to spin-orbit coupling which mixes the singlet ground state (where $L = 0$) with other states ($L > 0$), thereby introducing orbital angular momentum into the wave function and shifting the g-factor away from the $g_e = 2$ region. The amount of mixing (and the amount of shift) can be predicted using second-order perturbation theory (SOPT). The correction term from SOPT contains the spin-orbit coupling term in the numerator and the energy difference between the ground state (W_g) and mixed state (W_m) in the denominator

$$g = g_e - \frac{(\text{spin} - \text{orbit coupling term})}{(W_m - W_g)} \qquad (17)$$

The most important thing to note is that the energy difference is in the denominator while the spin-orbit term is positive. Therefore, the direction of the shift of the g-factor from the free electron depends on the sign of the energy difference. For metals with d orbitals less than half filled, mixing mainly occurs between the ground state and orbitals of greater energy so that $(W_m - W_g) > 0$ yielding $g_{ave} < g_e$. Conversely, metals with d orbitals more than half filled will have $(W_m - W_g) < 0$ and $g_{ave} > g_e$. It is equally valid to treat this latter case as a hole (i.e., electron vacancy) coupling with filled orbitals.

11.2 Copper (Cu^{2+})

Cu^{2+} is a d^9 system with one unpaired electron in the highest energy level. As such the ion would be $S = 1/2$ with $g_{ave} > g_e$. Since hyperfine interaction is present, the anisotropy of the hyperfine coupling must also be considered when interpreting the powder spectrum. While the pattern of hyperfine coupling is the same for each of the principal g-factors, the magnitude of the coupling differs (see example with nitroxide in preceding text) due to anisotropic effects. The Cu^{2+} ion typically yields an axial (or near-axial) EPR spectrum with $g_\parallel > g_\perp$. The two principal isotopes of copper, ^{63}Cu (69%) and ^{65}Cu (31%), both have nuclear spins of $I = 3/2$ (Table 2), so the Zeeman line will be split into four lines ($m_I = 3/2, 1/2, -1/2, -3/2$) by each. Since the magnetic moments of these two isotopes are very similar, the hyperfine couplings are nearly coincident and often difficult to resolve.

The hyperfine coupling along $g_\parallel$ for Cu^{2+} is always much greater than that along $g_\perp$ resulting in a large splitting of the $g_\parallel$ line with only minor (sometimes unobservable) splitting of the line at $g_\perp$. Figure 6 shows the typical powder spectrum of Cu^{2+} with $g_\parallel = 2.27$; $g_\perp = 2.05$; $A_\parallel = 43 \times 10^{-4}\,\text{cm}^{-1}$ with $g_{ave} > 2$.

11.3 Vanadium (V^{4+})

Although vanadium has a relatively large natural abundance on the earth and is known to be an important element for life functions, to date it has been found present only in a few enzymes, most notably V-bromoperoxidase and V-nitrogenase. Of these enzymes, vanadium EPR signals have been observed only in V-bromoperoxidase.

Bromoperoxidase reaction

$$Br^- + H_2O_2 + RH \rightarrow RBr + OH^- + H_2O \qquad (18)$$

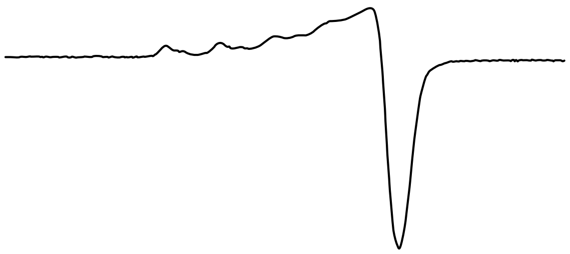

Figure 6 Powder spectrum of a typical Cu^{2+} ion with axial structure and $g_\parallel > g_\perp$. Note the hyperfine structure on $g_\parallel$ (four lines arising from the two $I = 3/2$ isotopes of Cu with similar splitting constants). The hyperfine splitting on $g_\perp$ is small and undetectable

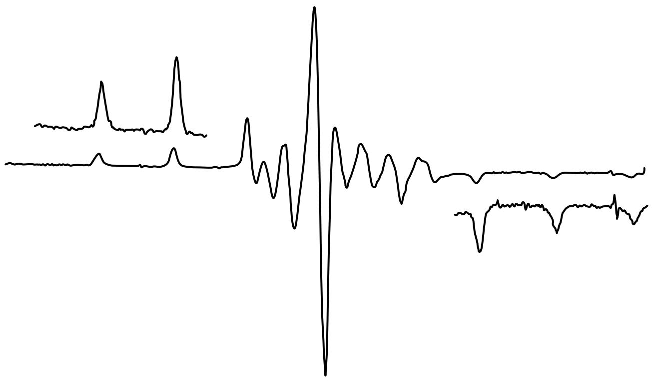

Figure 7 Powder spectrum of V-bromoperoxidase. Spectrum is axial ($g_{\parallel} < g_{\perp}$) with hyperfine structure (8 lines from $I = 7/2$) on both $g_{\parallel}$ and $g_{\perp}$

During enzymatic activity, vanadium in bromoperoxidase is EPR silent. However, its spectrum can be observed at X-band by reduction of the enzyme with dithionite to generate V^{4+} (d^1), as shown in Figure 7. Because vanadium has axial symmetry, its powder spectrum consists of two major inflections ($g_{\parallel} = 1.948$ and $g_{\perp} = 1.979$; $g_{ave} < 2$). Vanadium possesses one stable isotope ^{51}V with $I = 7/2$ (Table 2). Therefore, each Zeeman inflection will be further split into eight ($2I + 1$) lines ($A_{\parallel} = 164 \times 10^{-4}\,cm^{-1}$ and $A_{\perp} = 54 \times 10^{-4}\,cm^{-1}$). Due to spectral overlap, not all lines are observed. For comparison, the room temperature solution spectrum of aqueous $VO(H_2O)_5^{2+}$ is shown (Figure 8). The variation in the amplitude of each line arises from anisotropy observable during slow tumbling.

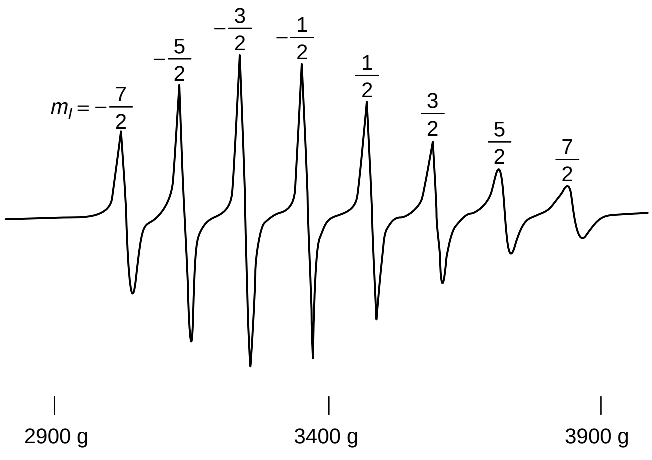

Figure 8 Solution spectrum of $VO(H_2O)_5^{2+}$ showing eight lines ($I = 7/2$). Line intensity variation arises from slow tumbling of the ion resulting in coupled g-factor and hyperfine splitting anisotropy effects

11.4 Molybdenum (Mo^{5+})

Molybdenum is present in many enzymes and is often EPR detectable (except for Mo-nitrogenase, where it exists in a complex $MoFe_7S_9$•homocitrate cluster). Shown in Figure 9 is the Mo^{5+} (d^1) X-band spectrum of one form of xanthine oxidase,[4] called the *Very Rapid* form. Xanthine oxidase is a homodimer containing one Mo center, two Fe–S, centers and one molecule of flavin adenine dinucleotide per subunit. This enzyme catalyzes the oxidation of xanthine at the Mo center with subsequent reduction of O_2 at the flavin center. In this enzyme Mo^{5+} exhibits a slightly rhombic EPR spectrum ($g_z = 2.0252$, $g_y = 1.9550$, $g_x = 1.9495$; $g_{ave} < 2$). Of all the isotopes, only ^{95}Mo (16%) and ^{97}Mo (9%) possess nuclear magnetic moments ($I = 5/2$ for both; see Table 2). Therefore, these two isotopes only contribute to 25% of the total spectrum with the remaining 75% not showing any hyperfine interaction. To further illustrate this, Figure 9 shows the X-band spectrumof Mo^{5+} in ''Very Rapid'' xanthine oxidase using natural abundance Mo (top) or ^{95}Mo-enriched enzyme (bottom).[4] For ^{95}Mo the hyperfine coupling constants are: $A_z = 113\,MHz$, $A_y = 54.7\,MHz$, $A_x = 57.3\,MHz$.

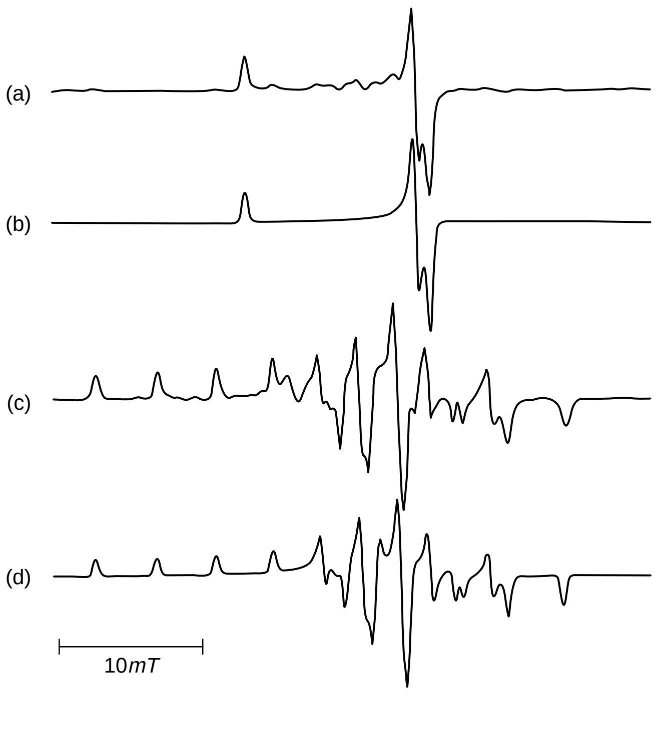

Figure 9 Powder spectra of Mo^{5+} in ''Very Rapid'' form of xanthine oxidase. Spectrum (a) represents natural abundance Mo with 16% ^{95}Mo and 9% ^{97}Mo (both isotopes have $I = 5/2$). The remaining isotopes have $I = 0$. These two isotopes contribute to the small structure observed in (a). Spectrum (b) represents a simulation of (a) without any hyperfine splitting. Spectrum (c) represents the sample enriched in ^{95}Mo while (d) is a simulation of (c). (Reprinted with permission from George and Bray.[4] © 1988 American Chemical Society)

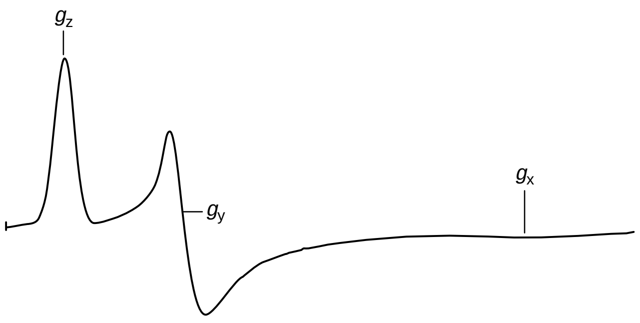

Figure 10 Powder spectrum of a Aquometmyoglobin heme (Fe^{3+}) protein. Note the increase in line width from left to right with increasing magnetic field and decreasing g-factor

11.5 Low-spin Heme (Fe^{3+})

Iron in a heme structure can exist in the low-spin ($S = 1/2$) form. In cytochrome c, the principal axes approximately coincide with a rectangular coordinate system with two of the axis fixed on the heme. The observed g-factors (Figure 10) are 1.45, 2.22 and 3.06. The broadening of the spectrum with increasing field is attributed to *g-strain*. When solutions of metalloproteins (or similar systems) are frozen there exist a range of environments surrounding the metal ion. This arises from the flexibility of the protein prior to freezing. Each environment has its own set of g-factors, differing only slightly from one another. The resultant powder spectrum will be broadened due to the overlap of all the different g-factors. For a given variation of g-factor (say 10%), the broadening (in terms of magnetic field-width) will vary across the spectrum. A simplistic example is that a 10% variation of a g-factor at 1000 G will be 100 G while the same variation for a g-factor at 3000 G will be 300 G. This field-dependent broadening is termed *g-strain* and results in a spectral broadening that increases toward the high-field region. It is not unusual for the high-field inflections to be unobservable due to excessive broadening.

11.6 Iron–Sulfur Clusters

Paramagnetism in a metalloprotein does not have to be associated with only a single metal site but can arise from metal clusters. In these clusters the spins of the different metal sites couple either ferromagnetically or antiferromagnetically to produce a net spin state of the cluster.

Fe–S proteins provide some of the best-characterized examples of multimetal paramagnetic clusters in proteins. Most of these proteins exhibit redox functions with the Fe–S clusters existing in two different oxidation states where one of the states (even numbers of electrons) is diamagnetic or integer spin. The other oxidation state is one electron different from the integer state and, therefore, is a paramagnetic half-integer state. This latter state is most often $S = 1/2$, although mixtures with states having $S > 1/2$ have been observed. Even though the iron ions in these clusters are usually high

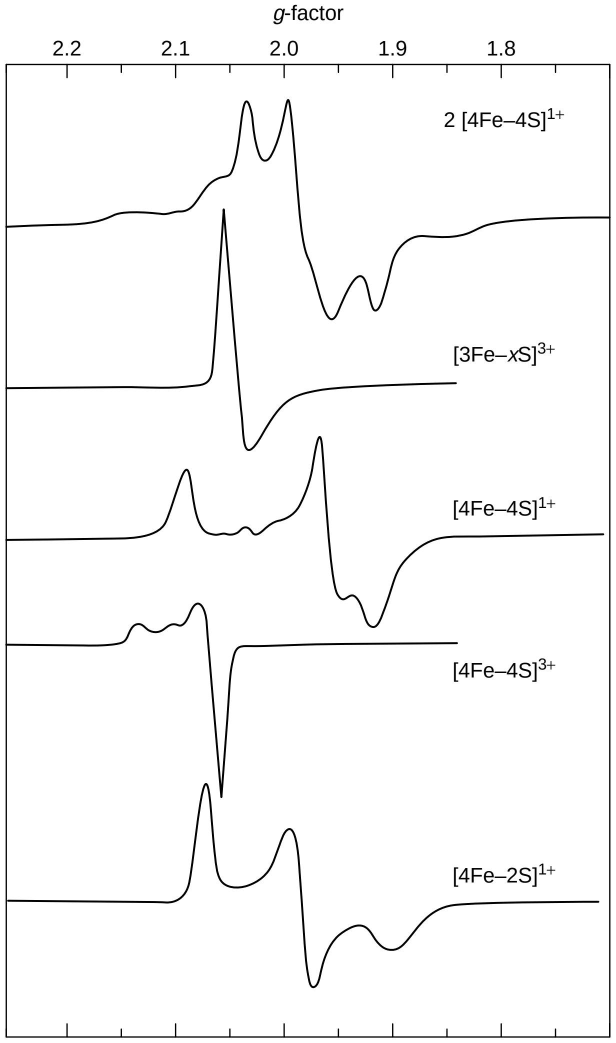

Figure 11 Representative EPR powder spectra of different classes of common FeS clusters. All spectra represent clusters in the paramagnetic $S = 1/2$ state. (Reproduced with permission from Cammack, Patil and Fernandez.[5] © 1985 The Biochemical Society)

spin ($S = 5/2$ or 2), antiferromagnetic coupling between them produces a net $S = 1/2$ state for the cluster. Since ^{32}S and ^{56}Fe have no nuclear spin ($I = 0$), the EPR spectra of isolated Fe–S clusters possess no observable fine structure. Shown in Figure 11 are representative X-band spectra of different Fe–S clusters[5]. Note that $[4Fe\text{-}4S]^{1+}$ and $[2Fe\text{-}2S]^{1+}$ have $g_{ave} < 2$ while $[3Fe\text{-}4S]^{1+}$ and $[4Fe\text{-}4S]^{3+}$ have $g_{ave} > 2$ (where $g_{ave} = \surd\{[g_x^2 + g_y^2 + g_z^2]/3\}$).

12 $S > 1/2$ SPECTRA

12.1 The Energy Equation

When interpreting the EPR spectra of metals or metal clusters with $S > 1/2$, an extra term is added to the energy

equation. Until now we have included the Zeeman interaction and the hyperfine interaction. For $S > 1/2$ systems we must include an energy term describing the interaction between two or more unpaired electrons. The magnitude of this interaction depends on the system. In organic triplet states ($S = 1$), the magnitude of this interaction is generally small and primarily arises from dipole–dipole interaction between the magnetic moments of the two electrons. On the other hand, in transition metals this interaction is large and occurs via spin-orbit coupling of the electrons. Regardless of the origin or magnitude, the added term describing the energy of this interaction is the same,

$$W_{S>1/2} = D\left[\mathbf{S}_z^2 - \frac{1}{3}S(S+1) + \frac{E}{D}(\mathbf{S}_x^2 - \mathbf{S}_y^2)\right] \tag{19}$$

where D and E are the axial and rhombic zero-field splitting (zfs) parameters, respectively. All bold spin terms are quantum mechanical operators. The term E/D, called the *rhombicity*, is defined such that $0 \le E/D \le 1/3$ where $E/D = 0$ represents a completely axial system and 1/3 is a completely rhombic system.

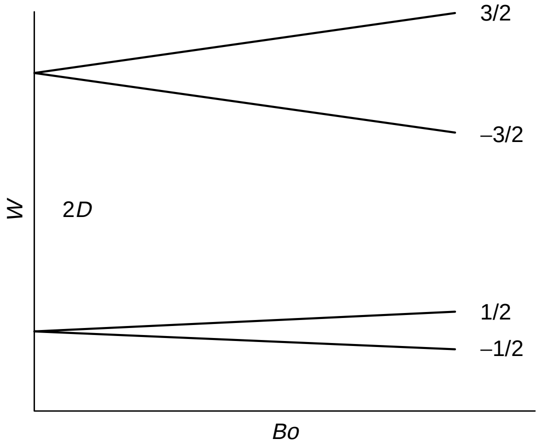

Figure 12 Energy diagram for $S = 3/2$ spin system with $E/D = 0$. Typically the separation ($2D$) between each pair of doublets is much larger than the irradiating microwave field inducing transitions. Therefore, transitions only occur within each doublet and not between them

12.2 Half-integer (Kramers) Systems

Half-integer systems with $S > 1/2$ are referred to as Kramers systems. These systems have a degeneracy in the ground state that is relieved through Zeeman interaction. The simplest example to consider is $S = 3/2$. To make things easier, we will assume an axial system ($E/D = 0$) in a zero external field (B_o). Therefore, the total energy is

$$W_{S>1/2} = D\left[\mathbf{S}_z^2 - \frac{1}{3}S(S+1)\right] \tag{20}$$

When $S = 3/2$ there are four sublevels ($m_s = S_z = 3/2, 1/2, -1/2, -3/2$). Because equation (20) contains S_z only as a squared term, all $|S_z|$ levels will be degenerate. Using the above equation, we can calculate the energies of these doublets in zero field (assuming D to be positive) as

$\underline{S = 3/2, S_z = \pm 3/2}$

$$W_{S=3/2;Sz=\pm 3/2} = D\left[(\pm 3/2)^2 - 1/3\,(3/2)\,(3/2+1)\right] = +D$$

$\underline{S = 3/2, S_z = \pm 1/2}$

$$W_{S=3/2;Sz=\pm 1/2} = -D$$

When D is negative, this order is just reversed and the $S_z = \pm 3/2$ doublet is the ground state. These equations demonstrate that, in the absence of an external field, the levels exist as two sets of doublets (Figure 12) separated in energy by $2D$. Generally for metalloproteins, $D \gg h\nu$ (i.e., the splitting is greater than the energy of the irradiating microwaves), meaning that the irradiation energy is not large enough to induce transitions between $|S_z|$ levels. Therefore, only transitions within each doublet are observed.

As such, each doublet looks more like an isolated $S = 1/2$ system than part of an $S = 3/2$ system. We will refer to these sets as ''effective'' $S = 1/2$ states. Since there are two sets, we have the possibility of observing two different transitions, one from the ground state and the other from the excited state. The ''effective'' g-factor for each state is easily calculated by assuming that the g-factor of the actual state is g_e and use this to calculate the effective g-factor (g) for an effective $S = 1/2$ state. For example, for the $m_s = -3/2$ to $+3/2$ transition, $\Delta m_s = 3$ and $\Delta W = g_e\beta B_o\Delta m_s = 6\beta B_o$ while for an effective $S = 1/2$ transition ($m_s = -1/2$ to $+1/2$ or $\Delta m_s = 1$) $\Delta W = g\beta B_o\Delta m_s$. These two energies represent the same transition meaning $6\beta B_o = g\beta B_o$ or $g = 6$. A similar calculation of the $m_s = \pm 1/2$ state with the magnetic field along the z axis yields $g = 2$.

As with pure $S = 1/2$ states, the g-factors for each of these transitions will be anisotropic producing two inflections for an axial system and three for a rhombic system. In other words, for our two-level $S = 3/2$ system we have the possibility of observing two or three transitions for each level or four or six inflections for axial or rhombic, respectively. Normally, not all of these inflections are observable. Using quantum mechanics to solve the above energy equation for $S = 3/2$, $E = 0$ and $D \gg h\nu$ yields the g-factors $g_\perp = 4.0$ and $g_\parallel = 2.0$ for the $m_s = \pm 1/2$ level and $g_\perp = 0.0$ and $g_\parallel = 6.0$ for the $m_s = \pm 3/2$ level. Solving this equation for various values of E/D from 0 to 1/3 allows the determination of the possible values of the six different g-factors.[6] A plot of these g-factors is shown in Figure 13.

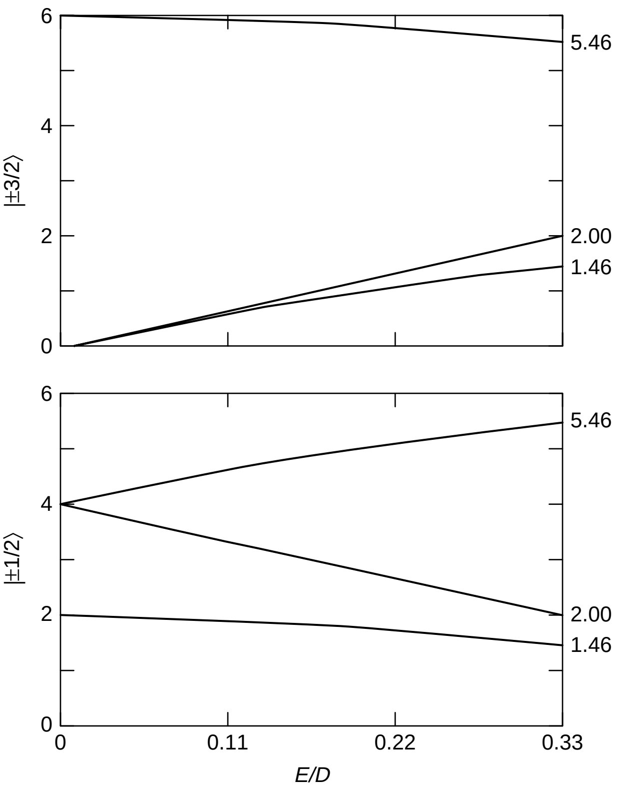

Figure 13 Variation of the principal g-factors for the $m_s = \pm 1/2$ and $\pm 3/2$ states with rhombicity (E/D) for an $S = 3/2$ state. (Adapted from Hagen[6] with permission, © 1992, Academic Press)

13 EXAMPLE OF $S = 3/2$ SYSTEM—MoFe PROTEIN OF NITROGENASE

One of the best examples of a metalloprotein with a paramagnetic $S = 3/2$ state is the MoFe protein of nitrogenase (Nitrogenase catalyzes the reaction

$$N_2 + 6H^+ + 6e^- \rightarrow 2NH_3 \quad (21)$$

The MoFe protein of the enzyme contains two different types of metal clusters: an Fe_8S_7 cluster called the *P-cluster* and a $MoFe_7S_9\bullet$ homocitrate cluster known as the *M-center* or *MoFe-cofactor*. The latter cluster is believed to be the site of substrate (N_2) reduction. The cofactor cluster is paramagnetic in the as-isolated form of the protein with $S = 3/2$ while the P-clusters are diamagnetic. Inflections for the resting-state cofactor cluster occur at $g = 4.6$, 3.7 and 2.0. These inflections (Figure 14) are associated with an $S = 3/2$ signal with an apparent rhombicity (Figure 13) of $E/D = 0.05$.

14 EXAMPLE OF $S = 5/2$

14.1 Aquometmyoglobin

The iron in aquometmyoglobin (Figure 15) exists in an axial environment ($E/D = 0$) in the high-spin ($S = 5/2$) state of Fe^{3+}. This can be compared to iron in a purely rhombic ($E/D = 1/3$) high-spin system as exemplified by hexaaquo iron and *D. gigas* rubredoxin (Figure 15). Note that the middle energy level of a purely rhombic system (Figure 15) has all three g-factors coincident at about 4.3. Even though these inflections arise from an excited state, their intensity is confined to one g-factor producing a dominant signal observed even at very low concentrations. Because of the ubiquitous nature of hexaaquo iron, this signal is observable in most biological spectra and should not be assumed to be associated with the sample under investigation.

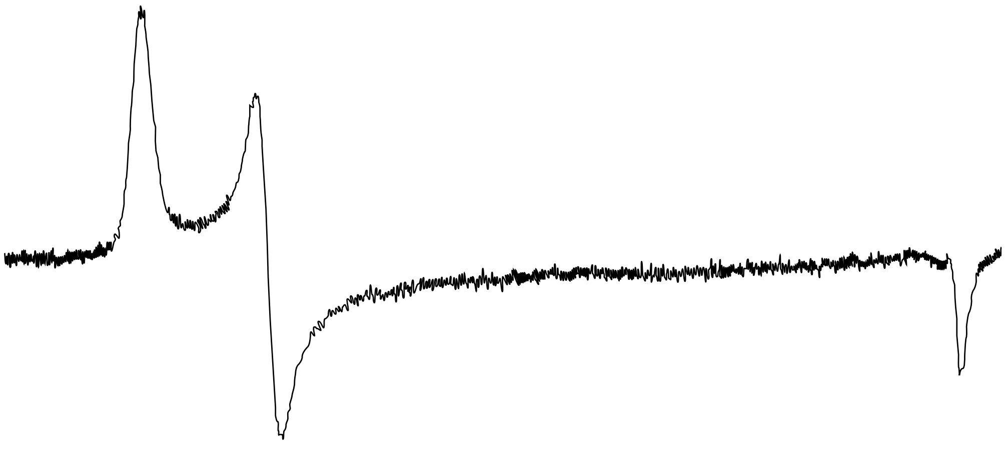

Figure 14 EPR powder spectrum of the MoFe protein of Mo-nitrogenase taken at 4 K. The spectral g-factors of 4.6, 3.7 and 2.0 represent the lower $m_s = \pm 1/2$ transition of an $S = 3/2$ system with $E/D = 0.05$

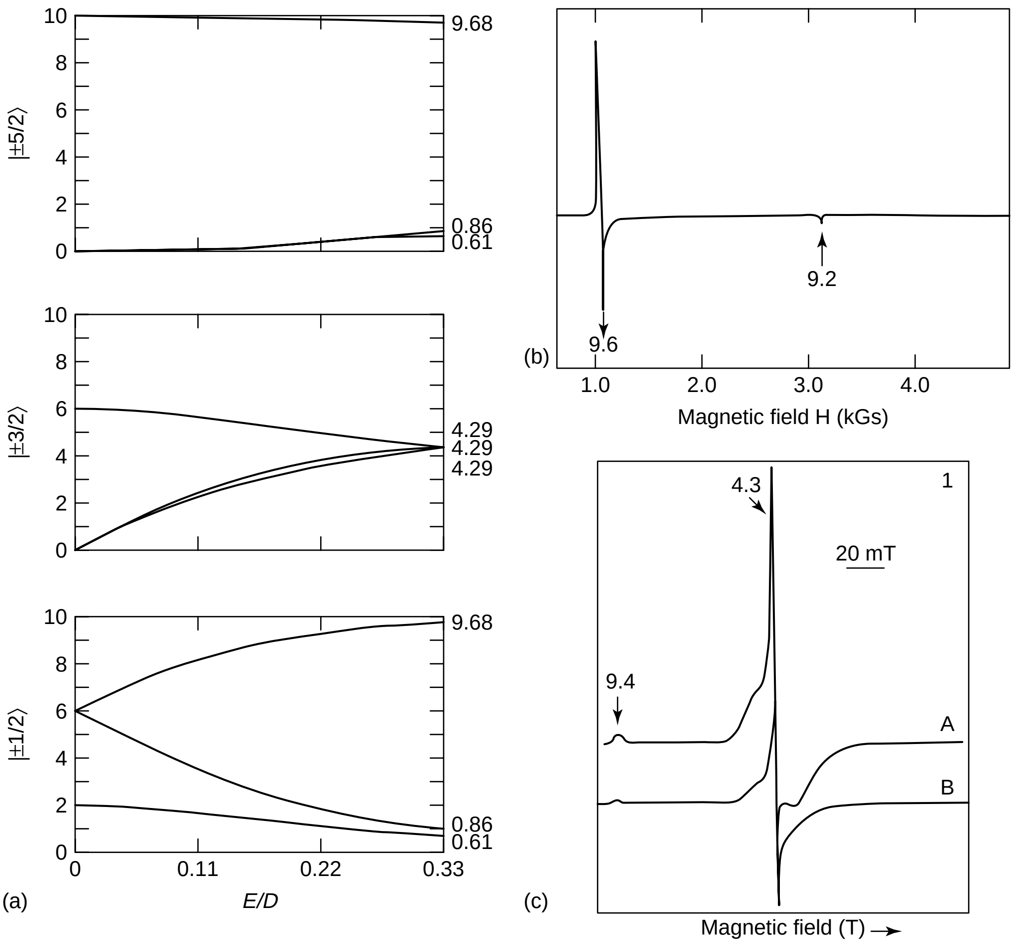

Figure 15 Variation of the principal g-factors for the $m_s = \pm 1/2, \pm 3/2$ and $\pm 5/2$ states with rhombicity (E/D) for an $S = 5/2$ state (a). (Adapted from Hagen[6] with permission, © 1992, Academic Press). Spectra of an $S = 5/2$ state with pure axial $(E/D = 0)$ (aquometmyoglobin)(b), and pure rhombic $(E/D = 1/3$; rubredoxin) (Sc) symmetries. Note the high intensity of the $g = 4.3$ line in the rhombic spectrum even though this line arises from a high energy transition

15 INTEGER-SPIN (NON-KRAMERS) SYSTEMS

Integer-spin (non-Kramers) systems are not required to be degenerate in the absence of an external magnetic field. The simplest example occurs with $S = 1$. Equation (19) is again used to calculate the energies in zero magnetic field. When a magnetic field is present (without any hyperfine interactions), the energy becomes

$$W = g\beta B_o S_z + D\left[S_z^2 - 1/3S(S+1) + E/D(S_x^2 - S_y^2)\right] \qquad (21)$$

Solving this equation for $S = 1$ yields three energy levels,

$$W_1 = -2\frac{D}{3} \qquad (22)$$

$$W_2 = \frac{D}{3} - [E^2 + (g\beta B_o)^2]^{1/2} \qquad (23)$$

$$W_2 = \frac{D}{3} + [E^2 + (g\beta B_o)^2]^{1/2} \qquad (24)$$

Figure 16 shows plots of the energy levels for both axial $(E = 0)$ and rhombic $(D > 3E > 0)$ systems with $D \gg h\nu$. In the axial system, it is obvious that a transition cannot be induced between $m_s = 0$ and $m_s = \pm 1$ because of the large energy separation (D). A transition also cannot be induced between $m_s = +1$ and $m_s = -1$, since this is forbidden by selection rules (i.e., this is a $\Delta m_s = 2$ transition while only $\Delta m_s = 1$ transitions are allowed). Therefore, transitions are almost never observed in purely axial integer-spin systems.

In rhombic systems, transitions between $m_s = +1$ and $m_s = -1$ become allowed through wave function mixing. However, a new complication arises, one not previously encountered with half-integer systems. Namely the $m_s = +1$ and $m_s = -1$ levels are now split in zero-field. If this separation is larger than the microwave energy $(2E > h\nu)$, a transition cannot be induced. This is why so many integer-spin paramagnetic metalloproteins are EPR silent.

EPR transitions have been observed from some integer-spin systems. From the above discussion it is obvious

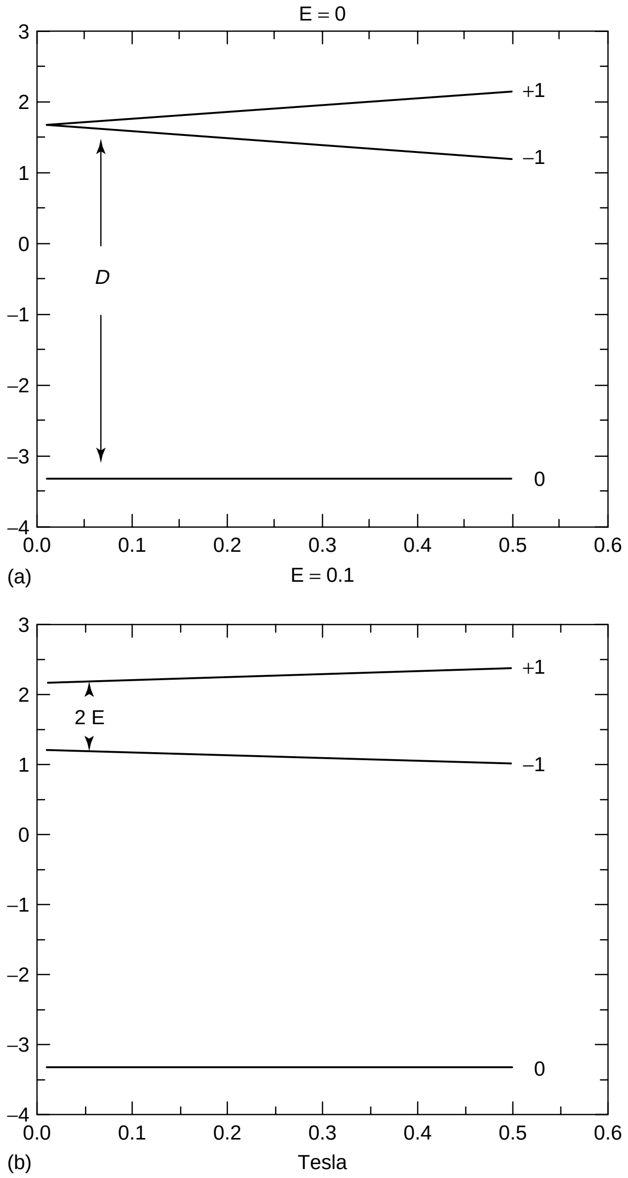

Figure 16 Theoretical variation of the energies of the $m_s = +1$, 0 and -1 states for an $S = 1$ system with $E/D = 0$ (a) and $E/D = 0.1$ (b). Bottom plot illustrates the splitting of the $m_s = \pm 1$ levels even in the absence of an external magnetic field

that to be able to observe a transition in these systems (1) the system *must have* $E \neq 0$ and (2) the zero-field separation between any set of doublets ($m_s = \pm n$ where $n < S$) *must be less than the microwave energy*. This latter requirement has the best chance of occurring for low-field inflections for the $m_s = \pm$n doublet of an $S = n$ system where $n > 2$. The low-field g-factor for this transition is normally around $g = 4S$. A dual-mode cavity can be used to accentuate the transition probability (intensity) of an integer-spin system. These cavities have the magnetic field component of microwave radiation oriented parallel to the direction of the external magnetic field (as opposed to the more typical perpendicular mode). While the perpendicular mode induces transitions corresponding to $\Delta m_s = \pm 1$, parallel mode allows one to observe $\Delta m_s = 0$ transitions, which tend to have a greater probability among $m_s = \pm$n integer-spin states.

16 ABBREVIATIONS AND ACRONYMS

ENDOR = electron nuclear double resonance; EPR = electron-paramagnetic resonance; ESR = electron-spin resonance; NMR = nuclear magnetic resonance; MA = modulation amplitude; SOPT = second-order perturbation theory; s-o = spin-orbit; zfs = zero-field splitting (for $S > 1/2$); D = uniaxial zfs; E = rhombic zfs; g = g-factor with principal components g_x, g_y, and g_z; g_e = free electron g-factor; a = hyperfine splitting constant; A = hyperfine coupling constant for a given nucleus N (nuclear spin $I > 0$).

METHOD SUMMARY

Acronyms, Synonyms

- Electron Spin Echo Envelope Modulation
- Electron Spin Echo Modulation
- HYperfine Sublevel CORrElation Spectroscopy.

Measured physical quantities

- The integrated intensity of electron spin echoes as a function of the time between one or two pairs of microwave pulses.

Information available

- the identity and number of nuclei magnetically coupled to a paramagnetic center
- hyperfine and nuclear quadrupole couplings
- coupling tensor orientation with respect to magnetic axis
- the distribution of unpaired electron spin density about a structure

Information not available, limitations

- The system must be paramagnetic.
- The nuclei to be studied must have a magnetic moment.

Examples of questions that can be answered

- The ligation structure of a paramagnetic metal ion can be quantified.
- The freeze quench sample preparation can allow characterization of reaction intermediates.
- The electronic structure and conformation of organic radicals can be measured.

Major advantages

- The experimental approach is systematic.
- ESEEM data are self-normalizing, allowing one to take difference spectra and simplify complicated spectra.
- Structural information can be gained from powder and frozen solution samples.

- The experiment only provides information on a small volume of the system within 5–10 Å of a paramagnetic center, so it is not limited by molar mass.

Major disadvantages

- A pulse EPR spectrometer is needed.
- The experiments usually require sample temperatures from 2 to 80 K.
- Sample concentrations are high in comparison to optical methods.
- Data reduction often requires spectral simulation.

Sample constraints

- Samples can be frozen solutions, powders, or single crystals.
- Samples are normally housed in 3–5 mm OD quartz tubes with an active sample volume of 50–150 µL.
- Sample concentrations depend on spin relaxation dynamics, the intensity of ESEEM and the width of the EPR absorption spectrum, typical concentrations needed for quality data are: organic radicals, Mn(II), 10–100 µM; Cu(II), 100–500 µM; Fe(III), 0.2–2 mM.

1 INTRODUCTION

The potential for electron paramagnetic resonance (EPR), (*see* ***Electron Paramagnetic Resonance (EPR) Spectroscopy***) spectroscopy to contribute important structural and mechanistic information to problems in inorganic chemistry has never been higher than it is at present. In biology and materials science, transition ions play important roles in the catalysis of oxidation-reduction reactions. These metal centers are often paramagnetic in at least one step of a catalytic cycle allowing EPR spectroscopy to probe the details of the center's magnetic structure. Much of this information relies on the measurement of ligand hyperfine couplings, weak spin–spin couplings between the paramagnetic center and magnetic nuclei that belong to ligand groups or nearby molecular entities of chemical interest. Because inhomogeneous broadening of the EPR spectrum precludes the measurement of these weak hyperfine couplings for powder and frozen solution samples, the experimentalist must use a combination of multifrequency EPR, electron-nuclear double resonance (ENDOR), (*see* ***Electron-Nuclear Double Resonance (ENDOR) Spectroscopy***), and electron spin echo envelope modulation (ESEEM) spectroscopies to measure them. Although there is overlap in the capabilities of these methods, experience over the past 30 years has revealed their relative strengths and weaknesses. Fortunately, these are of a complementary nature and EPR spectrometers that can perform all of these measurements from a single platform are commercially available. This article will begin with a brief historical perspective on the development of ESEEM spectroscopy and will end with a case study that illustrates its power in solving problems in bioinorganic chemistry. Facets of this methodology that remain problematic will be discussed.

The first observations of ESEEM were published in two separate articles that appeared in Physical Review during the fall of 1961. The first of these reports was authored by W.B. Mims, K. Nassau and J.D. McGee and focused on using electron spin echoes (ESE) to study spectral diffusion and relaxation dynamics for the EPR spectra of Ce(III) and Er(III) doped into $CaWO_4$ crystals. During the course of this work, deep modulations of the Ce(III) ESE amplitude were measured as a function of varying the inter-pulse spacing, τ, in two-pulse $(90° - \tau - 180°)$ experiments. This modulation occurred at the ^{183}W Larmor frequency and its amplitude was markedly dependent on crystal orientation with respect to the direction of the applied magnetic field.[1] Two months later, J.A. Cowen and D.E. Kaplan reported deep modulations of the Ce(III) ESE decay envelope when using $2\text{–}(90° - \tau - 180°)$ and three-pulse $(90° - \tau - 90° - T - 90°)$ techniques to measure electron spin relaxation times for the metal ion doped into lanthanum magnesium nitrate crystals. These modulations were recorded as a function of varying τ, from 0.5–4.0 µs, in two-pulse measurements, and T, from 1.0 to 8.0 µs, in three-pulse measurements. Cowan and Kaplan assigned these modulations to weak hyperfine interactions between Ce(III) and ^{14}N of the host lattice and commented, ''this technique should prove useful for investigating nuclear-electron coupling.''[2] It was probably no accident that both Mims and Kaplan were located at companies, Bell Laboratories and Lockheed, respectively, where there was access to sophisticated microwave equipment. The Mims spectrometer operated at 6.7 GHz and used a fast grid-modulated traveling wave tube amplifier (TWTA) to achieve the high pulse powers and fast pulse recovery times (250 ns) required to generate and detect electron spin echoes while the Kaplan system operated at 9.3 GHz and used pulsed magnetrons capable of producing 50 ns pulses with 100 W peak power for exciting the samples.

A full-length paper on ESEEM studies of Ce(III) doped into $CaWO_4$ and CaF_2 was published in 1965 by Rowan, Hahn and Mims.[3] These authors called attention to the similarities of the ESEEM experiment to experiments

done in the early 1950s on nuclear spin echo modulation where spin–spin couplings between nuclear spins gave rise to similar interferences.[4,5] They developed the theory for ESEEM and used it to analyze the two-pulse modulation data obtained for the two Ce(III) crystal systems mentioned above.[3] The first ESEEM studies of glassy samples were published in 1968 by Zhidomirov, Salikov, Tsvetkov, Yudanov and Raitsimring and focused on measuring ^{1}H and ^{2}H-ESEEM in γ-irradiated sulfuric acid glasses and in frozen solutions of 2,2-diphenyl-1-picrylhydrazyl (DPPH) in CH_3OH and CH_3OD. The theory developed for the analysis of these data was published separately.[6,7]

During the 1970s, the development of ESEEM continued in the laboratories of W.B. Mims at Bell Laboratories (Murray Hill, New Jersey, USA) and of Yu.D. Tsvetkov at the Institute of Chemical Combustion and Kinetics (Novosibirsk, Russia). Mims continued his focus on inorganic systems and in collaboration with J. Peisach (Albert Einstein College of Medicine) began investigations on frozen solutions of model transition metal ion complexes and metalloproteins.[8–11] The Novosibirsk group maintained an interest in glassy materials and together with L. Kevan (then at Wayne State University) used careful ESEEM measurements and theoretical analysis to define the locales of trapped electrons in γ-irradiated glasses.[12–14] By the late 1970s, advances in microwave technology and digital electronics made the construction of pulsed EPR spectrometers straightforward and many labs built systems for ESEEM and ESE-detected ENDOR applications. A list of these instruments, compiled by J. Peisach in 1986, showed that 33 laboratories worldwide housed at least one pulse EPR spectrometer. These homebuilt spectrometers typically operated at X-band (8–12 GHz), featured a pulse transmitter capable of 1 kW pulses, a homebuilt pulse programmer that utilized commercial, programmable delay and gate generators to achieve the accurate 1–10 ns timing requirements of the experiments, a gated integrator to record spin-echo intensities, and locally constructed, high filling factor probes that could accommodate samples in standard EPR tubes. This second wave of homebuilt pulse EPR spectrometers were also computer controlled, making the standard two- and three-pulse ESEEM experiments more routine and providing researchers with ESEEM data that were in digital form. Spectral analysis methods that were primarily built around fast fourier transformations (FFT) of the data became common and the resulting ESEEM spectra became the most common way to report experimental findings.

Along with this expansion in instrumentation came the development of new data acquisition strategies to improve instrument performance and tailor data acquisition for more precise measurements of hyperfine couplings. Sophisticated approaches to data analysis, spectral simulation and improved probe designs were developed. These improvements were driven by an even greater expansion in applications.[15] No field of modern scientific investigation benefited more from this expansion than inorganic chemistry. In materials chemistry, many papers using ESEEM to probe the structures of solid phase catalysts were published. In bioinorganic chemistry, a vast array of transition metal ion centers in metalloenzymes and model complexes were studied by ESEEM. This growth in applications led to the development of the first commercial FT/EPR spectrometer, the Bruker ESP 380, in 1987. Although the EPR community was slow to adopt the ESP 380 and Bruker's most recent offering, the ElexSys E 580, the advantages of these spectrometers over the majority of homebuilt instruments are considerable. These advantages are listed below.

1. The pulse programmer is flexible and controlled by a simple scripting language that makes it easy to implement new pulsing schemes with phase cycling and multiple pulse channels.
2. The transient recorder can be used as a digital oscilloscope for instrument tuning and diagnostics, as a gated integrator for ESEEM studies and as a transient recorder for FT-EPR. The maximum repetition rate is often limited by the TWTA duty cycle, but it is routine to operate the instrument at 1–2 kHz repetition rates.
3. The microwave bridge is stable for days making two-dimensional ESEEM experiments routine.
4. Sensitive probes that feature high filling factors and coupling assemblies that allow adjustment from critical coupling for cw-EPR to overcoupling for pulse operation with 60 ns dead times are available. These probes are fitted with magnetic field modulation coils, so it is routine to measure the cw-EPR spectrum of a sample prior to switching to pulse operation. An ENDOR probe that features a 4-mm dielectric resonator allows one to collect cw-EPR spectra and then switch to pulse operation where ESE-ENDOR and ESEEM studies can be undertaken.
5. The Xepr software package that runs the instrument is easy to learn and contains many useful features for spectral manipulation and analysis. It runs on a personal computer under the Linux environment so it is possible to gain network access to the spectrometer from any networked computer that has an X-11 terminal emulator. This allows several users to log in and analyze their data while the spectrometer is busy collecting more.

Finally, before moving on to the scientific portion of this article, a disclaimer concerning the above text needs to be offered. Although the origins of the ESEEM experiment were presented in some detail with specific mention of a few scientists and references, the majority of investigators who played key roles in bringing ESEEM to where it is today, are lumped into two or three sentences about the period from the late 1970s to the present. Some of these oversights will be remedied below as background material and applications are presented. Also, the above comments regarding the advantages of the commercial pulse EPR instrument over the homebuilt instruments of

the last 30 years are strongly influenced by my own experiences. There are labs where homebuilt machines have achieved performance equal or superior to that offered by Bruker, or they have a unique capability not offered by the Bruker instruments. These laboratories have access to engineers and technical help that are not found in a typical academic setting.

2 TECHNICAL BACKGROUND

The goal of an ESEEM experiment is to gain an understanding of the detailed electronic and geometric structure of a paramagnetic center through the measurement of electron-nuclear hyperfine couplings. For problems in inorganic chemistry, ESEEM is most often used to measure ligand hyperfine couplings to a paramagnetic metal ion center that will help identify the ligands and determine their orientation with respect to the paramagnetic center's magnetic axis system. Hyperfine couplings to magnetic nuclei outside the primary coordination sphere can also be measured. It is often these weaker couplings that provide key information on the chemical problem to be addressed. In an ESEEM experiment, the magnetic field is set to a fixed position within the EPR absorption spectrum and the sample is excited with resonant microwave pulses that lead to the formation of electron spin echoes. In this section, three basic ESEEM pulse schemes, two-pulse or primary echo, three-pulse or stimulated echo, and the two-dimensional hyperfine sublevel correlation (HYSCORE) will be discussed in detail. Mathematical formulas for the spin echo modulation functions of a simple $S = 1/2$, $I = 1/2$ coupled spin system will be presented and discussed for each technique because they provide the clearest explanation of what is measured. Sample spectra for each experiment will be presented to support this discussion. There are several good references available where this information is covered in greater detail, with more thorough explanations and with better coverage in terms of experimental examples (see *Further Reading* at the end of this article).

2.1 Two-pulse ESEEM

For a two-pulse ($90° - \tau - 180°$), or primary echo experiment, the integrated intensity of the spin echo, which occurs at time τ after the 180° pulse, is measured as a function of increasing τ from the probe's ''dead-time'' (~100 ns) to a time where the echo amplitude has decayed to a few percent of its initial amplitude (2–8 μs for most powder samples). A two-pulse ESE decay envelope for the type-1 Cu(II) site of a multi-copper oxidase, Fet3p, is shown in Figure 1(a). The data show an overall decay characterized by a phase memory time, T_M or T_2^*, of <1.0 μs. Superimposed on this decay are echo modulations that arise from hyperfine coupling to the ^{14}N nuclei of two histidyl imidazole ligands and the protons of the surrounding matrix.

The most straightforward way to understand the origin of ESEEM and the physical chemistry behind its detection and analysis is to step back from this Cu(II) center and focus on an $S = 1/2$, $I = 1/2$ coupled spin system. The spin Hamiltonian for this system consists of electronic Zeeman, nuclear Zeeman, and electron-nuclear hyperfine interaction terms. For the case of an isotropic electron g-matrix and an axial hyperfine interaction, this Hamiltonian can be conveniently written in the laboratory reference frame,

$$\mathrm{H}/\hbar = \omega_S \hat{S}_Z + A_{zz}\hat{S}_Z\hat{I}_Z + A_{xz}\hat{S}_Z\hat{I}_X - \omega_I\hat{I}_Z \quad (1)$$

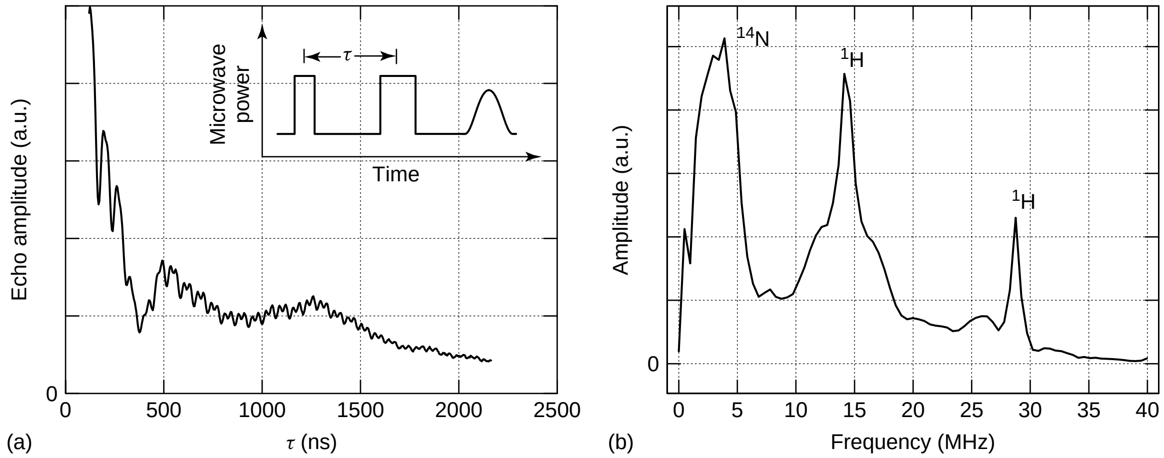

Figure 1 Two-pulse or primary ESEEM data collected for the type-1 Cu(II) site of the Fet3p enzyme. Figure 1(a) shows the time domain data recorded under the following conditions: microwave frequency, 9.6883 GHz; field strength, 337.0 mT; pulse power, 250 W; 90° pulse length, 16 ns full width at half maximum (FWHM); sample temperature, 10 K. Figure 1(b) shows the ESEEM spectrum derived from the data of Figure 1(a) by subtraction of a biexponential decay function, application of a Hamming window function, and Fast Fourier Transformation (FFT). The absolute value spectrum is displayed

where $A_{zz} = A = A_{\parallel}\cos^2\theta + A_{\perp}\sin^2\theta$, $A_{xz} = B = (A_{\parallel} - A_{\perp})\cos\theta\sin\theta$, $\omega_S = g\beta B_o/\hbar$ and $\omega_I = g_n\beta_n B_o/\hbar$. $A_{\parallel}$ and $A_{\perp}$ are the principal values of an axially symmetric hyperfine tensor that can be expressed in terms of a Fermi contact coupling, A_{iso}, and a dipole–dipole coupling term, $T = gg_n\beta\beta_n/r^3$, with $A_{\parallel} = A_{iso} + 2T$ and $A_{\perp} = A_{iso} - T$. The angle θ describes the orientation of the principal axis of the hyperfine tensor, $A_{\parallel}$, with respect to the laboratory field, B_o. The remaining terms in the above equations are: g, the electron g-factor; g_n, the nuclear g-value; β, the Bohr magneton; and β_n, the nuclear magneton. The Hamiltonian matrix is easily constructed in a general basis set consisting of electron and nuclear spin product states, $|m_S, m_I>$. Diagonalization to yield the eigenvalues and eigenvectors of equation (1) can be carried out independently for the two electron spin manifolds since the only term in the operator that gives rise to off-diagonal matrix elements is that involving $\hat{I}_x$. The results are summarized in the energy level scheme of Figure 2.

The normalized probability amplitudes for the EPR transitions marked $|u|$ and $|v|$ in Figure 2 are given by

$$|u| = \frac{\left\langle 2\left|\hat{S}_x\right|3\right\rangle}{(0.5g\beta B_1)} = \sin\left\{\frac{(\varphi_\alpha - \varphi_\beta)}{2}\right\} \quad (2)$$

and

$$|v| = \frac{\left\langle 1\left|\hat{S}_x\right|3\right\rangle}{(0.5g\beta B_1)} = \cos\left\{\frac{(\varphi_\alpha - \varphi_\beta)}{2}\right\} \quad (3)$$

The angles φ_α and φ_β define the axis of quantization for the α and β electron-spin manifolds, respectively, and are given by $\sin\varphi_\alpha = B/2\omega_\alpha$ and $\sin\varphi_\beta = B/2\omega_\beta$, where ω_α and ω_β are the angular hyperfine frequencies as defined in Figure 2. In general, all four of the possible EPR transitions for the $S = 1/2$, $I = 1/2$ spin system of Figure 2 are allowed. These transitions will be excited simultaneously in a pulsed EPR experiment, provided that the microwave pulses have sufficient bandwidth.

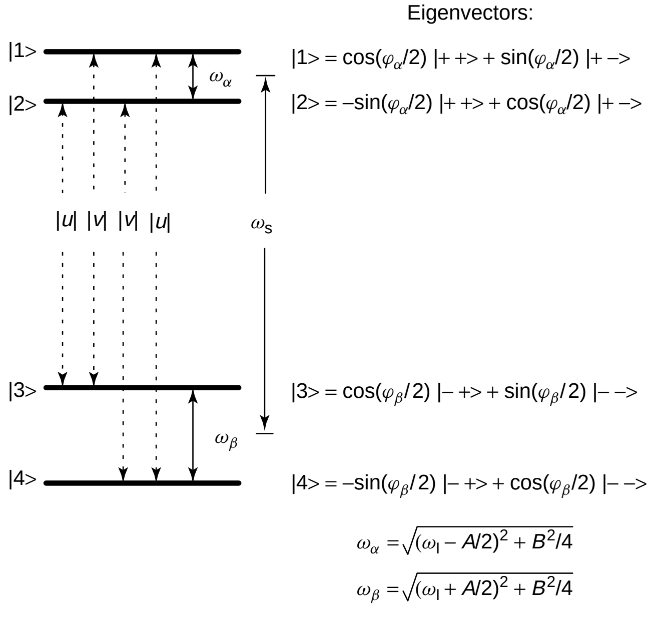

Figure 2 Energy level scheme and eigenvectors for the $S = 1/2$, $I = 1/2$ coupled spin system described in the text

Analytical expressions for the primary echo modulation function of an $S = 1/2$, $I = 1/2$ system were worked out for some of the earliest ESEEM studies that appeared in the literature. Perhaps the most general of these theoretical treatments is that of Mims[8] where the two-pulse ESEEM function is given by

$$E_{mod}(\tau) = |u|^4 + |v|^4 + |u|^2|v|^2[2\cos\omega_\alpha\tau + 2\cos\omega_\beta\tau - \cos(\omega_\alpha - \omega_\beta)\tau - \cos(\omega_\alpha + \omega_\beta)\tau] \quad (4)$$

Equation (4) shows that modulations of the two-pulse echo amplitude occur at the fundamental hyperfine frequencies and at their sum and difference combination frequencies. The amplitude of the modulations is given by the product of the transition probabilities for the two different transitions associated with ‘‘branching’’, $|u|^2|v|^2$, while the nonmodulated portion of the echo envelope depends only on the product of the transition probabilities for the ‘‘nonbranching’’ spins, $|u|^4$ or $|v|^4$. Substituting the expressions for $|u|$ and $|v|$ given by equations (2) and (3) into equation (4) yields

$$E_{mod}(\tau) = 1 - \left(\frac{k}{2}\right)[1 - \cos\omega_\alpha\tau - \cos\omega_\beta\tau + 0.5^*\cos(\omega_\alpha - \omega_\beta)\tau + 0.5^*\cos(\omega_\alpha + \omega_\beta)\tau] \quad (5)$$

where

$$k = \sin^2(\varphi_\alpha - \varphi_\beta) = \left[\frac{\omega_I B}{(\omega_\alpha\omega_\beta)}\right]^2 \quad (6)$$

is often referred to as the modulation depth parameter.

From the above discussion, it is clear that observation of ESEEM requires that the microwave pulses affect ‘‘branching’’ of the EPR transitions. This places a quantum mechanical constraint on the ESEEM experiment, in that each energy level must be involved in at least two different microwave transitions, and an experimental constraint that requires the microwave pulse bandwidth to cover the spread in frequencies needed to fully excite the ‘‘branching’’. The experimentally observed ESEEM function is a product of the quantum mechanically derived modulation function and a decay function that describes the loss of magnetization due to spin relaxation. These decay functions are typically modeled with exponential forms: $\exp(-\tau/\tau_o)^n$ where $n = 1, 2$ or 0.5.[16] For a $90° - \tau - 180°$ or two-pulse echo experiment, $\tau_o = T_2^*$, a time that is typically on the order of 1 µs, as evidenced by the data shown for the Cu(II) center in Figure 1. This

rapid ''background'' decay serves to reduce the frequency resolution of the two-pulse measurement. A further complexity of the ESEEM experiment is introduced when multiple nuclei contribute to the modulation of a single paramagnetic center. The modulation function in this instance is given by the product of the individual modulation functions, due to each coupled nucleus giving an overall ESEEM function of the form

$$E(\tau) = V_{\text{decay}} \prod_{i=1}^{N} E^{i}_{\text{mod}}(\tau) \tag{7}$$

where N represents the number of coupled nuclei.[3,8] Equation (7) shows that the two-pulse ESEEM data, or the corresponding ESEEM spectrum obtained from Fourier transformation of the time domain data,[17] can become complex when only a few nuclei contribute. Not only will each nucleus give rise to fundamental, $\Delta m_I = \pm 1$, frequencies and combination frequencies, but the product of equation (7) will lead to frequencies that are combinations of the frequencies arising from different nuclei. This increased complexity, when combined with the reduced resolution that results from a rapid phase memory time, can hamper two-pulse ESEEM analysis. These aspects of two-pulse ESEEM can be readily seen from the corresponding ESEEM spectrum shown in Figure 1(b) for the time domain data of Figure 1(a). It will be shown below that two histidyl imidazole side chains that have different hyperfine coupling strengths coordinate the Cu(II) under investigation. The broad peak centered at ~4 MHz shows the contribution of the remote nitrogen of both of these ligands and provides few details regarding their hyperfine coupling. The matrix ^{1}H peak, centered at 14.3 MHz, shows shoulders that originate from combination frequencies with ^{14}N. The peak at 28 MHz is due to the matrix proton sum combination frequency.

2.2 Three-pulse ESEEM

Some of the above problems are alleviated by use of the three-pulse or $90° - \tau - 90° - T - 90°$ sequence where the amplitude of the stimulated echo, occurring at τ after the third pulse, is normally monitored as a function of T (inset, Figure 3a). The background decay for this sequence is governed by electron spin-lattice relaxation, electron cross relaxation, and nuclear spin–spin relaxation processes. All of these processes are much longer than the electron spin–spin relaxation time and lead to better frequency resolution than typically found for the two-pulse experiment. Figure 3(a) shows three-pulse ESEEM data collected for the same sample and under the same conditions as used for the two-pulse ESEEM study of Figure 1. For a typical three-pulse measurement, τ is fixed to a value short with respect to the spin–spin relaxation time of the paramagnetic center, and the interval between the second and third microwave pulses is scanned from about 40 ns to ~10 µs. For the specific case of the type-1 Cu(II) site data shown in Figure 3(a), τ was set to 120 ns and T was stepped in 16 ns increments from 40 ns to >8 µs. The following analytical expression (equation 8) for the three-pulse modulation function of our model $S = 1/2$, $I = 1/2$ system

$$\begin{aligned} E_{\text{mod}}(\tau, T) = {} & |u|^4 + |v|^4 + |u|^2|v|^2 \\ & \times [\cos(\omega_\alpha \tau) + \cos \omega_\beta \tau + 2\sin^2(\omega_\alpha \tau/2)\cos\{\omega_\beta(\tau + T)\} \\ & + 2\sin^2(\omega_\beta \tau/2)\cos\{\omega_\alpha(\tau + T)\}] \end{aligned} \tag{8}$$

has a simplified form, when compared to its two-pulse counterpart, in that only modulations at the fundamental hyperfine frequencies are observed. Equation (8) also shows that the τ-value chosen for a particular measurement will affect the amplitudes of modulations and allow one to enhance or suppress the contribution from an electron spin manifold by adjusting τ over a range of values determined by the period of the complementary hyperfine frequency. This effect is known as the τ-suppression effect and can be useful in making spectral assignments.[8,18,19] The product rule governing the form of the overall modulation function, when multiple nuclei are coupled to the paramagnetic center, is also simplified when compared to that of the two-pulse experiment in that products are taken

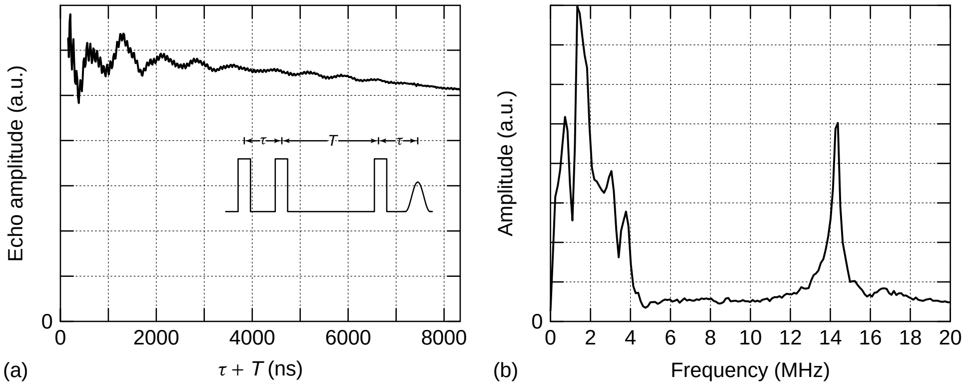

Figure 3 Three-pulse or stimulated echo ESEEM data (a) and associated FFT spectrum for the type-1 Cu(II) site of the Fet3p protein (b). Data were collected under the same conditions as those of Figure 1, except: τ-value, 120 ns; starting T, 40 ns; and time increment, 16 ns

only between frequencies belonging to the same electron spin manifold.[20]

$$E(\tau, T) = \left(\frac{V_{decay}}{2}\right)\left[\prod_{i=1}^{N} E_{\alpha}^{i}(\tau, T) + \prod_{j=1}^{N} E_{\beta}^{j}(\tau, T)\right] \quad (9)$$

The ESEEM spectrum for the three-pulse data of Figure 3(a) is shown in Figure 3(b). As in Figure 1, these data were collected in the $g_{\perp}$ region for the type-1 Cu(II) site of the Fet3p protein. The three-pulse ESEEM spectrum clearly shows resolved peaks at 0.75, 1.5, 3.0 and 3.8 MHz, in place of the broad ~4 MHz peak in the two-pulse spectrum (Figure 1b). These peaks are indicative of histidyl imidazole strongly bound to Cu(II) and are due to hyperfine coupling between Cu(II) and the remote ^{14}N of the ligand. The ^{1}H matrix peak also shows much higher resolution.

Figures 1 and 3 show that although the modulations of the three-pulse, or stimulated echo are less intense than those of its two-pulse counterpart, the resolution is much higher and the spectrum is simplified because combination peaks only enter into the data through the presence of multiple ESEEM-active nuclei. Equation (8) shows that for an $S = 1/2$, $I = 1/2$ spin system, judicious selection of the τ-value can control the ESEEM amplitudes of the hyperfine frequencies from α and β electron spin manifolds allowing them to be optimized or suppressed. For weakly coupled protons, where the modulation frequencies from both electron spin manifolds are centered at the proton Larmor frequency, τ can be set at an integer multiple of the proton Larmor frequency to suppress the contributions of this family of coupled nuclei from the three-pulse ESEEM spectrum. It is common for three-pulse ESEEM data to be collected at several τ-values, including integer multiples of the proton Larmor period, to accentuate the other low frequency modulations present in the data and to make sure that ESEEM components were not missed because of τ-suppression.

2.3 Two-dimensional ESEEM

In a paper that appeared in 1979, R.P.J. Merks and R. DeBeer pointed out that the sinusoidal dependence of the stimulated echo ESEEM experiment on τ and T (equation 8), presented the opportunity to collect ESEEM data in both time dimensions and then apply a two-dimensional FFT to derive two important benefits. The first benefit was that suppression-free spectra should be obtained along the zero-frequency axis for each dimension while the second benefit would be the appearance of cross-peaks at $(\omega_{\alpha}, \omega_{\beta})$ and $(\omega_{\beta}, \omega_{\alpha})$ that would allow one to identify peaks that belonged to the same hyperfine interaction. This ESEEM version of the NMR COSY experiment (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Metallobiomolecules***) would prove invaluable for ESEEM analysis of complex spin systems.[21] However, the disparity in spin relaxation times in the τ and T time dimensions precluded the general application of this method.

In 1986, P. Höfer, A. Grupp, H. Nebenführ and M. Mehring proposed another two-dimensional ESEEM experiment, Hyperfine Sublevel Correlation (HYSCORE) Spectroscopy, and demonstrated its ability to correlate hyperfine sublevels that belong to the same electron-nuclear coupling interaction. Four-pulse HYSCORE became the more popular of the two-dimensional experiments these authors initially proposed. They circumvented the relaxation time problem encountered for the three-pulse sequence by adding a 180° pulse to split the T dimension of the standard three-pulse experiment into two discrete time intervals, t_1 and t_2 (inset, Figure 4). In practice, data are collected with a fixed τ-value while $t1$ and $t2$ are systematically scanned from a minimum of 40–200 ns out to several microseconds. Because the electron spin-lattice relaxation time governs the decay of the four-pulse echo in both $t1$ and $t2$ domains, spectra with cross-peak intensities, $(\omega_{\alpha}, \omega_{\beta})$ and $(\omega_{\beta}, \omega_{\alpha})$, symmetric about the frequency diagonal ($|f_1| = |f_2|$) are realized. Because the data are collected at a fixed τ, HYSCORE spectra are not free from τ-suppression effects. The utility of HYSCORE spectroscopy can be readily seen by returning to our one-dimensional ESEEM data set of Figure 3. These are three-pulse data collected at $\tau = 120$ ns for the type-1 Cu(II) site of the Fet3p protein. X ray crystallographic studies of this site have shown that the Cu(II) ion is tricoordinate with two histidine and one cysteine residues supplying their side chains as ligands. Therefore, the four low frequency peaks shown in the ESEEM spectrum of Figure 3 originate from two histidyl ligands. The HYSCORE spectrum taken under identical conditions to those of Figure 3 is shown in Figure 4. These data are typical for weak ^{14}N hyperfine coupling in that the only appreciable

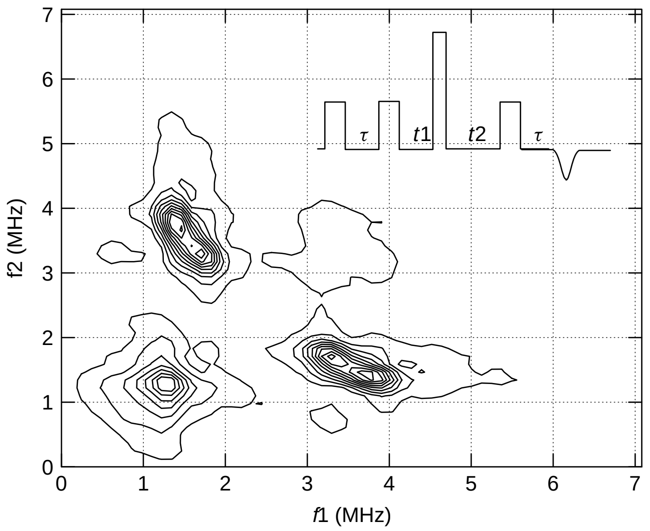

Figure 4 HYSCORE contour plot of the type-1 Cu(II) site of the Fet3p protein taken under identical conditions as the three-pulse data of Figure 3, except that: 90° pulses (pulses 1, 2 and 4), 32 ns FWHM and 90 W peak power; 180° pulse (pulse 3), 24 ns FWHM, 800 W; starting $t1$ and $t2$, 200 ns; and time increment, 32 ns

cross-peak intensity is found in the (+, +) quadrant of the two-dimensioanl-FFT spectrum (see the subsequent). For ^{14}N HYSCORE, the most intense cross-peaks are the correlations between the maximum hyperfine frequencies from the α and β electron spin manifolds (the ''double-quantum'' peaks). The HYSCORE result of Figure 4 shows two sets of cross-peaks at (1.7, 3.3 MHz) and (1.4, 3.8 MHz) that arise from two nonequivalent ^{14}N couplings. Such information is invaluable when trying to interpret ESEEM data like that shown in Figure 3. Specifically, the HYSCORE data show that the 1.5 MHz peak in Figure 3(b) is a composite of a peak at 1.4 MHz and a shoulder at 1.7 MHz and that the 1.7 and 3.3 MHz peaks are partners in one ligand hyperfine coupling while the 1.4 and 3.8 MHz peaks belong to the other. Once these peaks are sorted in this matter, analysis to determine the hyperfine couplings is more robust.

In addition to telling the spectroscopist that there are two inequivalent ^{14}N's, the HYSCORE spectrum also shows that the hyperfine coupling is weaker than that normally found for imidazole ligands strongly bound to Cu(II). This information comes from the cross-peak contours of Figure 4 and from the observation of negligible cross-peak intensity in the (−, +) quadrant of the two-dimensional FFT. Gemperle *et al.*[22] derived an expression for ESEEM obtained using the general four-pulse scheme of HYSCORE for an $S = 1/2$, $I = 1/2$ spin system. The amplitudes of the cross-peaks for this case are given by

$$S(t_1, t_2) = \left(\frac{1}{4}\right) kC[c^2 \cos(\omega_\beta t_2 + \omega_\alpha t_1 + \phi_+) + c^2 \cos(\omega_\alpha t_2 + \omega_\beta t_1 + \phi_+) + s^2 \cos(\omega_\beta t_2 - \omega_\alpha t_1 - \phi_-) + s^2 \cos(\omega_\alpha t_2 - \omega_\beta t_1 - \phi_-)]$$

where

$$\begin{aligned} C &= -2\sin(\omega_\alpha \tau/2)\sin(\omega_\beta \tau/2) \\ \phi_\pm &= (\omega_\alpha \pm \omega_\beta)\tau/2 \\ s^2 &= |\omega_I^2 - (\omega_\alpha + \omega_\beta)^2/4|/(\omega_\alpha\omega_\beta) \\ c^2 &= |\omega_I^2 - (\omega_\alpha - \omega_\beta)^2/4|/(\omega_\alpha\omega_\beta) \end{aligned} \tag{10}$$

and $k = 4c^2s^2$. This expression allows for a straightforward separation of the ESEEM contributions of strongly coupled nuclei from those that show weak electron-nuclear hyperfine coupling. Because the data are processed by taking a complex two-dimensional-FFT, the cross-peaks will separate into different frequency quadrants according to the sign of the dominant phase of $S(t_1, t_2)$. For weak hyperfine couplings $\omega_\alpha \cong \omega_\beta \cong \omega_I$, s^2 approaches zero, while c^2 goes to one. The cross-peaks for these couplings will then be sorted by the complex FFT into quadrants one and three where both frequency partners (ω_1, ω_2) are of the same sign. For strong electron-nuclear couplings, the situation is reversed, with cross-peaks being found in quadrants 2 and 4 where frequency partners are of opposite sign. For an axial hyperfine coupling without appreciable nuclear quadrupole interaction, if $A_\parallel > 2\omega_I$, cross-peaks will be found at $(-\omega_\alpha, \omega_\beta)$ and $(-\omega_\beta, \omega_\alpha)$ (quadrant 2). When $A_\parallel < 2\omega_I$, the cross-peaks are found at $(\omega_\alpha, \omega_\beta)$ and $(\omega_\beta, \omega_\alpha)$ (quadrant 1). This facet of HYSCORE has been used to isolate the ESEEM contributions of weakly coupled nitrogens from those of nitrogen atoms that showed stronger couplings characterized by ''deep'' or intense ESEEM in a bacterial photosynthetic reaction center[23] and in an iron–sulfur protein.[24]

One of the serious shortcomings of three-pulse ESEEM for frozen solution samples is its failure to detect broad hyperfine lines. For example, water molecules bound to a paramagnetic transition ion typically feature anisotropic hyperfine couplings of several MHz and can yield broad powder lineshapes about the proton Larmor frequency. ESEEM methods to work around this problem include ^{2}H substitution to reduce the anisotropy and the use of two- or four-pulse one-dimensioanl ESEEM methods that detect the $\omega_\alpha + \omega_\beta$, or sum combination modulation frequency. Both of these approaches provide data with compromised precision with respect to what would be realized if the broad, fundamental hyperfine frequencies could be resolved. Theoretically, these couplings should lead to appreciable ESEEM modulation amplitudes because of their large anisotropy, however, such modulations damp quickly because of destructive interference and they are lost in the dead-time of the typical pulse EPR experiment. HYSCORE offers a way to recover these broad lines through the detection of nuclear coherence transfer echoes. These echoes are created by the refocusing of spin packets that occurs when the 180° pulse, applied at t_1, causes a transfer of spins between the two m_s manifolds. This refocusing leads to a nuclear coherence-transfer echo at $t_2 = t_1$ and can easily be seen in a stacked plot of HYSCORE time domain data as a complex modulation pattern centered on the $t_1 = t_2$ diagonal.[25–27] These echoes result in HYSCORE cross-peak patterns in the two-dimensional; frequency spectrum that are narrow ridges of an extent given by the hyperfine anisotropy. These ridges are perpendicular to the frequency diagonal and centered roughly about the nuclear Larmor frequency if $A_\parallel$ or $A_\perp < 2\omega_I$ (quadrants 1 and 3) and parallel to the frequency diagonal if $A_\parallel$ or $A_\perp > 2\omega_I$ (quadrants 2 and 4). A cartoon that illustrates this feature is shown in Figure 5. For the weaker coupling case, Figure 5(a) (quadrant 1), two broad peaks representing a hyperfine interaction of axial symmetry are centered about the nuclear Larmor frequency and their idealized hyperfine spectrum is drawn along both frequency axes. The HYSCORE spectrum is then constructed by marking off the $(\omega_\alpha, \omega_\beta)$ correlations remembering the orientation-dependent correspondence between the two m_s manifolds across their powder lineshapes. Figure 5(b) (quadrant 4) is constructed in the same fashion for the strong coupling case where the powder lineshapes are centered at $A/2$ and separated by twice the Larmor frequency.

An example of the resolution of broad hyperfine lines in the four-pulse HYSCORE experiment is shown

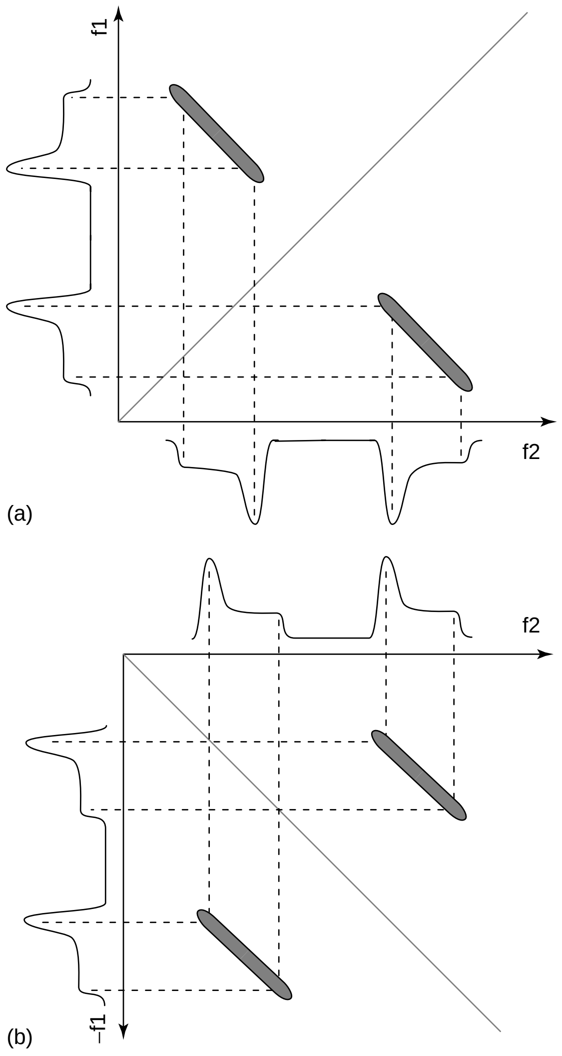

Figure 5 Diagram showing contours that arise from broad hyperfine lines detected by nuclear coherence transfer echoes under conditions of (a) weak and (b) strong hyperfine coupling

in Figure 6. Figure 6(a) shows the (+, +) quadrant of the four-pulse HYSCORE spectrum of $Cu(bipy)(H_2O)_4{}^{2+}$ collected at $g_\perp$ (inset) of the molecule's EPR spectrum. The spectrum shows an auto-correlation peak at the proton Larmor frequency and two correlation arcs or ridges ''perpendicular'' to the frequency diagonal. These ridges are indicative of an axial hyperfine coupling and can be analyzed for their dipole–dipole and isotropic hyperfine contributions, $|T|$ and $|A_{\rm iso}|$, respectively, using a graphical analysis developed by Dikanov and Bowman.[28] In this analysis, an arc is constructed down the long-axis of the contour and correlated frequency pairs (ν_α, ν_β) are read from points along the arc. One then constructs a plot of ν_α^2 versus ν_β^2 and extracts the slope, Q_α, and y-intercept, G_α, from a linear least squares fit to the points. This can easily be done with a graphing calculator or a spreadsheet program on a personal computer. $A_{\rm iso}$ and $|T|$ are then determined from knowing the Larmor frequency of the nucleus, ν_I, and the system of equations given below.

$$F_\alpha = [\pm 4\nu_I(Q_\alpha + 1)]/(Q_\alpha - 1)$$
$$|T| = (2/3)\{\pm[G_\alpha(F_\alpha \pm 4\nu_I)]/2\nu_I - 4\nu_I^2 + F_\alpha^2/4\}^{1/2}$$
$$A_{\rm iso} = (F_\alpha - T)/2. \quad (11)$$

In practice, the assignment of the labels α and β to the frequency pairs is arbitrary and one just has to pick a convention and stick to it. The signs for the first term in the square root argument for calculating $|T|$ are chosen to yield a real root. The result of using this system of equations is two unique pairs of values for $A_{\rm iso}$ and T. One set features $A_{\rm iso}$ and T parameters of the same sign, while for the other; $A_{\rm iso}$ and T have opposite signs. For the lower arc of Figure 6(a), the ν_α^2 versus ν_β^2 plot yielded $Q_\alpha = -0.789$ and $G_\alpha = 378$ MHz. Plugging these numbers into equation (11) gave $|T| = 5.1$ MHz and $A_{\rm iso} = \pm 0.8$ MHz, if T is of the same sign, or $A_{\rm iso} = \pm 5.9$ MHz if T is of opposite sign. Although this analysis ignores the orientation selection that must be taken into account for these data, and it restricts the hyperfine

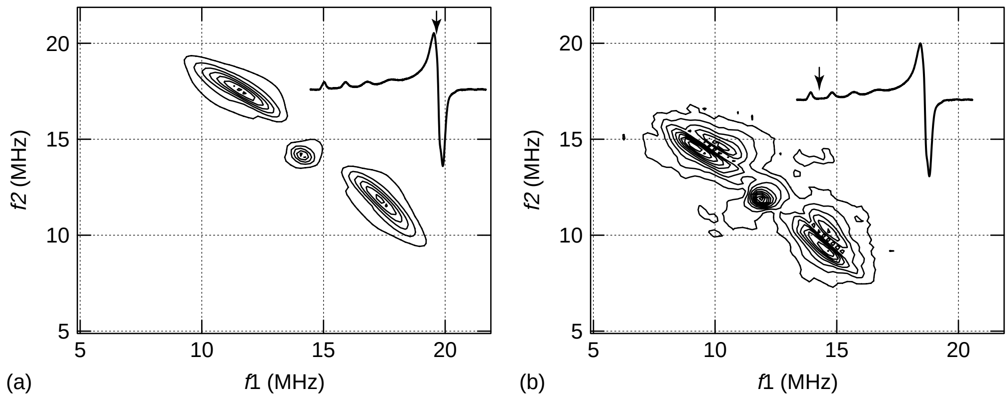

Figure 6 Four-pulse HYSCORE data collected for $Cu(II)(bipy)(H_2O)_4$ at (a) g-perpendicular and (b) g-parallel. Conditions for the measurements were: microwave frequency, 9.6864 GHz; field strength, (a) 332 mT, (b) 278 mT; 90° pulses (1, 2 and 4), 32 ns FWHM, 90 W; 180° pulse, 24 ns, 800 W; starting $t1$ and $t2$, 200 ns; time increment, 20 ns

tensor to axial symmetry, the $|T|$ value of 5.1 MHz is very close to the average $|T|$ value that can be computed from the results of single crystal ENDOR studies of equatorial water molecules bound to Cu(II) in the Tutton salts.[29] Figure 6(b) shows the four-pulse HYSCORE spectrum collected for the same sample at a magnetic field position corresponding to the lowest field $g_{||}$ feature of the Cu(II) EPR spectrum (inset, Figure 6b). Two sets of ^{1}H contours are observed in this spectrum, the top, or higher frequency contour is due to the equatorial water, while the lower contour, which is much more intense, is due to the axial water molecules of Cu(II)bipy$(H_2O)_4$. Graphical analysis of this lower ridge yields $|T| = 3.7$ MHz, which is exactly the same as the average value of T determined for the axial waters of Cu(II)$(H_2O)_6$ by single crystal ENDOR.

2.4 Practical Aspects of ESEEM Experiments

The material in this section is derived from the author's experiences with homebuilt and Bruker equipment over the past 20 years. In practice, every spectrometer system is different, and everyone approaches problems in a unique way. In reality, researchers develop their own approaches to problems once they have some experience.

2.4.1 Sample Requirements

ESEEM experiments require solid samples and most of the systems studied by ESEEM have been in frozen solution form. If at all possible, a good glassing solvent should be used to suspend the sample, but it is not important to eliminate cracks that occur upon freezing—it is not an optical experiment. For aqueous samples, 50% v/v ethylene glycol or glycerol will make an adequate glass. For organic systems, toluene is the king of glassing solvents. There is a convenient table of glassing mixtures in the textbook by R.S. Drago.[30] For X-band measurements, samples are most often placed in 4-mm quartz tubes. Volume requirements vary from 50–150 µL depending on the length of the sample probe's active region. For Bruker's flexline probes, a 1 cm sample length is sufficient to fill the resonators and this corresponds to about a 70 µL volume. Concentrations depend more on relaxation dynamics than anything else, so the user will have to rely more on experience here. For example, if one is studying a Mn(II) site in a protein, two- and three-pulse spin echoes can be detected at a sample temperature of 4.2 K with a signal-to-noise (S/N) ratio of 10 with sample concentrations of 10 µM. For Cu(II), the same S/N can require 100 µM concentration if the paramagnetic center features intense ESEEM (a good problem to have). Fe(III) centers, both low- and high-spin can be studied at 100 µM concentration, but the S/N will be <5 and the sample temperature has to be kept below 6 K. If sample concentration is not a problem, ESEEM experiments are not adversely affected by higher concentrations until one gets above 10 mM.

2.4.2 Sample Temperature

Because of spin relaxation, ESEEM studies are normally carried out in the 4–50 K temperature range. Most spectrometers use liquid helium flow cryostats that allow one to maintain temperatures of 5 K with cryogen consumption rates of 1–2 L/hr. As indicated above, some paramagnetic centers require temperatures <6 K for ESE detection at the 100 µM concentration levels that one often encounters. For Cu(II) samples, the electron T_1 is long enough that the best sensitivity is at 10 K where echo amplitudes are somewhat lower than they are at 5 K, but the repetition rate of the ESEEM experiment can be increased to $\sim$500 Hz and better S/N gained by signal averaging. There is no recipe for making these adjustments. Once an echo is detected during the tuning process, the spectroscopist needs to vary the repetition rate of the pulse sequences and the sample temperature to determine the conditions of optimal performance.

2.4.3 Continuous-wave Spectra

Every ESEEM experiment should begin with collection of a cw-EPR spectrum (*see* ***Electron Paramagnetic Resonance (EPR) Spectroscopy***) or an ESE-detected EPR spectrum of the sample to be studied. The Bruker flexline probes make this task straightforward as the probes can be critically coupled and are fitted with magnetic field modulation coils. Because the energy density in these probes is so high, one ends up using very low powers in cw-mode to avoid saturation and adiabatic rapid passage conditions where lineshape distortions occur. Also, for this reason, one ends up using field modulation frequencies of 1–10 kHz on a regular basis.

2.4.4 Tuning for ESEEM Studies

ESEEM studies require microwave pulse widths that are short in comparison with the period of the highest frequency modulation to be studied. 90° pulse widths of 16–20 ns are typical for X-band ESEEM studies where the period of the proton Larmor frequency is about 70 ns at $g = 2$. One typically adjusts the sample probe's microwave coupling to the maximum overcoupling position, sets up a two- or three-pulse ESE sequence, and optimizes the echo amplitude as observed on an oscilloscope or transient recorder display by adjusting the pulse power and reference arm phase. If sensitivity is low, the probe coupling can be adjusted some to increase the probe Q without giving up too much in terms of the instrument's dead-time.

2.4.5 ESEEM Data Acquisition

The discussion of the two-pulse ESEEM experiment given above might cause one to conclude that the measurement is of little use. There are a few reasons why these data should be collected as part of the overall routine of an ESEEM

study. Two-pulse ESEEM data show deeper modulations than those found in a three-pulse study and because one does not need to worry about suppression, the two-pulse spectrum can be an invaluable guide to the higher resolution, three-pulse and HYSCORE work to follow. The sum combination frequencies that are easily resolved in the two-pulse ESEEM experiment can show shifts that result from large hyperfine anisotropies and these can guide additional four-pulse ESEEM and HYSCORE studies.[15] Phase cycling is typically done with two-pulse measurements to help clean up the early portion of the ESEEM pattern when the echoes are close to the excitation pulses and to eliminate the DC offset from the system's amplifiers.

Three-pulse, or stimulated echo experiments are essential to an ESEEM investigation. Because of τ-suppression, several different scans should be made at each field position studied within the EPR absorption envelope. One should start with a short τ value, close to the measurement's dead-time (100 ns), and collect a few scans at proton Larmor period harmonics. For ^{14}N studies, this is usually a satisfactory amount of data to ensure that nothing is being missed because of the choice of τ. In a typical scan, the third pulse is scanned from a starting value of about 40 ns to a final value determined by where the modulations cease. Typical data sets are 512 points and care needs to be taken to ensure that the increment in T is short enough to avoid aliasing ($1/(2T_{\mathrm{increment}})$ is the highest frequency that can be accurately recorded). Phase cycling is critical to the stimulated echo experiment in that it eliminates discontinuities in the ESEEM that arise from overlap of two-pulse echoes with the three-pulse echo in addition to eliminating DC offsets from the system's amplifiers.

In general, HYSCORE measurements should be made at short τ values where all of the ESEEM frequencies are present in the data. Therefore, three-pulse data should be used to select appropriate τ's for HYSCORE studies. For recovering broad hyperfine lines with nuclear coherence transfer echoes, as in Figure 6, the τ value must be kept short. This is because the mechanism of the transfer relies in part on the spin packets for correlated α and β spins being collinear at the start of the t_1 period immediately following the second $\pi/2$ pulse. It is suggested that for use of the graphical analysis strategy of equation (11), HYSCORE spectra be collected for several τ values and combined to provide arcs of maximum extent without blind spots. This sounds nice, but for many samples, HYSCORE data sets take a few hours to collect, so it may not be practical. It is straightforward to include the τ dependence in a spectral simulation of the HYSCORE contours so this should never be a serious problem.

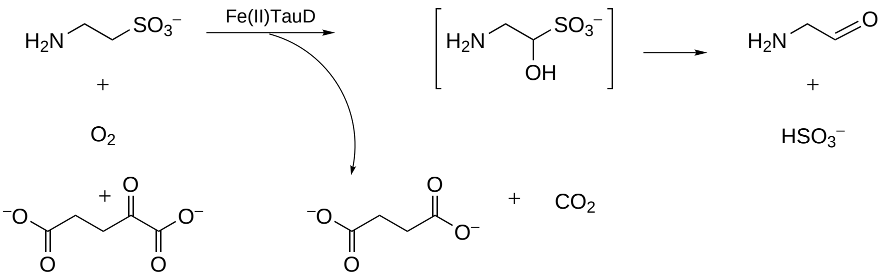
2.4.6 *Spectral Processing*

The analysis of ESEEM data usually involves simulation of the ESEEM spectrum from a spin Hamiltonian that models the nuclear transition frequencies. Therefore it is important that ESEEM spectra accurately report on the frequencies, amplitudes and damping factors observed in experiments. The method of choice for deriving ESEEM spectra involves removal of the ESEEM decay by subtraction of an exponential or polynomial function, tapering of the resulting modulation function with a windowing function, Fourier transformation and display of the absolute value, or square root of the resulting power spectrum. If simulations are done in the time domain, they can be processed using the same protocol to facilitate comparison with experiment.

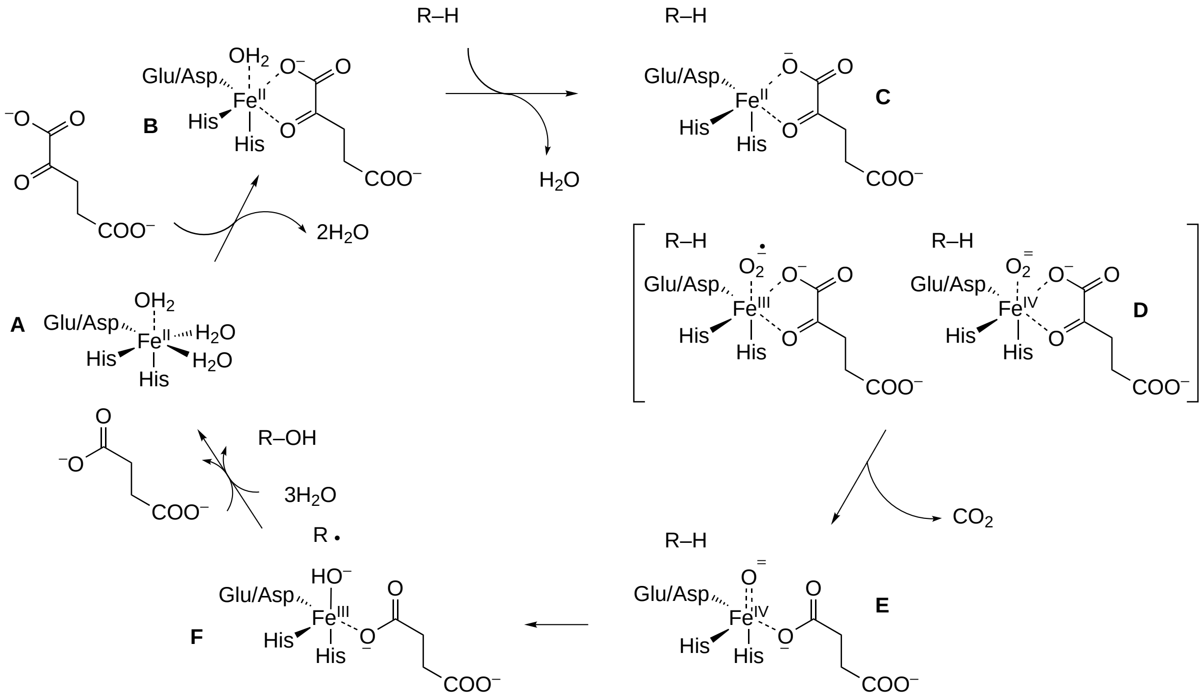
3 APPLICATION—ESEEM STUDIES OF Fe(II)/α-KETOGLUTARATE-DEPENDENT DIOXYGENASES

Perhaps the best way to illustrate the use of ESEEM in tackling problems in inorganic chemistry is to describe ongoing work in our laboratory on Fe(II)/α-ketoglutarate (αKG)-dependent dioxygenases. This work is collaborative with Professor R.P. Hausinger, whose lab has isolated and studied several members of this class of enzymes over the past 15 years. These enzymes use a common nonheme, mononuclear iron active site to catalyze key reactions in the biosynthesis or biodegradation of a wide range of compounds.[31] Well studied examples of this enzyme family include prolyl hydroxylases that function both in collagen biosynthesis[32] and intracellular signaling,[33,34] isopenicillin *N* synthase[35] and clavaminate synthase[36] that produce important antibiotics, TfdA that degrades the herbicide 2,4-dichlorophenoxyacetic acid,[37,38] and AlkB that repairs methylation damage to nucleic acids.[39,40] The Fe coordination for these proteins is thought to be octahedral in nature consisting of the side chains of two histidine residues, one carboxylate group supplied by an aspartate or glutamate residue and three water molecules. The three protein-based ligands are in a cis arrangement leaving an open coordination ''face'' occupied by three solvent molecules for the enzymes in their resting state. It has been proposed that this open coordination geometry is key to the diverse set of reactions catalyzed by this class of enzymes.[41]

The archetype Fe(II)/αKG hydroxylase is taurine/αKG dioxygenase (TauD), an *Escherichia coli* enzyme that catalyzes the conversion of taurine (2-aminoethanesulfonic acid) to sulfite and aminoacetaldehyde,[42] as illustrated in Scheme 1. TauD catalyzes the hydroxylation of a C−H bond on the carbon adjacent to the sulfonate group of taurine. The product of this reaction then decomposes to yield hydrogen sulfite, which serves as an important source of sulfur for many microorganisms.[43] A catalytic mechanism that has been proposed for these enzymes is provided as Scheme 2. Prior to the activation and hydroxylation of the C_1 carbon on taurine, αKG binds to the Fe(II) center as a chelate, displacing two of the coordinated waters. Taurine then binds to the enzyme in the vicinity of the Fe(II) center, displacing the remaining water.



Scheme 1 The hydroxylation of taurine leading to the formation of aminoacetaldehyde and bisulfite ion



Scheme 2 A general catalytic mechanism for the Fe(II)/α-ketoglutarate hydoxylases

The resulting five-coordinate Fe(II) then binds molecular oxygen and proceeds to carry out a two-electron reduction of coordinated αKG yielding, succinate, CO_2, and a high valent Fe(IV)-oxo species. It is this highly oxidized Fe center that abstracts hydrogen from taurine, initiating its hydroxylation. Because TauD is available in large amounts, highly soluble, and relatively stable, it has been the subject of numerous mechanistic studies.[44–53] In addition to these biochemical studies, this mechanism is supported by the X ray crystal structure for anaerobic taurine-αKG–Fe(II) TauD,[54,55] as shown in Figure 7. Insights gained from studies involving the oxidative chemistry of TauD are likely to apply to many other members of the Fe(II)/αKG dioxygenase family.

To convert the $S = 2$ Fe(II) active site into a species that can be studied robustly by ESEEM, we exploited the known ability of NO, a surrogate of molecular oxygen, to bind to nonheme iron sites and produce an electron spin $S = 3/2$ center.[56,57] We began our studies with the catalytically relevant NO-bound taurine-αKG–Fe(II) TauD species with the aim of using ^{2}H-ESEEM spectroscopy to measure the distance and orientation of specifically deuterated and perdeuterated taurines with respect to the magnetic axis of the Fe(II)NO center. When combined with the results of X ray crystallographic studies, these spectroscopic results provide a more detailed structure of the catalytic intermediate(s), **D**, in Scheme 2. Because catalysis involves the hydroxylation of a specific C–H bond on substrate taurine, spectroscopic studies that elucidate the structural relationship between Fe and substrate hydrogens provide important details for understanding enzyme mechanism. The crystal structure that provided the Fe(II)-site structure shown in Figure 7 was collected for an anaerobic sample where the Fe is five coordinate and the level of refinement is low. The resolution of the best structure is currently 2.8 Å, so the electron density

map for substrate taurine is not as well defined as Figure 7 leads one to believe!

3.1 Taurine Orientation

Continuous wave and pulsed-EPR data were collected on a Bruker E-680X spectrometer operating at X-band and equipped with a model ER4118-MD-X-5-W1 probe that employs a 5-mm dielectric resonator. The sample temperature was maintained at 4.2 K using an Oxford Instruments liquid helium flow system equipped with a CF-935 cryostat and an ITC-503 temperature controller. ESEEM data were collected using a three-pulse, stimulated echo sequence ($90° - \tau - 90° - T - 90°$) with 90° microwave pulse widths of 16 ns FWHM and peak powers of 250 W. A four-step phase cycling sequence, (+x, +x, +x), (−x, +x, +x), (+x, −x, +x), (−x, −x, +x), together with the appropriate addition and subtraction of the integrated spin-echo intensities served to actively remove the contributions of two-pulse echoes and baseline offsets from the data.[22] An integration window of 24 ns was used to acquire spin-echo amplitudes, and data set lengths were 512 points.

The ESE-detected EPR spectrum of the Fe(II)NO form of TauD treated with αKG and taurine shows axial symmetry with $g_\perp = 4.00$ and $g_\parallel = 2.00$ (insets, Figure 8a and 8c). This observation is typical for Fe(II)NO complexes and arises from the $m_s = \pm 1/2$ Kramer's doublet of the

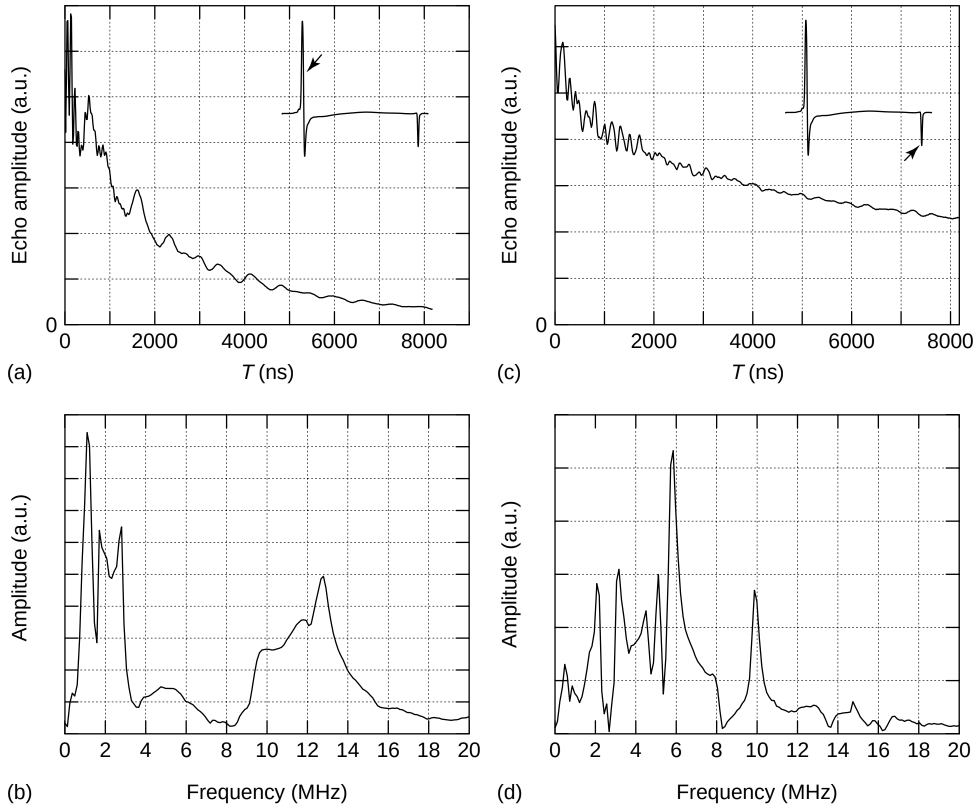

Figure 8 Three-pulse ESEEM data (a) and (c) and corresponding ESEEM spectra (b) and (d) for Fe(II)NO–TauD treated with αKG and taurine. ESEEM data were collected under the following conditions: microwave frequency, 9.723 GHz; magnetic field strength, (a) 171.0 mT and (c) 346 mT; $90° - \tau - 90° - T - 90°$ sequence with 16 ns pulses; τ value, 136 ns; T increment, 16 ns; repetition rate, 1 kHz; events averaged/time point, 100; scans, 4; and sample temperature, 4.2 K

$S = 3/2$ coupled spin system. The lineshape reflects an axially symmetric zero field splitting (ZFS) interaction with its principal axis directed along $g_{\|}$ and the Fe(II)NO bond.[56] Identical ESE-detected EPR spectra were obtained for Fe(II)NO–TauD treated with αKG and deuterated taurines.

Three-pulse ESEEM spectra were collected at 171.0, 172.8, 190.0, 290.0, 345.0 and 346.0 mT. ESEEM data and their corresponding spectra are shown for data collected at $g = 4$ in Figures 8(a) and 8(b), and at $g = 2$, Figures 8(c) and 8(d). These data are complex showing contributions from the histidyl ligands, bound NO and at least one set of strongly coupled protons. Two-dimensional ESEEM (HYSCORE) spectra and isotopic substitution studies were used to assign these peaks and will be presented below. To reveal the ESEEM contributions from substrate protons, Fe(II)NO–TauD samples treated with αKG and taurine deuterated at the C_1 carbon were compared to data collected under identical conditions using protonated taurine. The deuterium contribution to each ESEEM spectrum was elucidated by using the ratio method of Mims together with processing tools available in the Xepr data acquisition and processing software provided by Bruker. Specifically, three-pulse ESEEM data collected for enzyme samples prepared with ^{2}H- and ^{1}H-taurine were normalized by dividing each data set by its maximum amplitude. The normalized ^{2}H-ESEEM data were then divided by the corresponding, normalized ^{1}H-ESEEM data to obtain a resulting ESEEM pattern dominated by the ^{2}H contribution to the ESEEM. Short phase memory times precluded the use of τ values longer than 200 ns for three-pulse ESEEM, and the use of two-pulse ESEEM data, for the processing of ^{2}H data by using the ratio method.[58] The time domain data that resulted from this ratio process were tapered with a Hamming window and Fourier transformed.[25] ESEEM spectra were obtained by taking the absolute value of the transforms.

Figure 9(a) shows the time domain ESEEM contribution of the taurine deuterons at 171.0 mT obtained by dividing the normalized ESEEM data from the C_1 deuterated taurine sample by the normalized ESEEM data collected for enzyme treated with protonated taurine. The data of Figure 9 show pronounced modulations from deuteron hyperfine interactions that have an initial modulation depth of about 15% of the echo amplitude. For TauD samples, we found that the three-pulse data showed a background decay characterized by an e^{-1} time of about 2 μs. This led to substantial noise in the ratio data at longer times and often required that a first or second order polynomial fit be used to correct residual offsets and ''drifts'' of the baseline. The absolute value spectrum obtained after applying a Hamming window and cosine Fourier transform to the ESEEM ratio revealed ESEEM frequencies at 0.95 and 1.39 MHz that could be assigned to the C_1 deuterons of taurine (Figure 9b).

Figure 10 shows the ^{2}H-ESEEM spectra that result from repeating the measurement and processing procedure described for Figure 9 at 190.0 mT (Figure 10b), 290.0 mT (Figure 10c) and 346.0 mT (Figure 10d). Figure 10(a) shows that in the $g_{\perp}$ region, a pair of ESEEM frequencies at 0.95 and 1.39 MHz is observed. These coalesce to a single broad feature centered at 1.2 MHz at 190.0 mT (Figure 10b) and begin to split again at 290.0 mT (Figure 10c) where ^{2}H-ESEEM components at 1.8 and 2.0 MHz are resolved. At $g = 2.0$, 346.0 mT (Figure 10d), where one samples orientations of the enzyme with the laboratory magnetic field nearly parallel to the principal axis of the ZFS interaction, the ^{2}H-ESEEM shows two well-resolved peaks at 2.0 and 2.5 MHz. Further examination of Figure 10 reveals other frequencies in the ratio data. Specifically, a minor peak at 0.2 MHz is found in all of the spectra and we have attributed it to the baseline processing and windowing procedure used to process the data. The broad ESEEM peaks centered at 6.0 and 8.1 MHz for the spectra taken at 171 (Figure 10a) and 190 mT (Figure 10b), respectively, are likely due to protons and may reflect the proton difference portion of our study. The narrow peak at

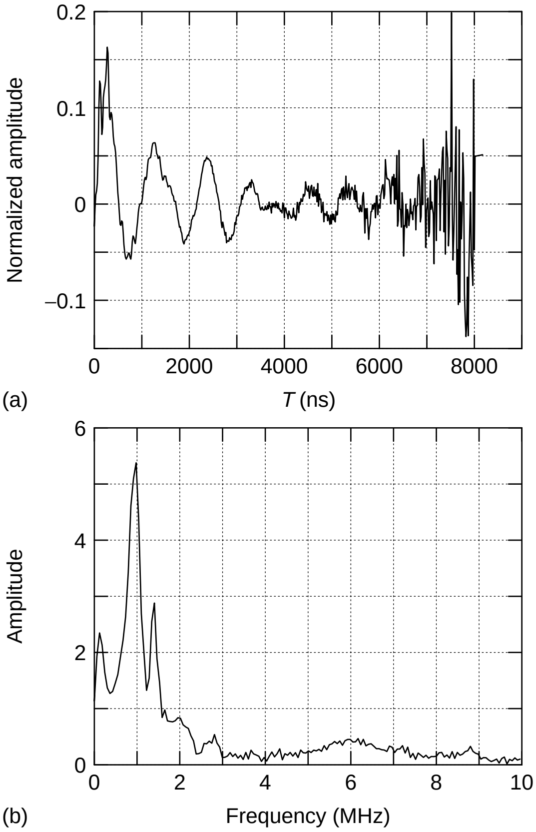

Figure 9 Time domain ESEEM ratio (a) and Fourier transform (b) generated by dividing time domain ESEEM data obtained for Fe(II)NO–TauD treated with αKG and C_1–^{2}H-taurine with data obtained under identical conditions for Fe(II)NO–TauD treated with αKG and taurine. Data sets were normalized to their maximum amplitudes prior to division. A second-degree polynomial was used to remove residual background decay. ESEEM data were collected under conditions identical to those of Figure 8(a)

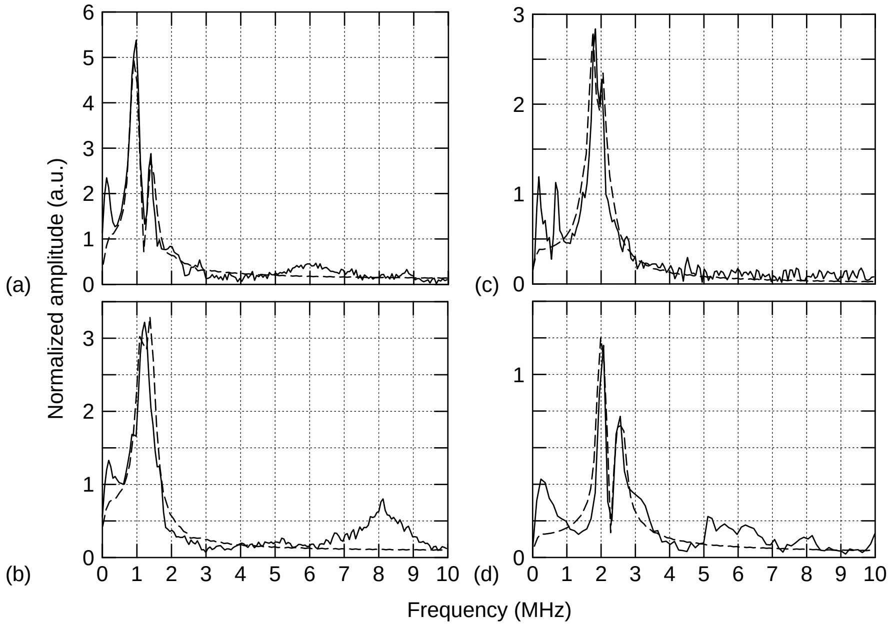

Figure 10 The magnetic field dependence of ^{2}H-ESEEM spectra (solid lines) obtained for Fe(II)NO–TauD samples treated with αKG and C_1–^{2}H-taurine using the ratio method described for Figure 9. The field positions displayed are: (a) 171.0 mT; (b) 190.0 mT; (c) 290.0 mT; and (d) 346.0 mT. Simulations of these ^{2}H-ESEEM spectra (dashed lines) are plotted along with the data. Hamiltonian parameters used for the simulations were: principal g-values, 4.0, 4.0, 2.0; principal deuterium hyperfine values, −0.25, −0.25, 0.50 MHz; Euler angles for hyperfine tensor, 0, 17°, 0; e^2qQ, 0.20 MHz; η, 0; and Euler angles relating nqi to hyperfine, 0, 23°, 0

0.7 MHz resolved in the 290 mT ratio (Figure 10c) and the broad features that range from 5–7 MHz for the 346 mT data (Figure 10d) are likely due to ^{14}N-ESEEM that is not fully compensated by the data division procedure. Approximations that stem from the data division procedure used to obtain the data presented in Figures 9–11 have been discussed in detail elsewhere.[59]

Figure 11 shows ^{2}H-ESEEM data for Fe(II)NO–TauD treated with αKG and taurine deuterated at both C_1 and C_2 positions. Figure 11(a) shows data collected in the $g_\perp$ region at 172.8 mT where three ^{2}H-ESEEM components at 0.9, 1.1 and 1.3 MHz are now resolved. A comparison of these data to data collected at 171.0 mT for the C_1 deuterated taurine sample showed that addition of two deuterons at the C_2 carbon served to add a new ESEEM feature at 1.1 MHz, the Larmor frequency of deuterium at this magnetic field strength. The ^{2}H-ESEEM spectra of Figures 11(b) and 11(c) are dominated by a single, broad peak centered at the deuterium Larmor frequency of 1.2 MHz (190 mT, Figure 11b) and 1.9 MHz (290 mT, Figure 11c), respectively. A comparison of the data of Figure 11(b) and 10(b) shows that the amplitude of the peak at 1.2 MHz increases for the perdeuterated taurine sample, indicating that addition of deuterons to the C_2 position of the substrate also serves to add an additional feature at the deuterium Larmor frequency. Similar conclusions can be made from comparing the ^{2}H-ESEEM data of Figures 11(c) and 11(d) with those of 10(c) and 10(d). For both cases, addition of the C_2 deuterons to taurine yields extra ESEEM intensity at the deuterium Larmor frequencies of 1.9 MHz (290 mT) and 2.25 MHz (346 mT).

Analysis of these ^{2}H-ESEEM data to determine the hyperfine parameters and the number of contributing nuclei requires spectral simulation. ESEEM simulations of the $I = 1$ deuterium ligand hyperfine couplings were accomplished by using software written in FORTRAN (Absoft). Calculations used the density matrix formalism of Mims to simulate the time domain ESEEM data.[8,18] MATLAB scripts were then used to assemble the simulations according to the product rule, equation (9), and to complete the Fourier analysis to obtain simulated ESEEM spectra. The processing and Fourier transformation procedures were identical to that outlined above for the Bruker software. Because the ESEEM experiment is done at a fixed magnetic field strength, each field position studied reports on a unique set of molecular orientations that fall on a contour of constant electron g-value with respect to the laboratory axis system. This orientation selection was accounted for using the method described by Hoffman and coworkers where the line integral about constant effective g-value is converted to a definite integral over ϕ, with the integrating factors being determined numerically.[60] A parabolic searching algorithm was used to compute orientations of the Fe(II)NO center that were resonant at a given field position.[61]

The spin Hamiltonian used to model the deuterium ligand hyperfine interaction consisted of nuclear Zeeman, electron-nuclear hyperfine and nuclear quadrupole terms.

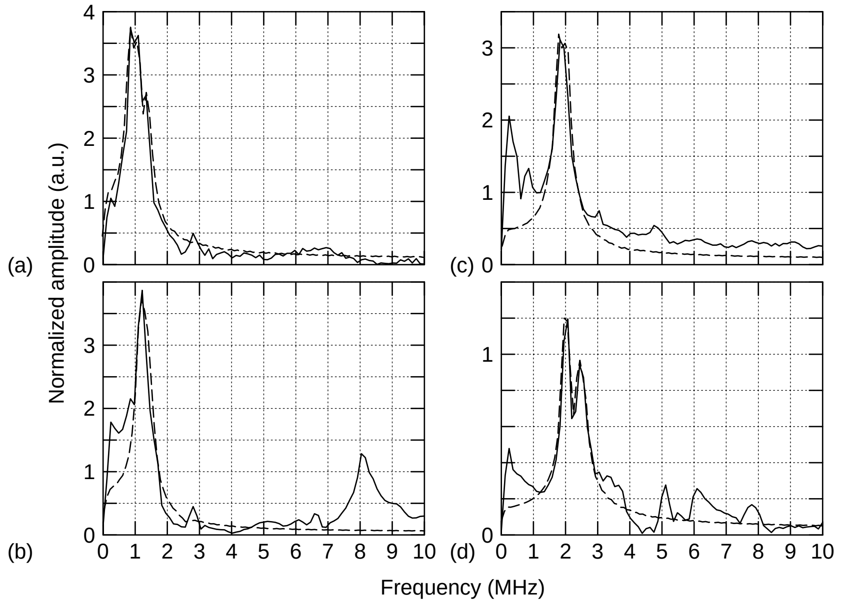

Figure 11 The magnetic field dependence of ^{2}H-ESEEM spectra obtained for Fe(II)NO–TauD samples treated with αKG and taurine deuterated at both C_1 and C_2. Data were obtained using the ratio method described for Figure 9. The field positions displayed are: (a) 172.8 mT; (b) 190.0 mT; (c) 290.0 mT; and (d) 345.0 mT. Simulated ^{2}H-ESEEM spectra (dashed lines) for the C_1,C_2-deuterated taurine are plotted along with the data. For the stronger coupled C_1 deuteron, Hamiltonian parameters identical to those of Figure 10 were used. Hamiltonian parameters used for a second deuteron on C_2 were: principal deuterium hyperfine values, −0.13, −0.13, 0.26 MHz; Euler angles for hyperfine tensor, 0, 63°, 0; e^2qQ, 0.20 MHz; η, 0; and Euler angles relating nqi to hyperfine, 0, 23°, 0

Because the microwave pulses used in ESEEM experiments have a finite bandwidth, ESEEM patterns were calculated over a 4 mT width of magnetic field strengths centered about the experimental field value with each discrete ESEEM pattern weighted according to a Gaussian distribution (e^{-1} width of 2 mT). Deuterium hyperfine and nuclear quadrupole tensors were transformed into the g-tensor axis system at the start of the calculation and the resonance conditions, magnetic field setting and microwave frequency, were used to compute orientations of the magnetic axis that contributed to the ESEEM.

For simulation of the ^{2}H-ESEEM data of Figure 10, we sought to determine a set of spin Hamiltonian parameters that would reproduce the frequencies, relative amplitudes and the initial modulation depths of the data. Furthermore, a single set of Hamiltonian parameters should be able to account for the data obtained at each field position studied. For our calculations, the nuclear quadrupole coupling constant, e^2qQ, was fixed at 0.2 MHz and the asymmetry parameter, η, was set to zero based on literature values from nuclear quadrupole resonance studies (*see* ***Nuclear Quadrupole Resonance (NQR) Spectroscopy***).[62] Because the deuterium hyperfine interaction is expected to be a through-space interaction (substrate taurine is not bound to the Fe(II)NO center), the isotropic hyperfine coupling was set to zero and the hyperfine tensor was fixed to axial symmetry. In practice, these hyperfine couplings must be scaled to their effective values using the ratio of the appropriate effective g-value that describes the EPR signal within the $m_s = \pm 1/2$ doublet of this $S = 3/2$ spin system with the free electron g-value, 2.00.[63,64] Examination of the C_1 ^{2}H-ESEEM data (Figure 10—solid lines) shows that a pair of frequencies separated by 0.4 and 0.5 MHz is resolved at both $g_\perp$ and $g_\parallel$, respectively. Because the effective g-value doubles as you go from $g_\parallel$ to $g_\perp$, the experimental results lead one immediately to the conclusion that the deuteron giving rise to the ESEEM is oriented close to $g_\parallel$ or the principal axis of the ZFS tensor.

Computer simulations of the C_1 ^{2}H-ESEEM spectra are shown with dashed lines in Figure 10 for the four field positions studied. Except for the details of the lineshape resolved at 190 mT, these simulations faithfully reproduce the observed ESEEM frequencies, relative amplitudes and modulation intensities, or depths. Because of the axial symmetry of g-, hyperfine- and nuclear-quadrupole tensors, the simulations were only sensitive to the ''y rotation'' of the Euler angle rotation schemes that were used to relate the deuterium hyperfine tensor to the g-tensor and the nuclear quadrupole tensor to the hyperfine tensor.[65] The deuterium peak frequency separations at 171 mT (Figure 10a) and 346 mT (Figure 10d) were best simulated by an electron-nuclear dipolar interaction of 0.30 ± 0.05 MHz, and a colatitude with respect to the $g_\parallel$ axis of $20 \pm 3°$. The angle describing the relative orientation of the deuterium hyperfine and nuclear quadrupole principal axis was $23 \pm 3°$. This range of hyperfine couplings corresponds to a range of dipole–dipole distances (based on our reference g-value of 2.00) of

3.4 ± 0.2 Å. The modulation depths were accounted for by considering that only one of the C_1 deuterons contributed to the observed ^{2}H-ESEEM.

Computer simulations of the ^{2}H-ESEEM spectra obtained for the samples with both taurine carbons deuterated are shown as dashed lines in Figure 11. The addition of deuterons to the C_2 carbon serves to add a feature centered at the Larmor frequency of deuterium to the ESEEM data obtained at the four magnetic field positions displayed in Figure 11. At $g_\perp$, 172.8 mT (Figure 4a), this feature is clearly resolved while at the other three field strengths, the addition of this ''matrix'' ESEEM component manifests itself in an apparent decrease in spectral resolution. The requirement that ^{2}H-ESEEM be resolved at the Larmor frequency across the entire Fe(II)NO EPR spectrum placed an upper limit on the value of the axial hyperfine coupling strength while the amplitude of this spectral feature at each field position placed restrictions on both the deuterium hyperfine coupling strength and a colatitude angle that describes the relative orientations of $g_\parallel$ and the hyperfine principal axis. For the simulations of Figure 11, a dipolar hyperfine coupling strength of 0.13 MHz and angle of 63° between $g_\parallel$ and the hyperfine principal axis were used. Application of the dipole–dipole model to the 0.13 MHz hyperfine field yields a distance of 4.5 Å for this weaker interaction. The simulations of Figure 11 yield initial modulation depths of 14, 19, 11 and 5% for spectra (dashed lines) Figure 11(a) to 11(d), respectively. These agree well with experimental values for the data of Figure 11 (solid lines) which were 17, 20, 12 and 6%, respectively. These simulations were not sensitive to the nuclear quadrupole coupling parameters of the weaker coupled deuteron, so the value of the angle between the hyperfine and quadrupole principal axis was fixed at the value obtained for analysis of the stronger coupling.

Only one C_2 deuteron was considered in the calculations discussed above and summarized in Figure 11. Because the addition of two deuterons to the C_2 carbon only resulted in the addition of a single spectral feature to the data, it is possible that both C_2 deuterons contribute to the ESEEM. The X ray crystallographic data (Figure 7) indicates that both deuterons on the C_2 carbon would be directed away from the open coordination site on the Fe where NO is likely bound. Computer simulations of the ESEEM arising from both C_2 deuterons yielded an average dipolar coupling strength of 0.09 ± 0.005 MHz and an angle between $g_\parallel$ and the hyperfine tensor principal axis of 63 ± 5°. These are ''average'' values as only one set of hyperfine parameters were used together with the spherical model approximation to the product rule to obtain simulations comparable to those of Figure 11.[19] The anisotropic hyperfine coupling range determined above translates to a dipole–dipole distance of 5.1 ± 0.2 Å if a reference g-value of 2.00 is used.

A detailed description of the electronic structure of the Fe(II)NO model complexes and other nonheme iron dioxygenases has shown that the paramagnetic center giving rise to the EPR spectrum (inset, Figure 8) is best described as a high-spin Fe(III) $S = 5/2$ ion antiferromagnetically coupled to an $S = 1$, NO^- ligand.[56] Furthermore, Brown *et al.* point out that the lack of ligand hyperfine coupling and the anisotropy observed in the ^{57}Fe hyperfine coupling of Fe(II)NO model complexes and the extradiol dioxygenases[66] show that the paramagnetism of this center is best described by a model where the two unpaired electrons on the NO^- ligand are spin paired with unpaired spins in the Fe d_{xz} and d_{yz} orbitals leaving the remaining three, unpaired 3d electrons to account for the $S = 3/2$ spin state. As noted above, the large ZFS interaction observed for these complexes gives rise to an EPR spectrum due to the $m_s = \pm 1/2$ Kramer's doublet. If the electron spin Hamiltonian is taken to consist of an axial ZFS term and an isotropic electronic Zeeman term with $g = 2.00$, it can be shown that the resulting EPR spectrum will range from $g = 2.00$, when the laboratory magnetic field is directed along the principal axis of the ZFS interaction, to $g = 4.00$ when the field is directed perpendicular to the principal axis of the ZFS tensor.[56]

This quantum mechanical model for the Fe–NO EPR spectrum was used by Yang *et al.* to interpret ligand hyperfine couplings resolved in ^{2}H-electron nuclear double resonance (ENDOR) experiments for substrate naphthalene bound to Fe(II)NO–naphthalene 1,2-dioxygenase (NDO). These authors used a point dipole–dipole model to extract Fe–^{2}H distances from the ^{2}H hyperfine coupling anisotropy and used tensor axis orientations to define the location of these coupled deuterons with respect to the Fe–N(O) bond axis.[63] Using an identical picture for the paramagnetic center, the dipole–dipole distances determined from analysis of our ESEEM spectra can be summarized as in Figure 12. Specifically, ESEEM results for taurine deuterated at the C_1 position are best described by a single deuteron that is 3.4 ± 0.2 Å from the iron atom and lies on a cone that makes a 20 ± 3° angle with the unique axis of the ZFS interaction,

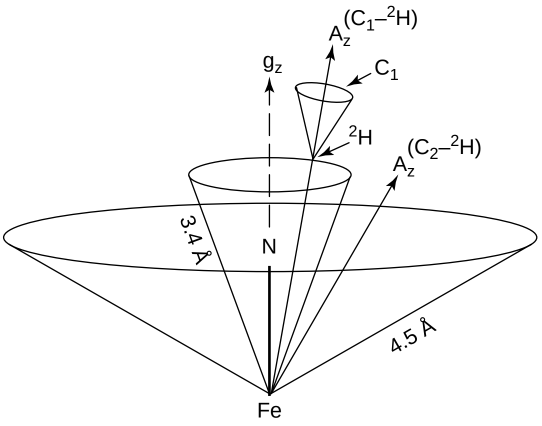

Figure 12 Schematic drawing of the geometrical relationship between the coupled deuterons at the C_1 and C_2 positions of taurine and the $g_\parallel$ (g_z) axis, coincident with the Fe–N(O) bond

or the Fe(III)−NO^- bond axis. For perdeuterated taurine, an additional deuterium ESEEM interaction could be accounted for by including a second deuteron, positioned 4.5 ± 0.2 Å from the iron on a cone that makes a $63 \pm 5°$ angle with the Fe−N(O) bond axis, in our simulations. Alternatively, both C_2 deuterons could be responsible for this weaker interaction showing an average distance of 5.1 Å from the Fe and also positioned on a cone making a 63° angle with the Fe−N(O) bond axis.

These results are similar to those reported from ^{2}H-ENDOR studies on the Fe(II)NO adduct of NDO where the C_1 and C_2 deuterons of substrate naphthalene were found at distances of 4.3 and 5.0 Å from the Fe atom, respectively. The principal axis of the hyperfine tensor for the C_1 deuteron of substrate naphthalene made a 10° angle with the Fe−NO bond axis. For NDO, X ray crystallographic analysis of reduced forms of the protein prepared with naphthalene and oxygen show distances from iron to the C_1 and C_2 naphthalene carbons of about 4 Å. This would place the naphthalene deuterons bound to these carbons at distances of 3–4 Å from the iron, somewhat shorter than what was found in the ENDOR studies, but in good agreement with the distance reported here for the proximal C_1 deuteron of substrate taurine.[67] If one takes the Fe−N bond length for the NO ligand as 1.8 Å, commensurate with X ray absorption fine structure spectroscopic results (*see* ***X-Ray Absorption Spectroscopy***) on FeEDTA-NO,[56] the proximal C_1 deuteron of taurine will be positioned 1.8 Å from the nitrogen of bound NO. The angle defining the orientation of the Fe−N(O) bond with the coupled C_1 deuteron of taurine, $20 \pm 3°$, is somewhat wider than that measured for the C_1 naphthalene deuteron of reduced NDO by ENDOR (10°) or estimated from X ray crystallography on that enzyme (∼13°).[63] These differences in substrate deuteron (proton) distances and orientations are modest given the different catalytic functions and cosubstrate requirements of TauD and NDO. In both cases, the measured deuterium hyperfine couplings provide metrical information that is commensurate with the substrate C−H bond(s) to be hydroxylated.

In our analysis of the ^{2}H-ESEEM data obtained from Fe(II)NO−TauD samples treated with taurine deuterated at C_1, we considered only the contributions of the proximal deuteron (Figure 10). The nuclear quadrupole interaction (nqi) for the stronger coupled deuteron is axial, with the principal axis of the nqi tensor directed along the C_1−^{2}H bond. In our simulations, we found that the principal axis of the nqi made a $23 \pm 3°$ angle with the principal axis of the deuterium hyperfine tensor. Taking the C_1−^{2}H bond length to be 1 Å, a third cone can be placed on Figure 12 at the position of the proximal C_1 deuteron to mark the locus of positions for the C_1 carbon of taurine. Taking the bonding about C_1 to be sp^3 hybridized, the ^{2}H−C−^{2}H bond angle to be 109°, the distal C_1 deuteron will lie at a distance of about 5 Å from the iron. The resulting dipolar hyperfine coupling for this deuteron will give rise to weak ESEEM as the modulation intensities are inversely proportional to the dipole–dipole distance raised to the sixth power.[19] The contributions of the distal deuteron to the ESEEM spectra of Figures 9 and 10 would be centered at the deuterium Larmor frequency. The best chance for seeing this contribution would be at $g = 2$ for the C_1-deuterated taurine sample (Figure 10d) where there is a fairly clean window in the ESEEM spectrum. Simulations of the ^{2}H-ESEEM for these conditions that consider a dipole–dipole distance of 5.0 Å and an angle of 11° between the Fe−N(O) bond axis and the principal axis of the ^{2}H hyperfine tensor, predict a modulation depth or intensity of 0.5%. Because the modulations due to the stronger coupled deuteron, characterized by a 3.4 Å dipole–dipole distance, are about 6% at $g = 2$, we conclude that the ESEEM from distal C_1 deuteron is too weak to resolve in our experiments. This decreased modulation depth for the distal C_1 deuteron stems from its increased dipolar distance and its orientation close to the Fe−N(O) or $g_{\|}$ axis where integrating factors in the orientation averaging are small.

Taken together, the relative contributions of the two C_1 deuterons to the ESEEM and the intermediate contribution of one, or both of the C_2 deuterons provide important details on how substrate taurine is positioned for specific hydroxylation of the C_1 carbon and the subsequent harvesting of sulfite. Considering NO to be a reasonable surrogate for ${O_2}^{2-}$ or $O_2^{-}\bullet$ in Scheme 2 (species D), our ESEEM measurements show that one of the C_1 deuterons is positioned 3.4 Å from the Fe at an angle with respect to the Fe−N(O) axis that would result in the distance to the NO nitrogen atom of 1.8 Å. Because the other C_1 deuteron does not contribute to the ESEEM, the C_1 carbon must be oriented so that this second deuteron is directed away from the NO nitrogen and close to the $g_{\|}$ axis. The larger angle and distance needed to describe the location of the C_2 deuteron(s) likely shows that substrate taurine has been oriented to position the C_2−H bonds so they are not able to react with the Fe(IV)-oxo species thought to trigger the C−H bond hydroxylation chemistry (Scheme 2, species E).

To compare our ESEEM results with the X ray structure,[55] the most recent TauD structure was downloaded from the PDB and the program Refmac was used to model protons onto the carbon framework of substrate taurine. Because the X ray results are from crystals grown anaerobically, the NO ligand was modeled into the crystal structure by using bond lengths and angles from model compound studies[56] and by placing the Fe−N(O) bond 180° from the ''axial'' Fe−N (histidine) bond. The results show that the proximal C_1 proton is 3.0 Å from the Fe atom and makes a 32° angle with the Fe−N(O) bond while the closest C_2 proton is 4.4 Å from the Fe and makes an angle of 52° with the Fe−N(O) bond. Given that there could easily be a 10° error in the orientation of the Fe−N(O) bond axis, one can justify moving the Fe−N(O) bond to match the corresponding angles from our ESEEM measurements (Figure 12). In addition, the low resolution of this structure and more specifically, the taurine electron density map, readily allows for modest reorientation of the taurine carbon framework. Figure 13 shows the results of these modest adjustments of the crystal structure and provides

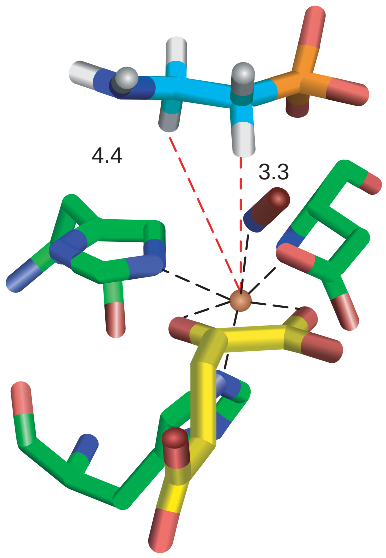

Figure 13 Structure of TauD active site as taken from monomer A of the four molecules per unit cell in PDB file LOS7. The taurine protons and NO ligand were modeled into the structure using the program, Refmac. The carbon framework of taurine was rotated slightly from the structure supplied to the PDB (Figure 7) to achieve Fe-proton distances of 3.3 Å for the C_1 proximal proton and 4.4 Å for the closest C_2 proton

a structure that is in excellent agreement with our ESEEM results.

3.2 ESEEM Assignments and TauD Coordination Chemistry

The ESEEM spectra of Figure 8 show complex sets of peaks for the ternary complex of Fe(II)NO–TauD with contributions from ^{14}N and ^{1}H. In the analysis of substrate orientation, we ignored this complexity by dividing it out of the data sets and focusing our analysis on the ESEEM from substrate deuterons. Certainly, the analysis of the spectra of Figure 8 hold important details concerning the electronic structure of the Fe(II)NO paramagnetic center. One of the most intriguing features of TauD is the opportunity that the crystal structure provides for understanding our ESEEM data in detail. The benefit of such an analysis is that details on outer coordination sphere interactions that are important for catalysis may be gained. Such details are what distinguish each member of this enzyme class. At $g = 4.00$, the ESEEM spectrum from the Fe(II)NO–TauD complex with cosubstrates αKG and taurine shows three sharp lines at 1.1, 1.8 and 2.7 MHz along with a broad line centered at 5.1 MHz and a broad line that covers a frequency spread from 9.8 to 12.7 MHz (Figure 8b). Because the Larmor frequency of ^{1}H at 171.0 mT is 7.3 MHz, and these data were collected at a τ value for which matrix protons are suppressed, it was clear from the beginning that ^{14}N and ^{1}H spectra were overlapped. The four-pulse HYSCORE spectrum that matches the experimental conditions for Figure 8(b) is shown in Figure 14(a). The data show pronounced correlation arc's that extend from 2 to 13 MHz defining at least one strongly coupled ^{1}H. These arcs likely arise from a ^{1}H that is oriented ~90° from the Fe(II)–N(O) axis because at $g_{\perp}$ one samples the full extent of the hyperfine tensor for such an orientation. The HYSCORE spectrum also shows two low frequency correlations, (1.0, 1.8 MHz) and (1.6, 2.5 MHz), that are most likely due to ^{14}N of one of the histidine ligands or a perpendicular component of the ^{14}N coupling due to the bound NO group.

At the other extreme of the Fe(II)NO EPR spectrum, $g = 2.00$, the three-pulse ESEEM spectrum of Figure 8(d) shows even more peaks. The HYSCORE spectrum is shown in Figure 14(b) where peaks in the $(-,+)$ quadrant that arise from strong hyperfine coupling are now observed. The strongest correlations are between peaks at (−5.9, 10.0 MHz) and (2.1, 3.1 MHz). Figure 14(b) also shows substantial correlations at (−4.8, 6.0), (−3.3, 5.2) and (−3.5, 4.4). A very weak proton correlation at (13.2, 16.4) is also observed. The strong ^{14}N hyperfine is likely from the axially bound histidine ligand or from NO. We are currently using isotopic substitution and model compound work to proceed with assignments. The disappearance of the proton arcs that were so clearly resolved at $g = 4$ supports the notion that the coupling is from an equatorial coordination position. The τ value used to collect both data sets of Figure 14 was near a matrix proton suppression value and that weakens the contributions of weakly coupled protons to the HYSCORE as well as to the one-dimensional ESEEM.

Proton arcs like that resolved in the HYSCORE spectrum of Figure 14(a) are common for water ligands bound to metal centers (see Figure 6). With that in mind, Fe(II)NO–TauD samples with αKG and taurine were studied for protein exchanged against D_2O. Figure 15 shows the HYSCORE data obtained under the same conditions as Figure 14(a) for such a sample and we conclude from this result that the ^{1}H giving rise to this strong ''equatorial'' hyperfine coupling is not exchangeable. Furthermore, this contribution is also detected for enzyme prepared with perdeuterated taurine and with an αKG surrogate, N-oxalylglycine. Analysis of the arc extent and curvature using the graphical procedure involving equation (11) in the *Technical Background* section yielded a dipolar coupling, $|T| = 5.0$ MHz, which translates to a dipole–dipole distance of 3.2 Å at $g = 4.00$. The isotropic coupling derived from this analysis was 1.1 MHz if A_{iso} and T have the same sign and 6.1 MHz if the signs are opposite. In searching the crystal structure for the possible source of this coupling, we found that the side chain of tryptophan 248 is the most likely candidate in terms of distance and orientation. The Hausinger lab at Michigan State has prepared a variant of TauD with this tryptophan residue mutated to phenylalanine and we are currently following up on this lead with further HYSCORE experiments.

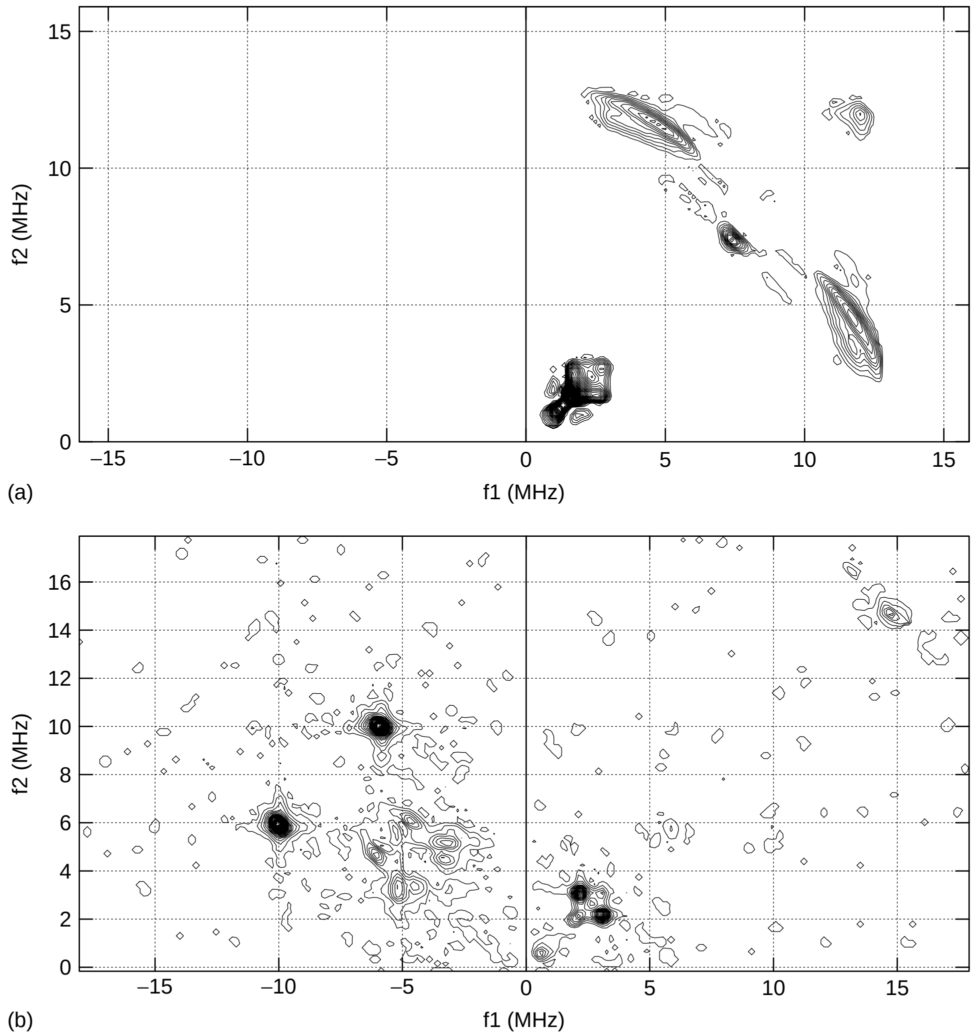

Figure 14 Four-pulse HYSCORE spectra of Fe(II)NO–TauD treated with αKG and taurine in aqueous buffer. Parameters common to these measurements were: microwave frequency, 9.724 GHz; magnetic field, (a) 171.0 mT and (b) 345.3 mT; 90° pulses, 16 ns (FWHM), 200 W; 180° pulse, 28 ns, 200 W; τ value, (a) 120 ns and (b) 136 ns; sample temperature, 4.2 K

One of our goals for studying TauD was to correlate our spectroscopic results with the structural information available from the X ray crystal structure of the ternary complex prepared under anaerobic conditions. Subsequently, this information could be used as a foundation to study similarities in catalytic mechanisms between different members of this enzyme class. Because the catalytic mechanism involves the displacement of bound water molecules from the Fe(II) cofactor, we studied samples of Fe(II)NO–TauD without cosubstrates and with just the αKG added to determine if HYSCORE could be used to follow this chemistry. Figure 16(a) shows the HYSCORE spectrum at $g = 4.00$ for Fe(II)NO–TauD in aqueous buffer without the two cosubstrates. Two water molecules should be coordinated to the Fe(II)NO center under these conditions. The HYSCORE shows a weak, disordered system of overlapping ^{1}H arcs for this sample, which most likely reflects a high degree of disorder at the site prior to cosubstrate addition. When αKG is added (Figure 16b), the ^{1}H cross-peaks become better defined and take on the appearance of a wedge-shape that could be indicative of a ^{1}H hyperfine coupling of rhombic symmetry. For both of these samples, the cross-peaks disappear from the spectrum when the samples are exchanged against D_2O buffer. This is in sharp contrast to what was observed for the ternary complex containing αKG and taurine, Figures 14(a) and 15, where D_2O exchange did not alter the intensity of the ^{1}H arc. From these observations, it appears that whatever residue gives rise to the broad ^{1}H-ESEEM captured in the HYSCORE ridges or arcs at $g_\perp$, it is only coupled to the Fe(II)NO center in this unique fashion when the cosubstrates are both bound. Perhaps this residue plays a role in positioning substrate or in guiding the chemistry of the center once the high valent Fe-oxo intermediate is prepared. It will be exciting to see where the spectroscopy takes us!

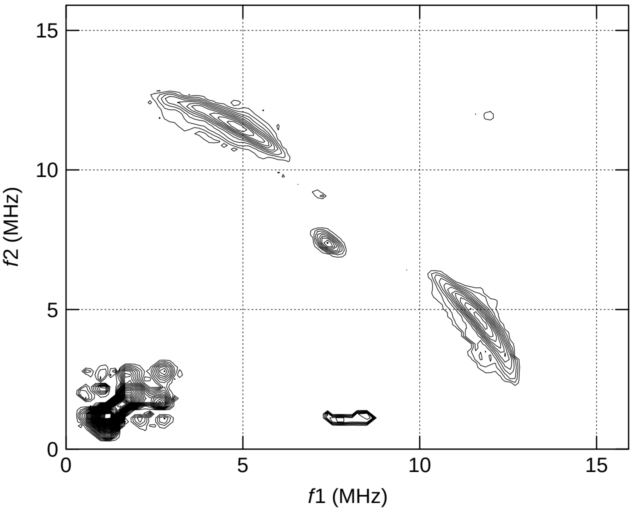

Figure 15 Four-pulse HYSCORE spectra of Fe(II)NO–TauD treated with αKG and taurine in D_2O buffer. Parameters were identical to those used to collect the HYSCORE spectrum of Figure 14(a)

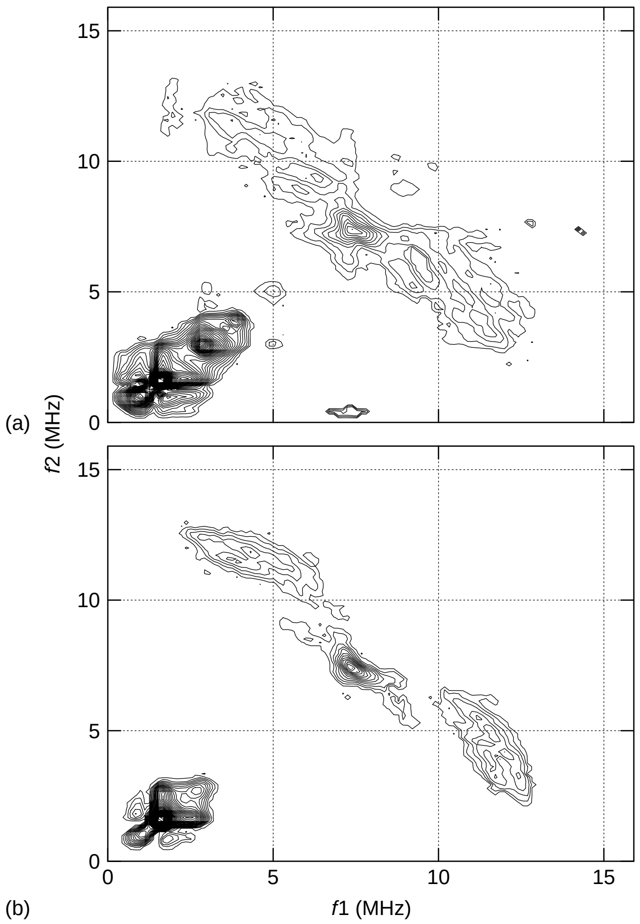

Figure 16 Four-pulse HYSCORE spectra of Fe(II)NO–TauD in (a) aqueous buffer and (b) treated with αKG and suspended in aqueous buffer. Measurement parameters were identical with those of Figure 14(a)

4 ACKNOWLEDGMENTS

The data shown for purposes of example in this chapter have come from long-standing collaborations with Professors R.P. Hausinger (Michigan State University) and D.J. Kosman (University at Buffalo). ESEEM experiments on TauD were performed by Dr. R.B. Muthukumaran and Ms. Meng Li at Michigan State University. Financial support for this work came from the NIH (GM 54065 and RR 15880) and the Michigan Economic Development Corporation.

5 ABBREVIATIONS AND ACRONYMS

DPPH = 2,2-diphenyl-1-picrylhydrazyl; ENDOR = electron-nuclear double resonance; EPR = electron paramagnetic resonance; ESE = electron spin echoes; ESEEM = electron spin echo envelope modulation; FFT = fast fourier transformations; FWHM = full width at half maximum; HYSCORE = hyperfine sublevel correlation; nqi = nuclear quadrupole interaction; TauD = taurine/αKG dioxygenase; TWTA = traveling wave tube amplifier; ZFS = zero field splitting.

METHOD SUMMARY

Acronyms, Synonyms
- UV-Visible Spectroscopy (UV-Vis)
- light absorption, emission and scattering
- laser spectroscopy, selective spectroscopy
- low temperature glass, single crystal, protein-cryoprotectant spectroscopy.

Measured physical quantities
- Electronic transition energies
- transition strengths
- transition polarizations
- ground and excited state splittings, linewidths, and excited state lifetimes
- time- and temperature-dependent spectra
- external stress- (Pressure), electric- (Stark) and magnetic-field (Zeeman) induced spectral changes.

Information available
- excited and ground state electronic properties and local geometries
- chromophore-environment interactions
- ground and excited state vibrational frequencies
- vibrational/phonon coupling strengths
- interchromophore interactions (excitonic/magnetic)
- local electronic variability and vulnerability (host-induced inhomogeneities).

Information not available, limitations
- The interpretation of electronic spectra is largely dependent on a prior knowledge of structure.
- There is an enormous dynamic range in electronic transition strengths ($f-f$, $d-d$, CT, $\pi-\pi^*$).
- Important chemical species may not exhibit UV-Vis spectra.
- Electronic spectra are characteristically broad, often showing minimal detailed structure.
- Solubility/concentration of a chromophore in an optically useful medium may be limiting.

Examples of questions that can be answered
- nature of the excited states
- concentration and orientation of a chromophore

- sensitivity to a specific electronic component of a more complex system
- identification of intrinsic and environmentally induced properties of a chromophore.

Major advantages

- Electronic spectroscopy is nondestructive and noninvasive.
- Most techniques in chemistry are limited to determining properties of the electronic ground state of a species. Electronic spectroscopy is one of the few techniques that *directly probes excited states*.
- Developments and improvements in quantum chemical computational methods are now able to address excited state properties of relatively large systems in a useful way.
- Laser and synchrotron light sources are particularly bright while conventional sources offer broad spectral coverage and ease of use.
- Visible-light detectors are extremely sensitive, efficient and may also offer high time resolution.
- Targeted optical spectroscopy experiments can be easily configured through the use of computer controllable modules.

Major disadvantages

- Optical spectra may be dominated by less interesting chromophoric species.
- The assignment and interpretation of electronic spectra is not always routine and may involve the understanding of a number of fundamental quantum mechanical concepts.

Sample constraints

- A species of interest needs to be either soluble or solubilized in an inert, transparent, isotropic and non light-scattering medium.
- There is a limited range of useful low-temperature glassing mixtures.
- Measurements on single crystals can be particularly informative but such measurements can be more demanding.

1 INTRODUCTION

Electronic spectroscopy in its broader sense involves the absorption, emission, or scattering of UV-visible light by a chromophoric system of interest. Many aspects of the large range of electronic spectroscopy techniques that are available to chemists are well established and relatively routine. Most often, measurements involve the use of solution samples at ambient temperatures. Practically all laboratories are equipped with instruments capable of measuring at least some of these optical phenomena. Companion articles in this volume deal with a number of electronic spectroscopies including Photoluminescence and Electroluminescence (*see* ***Photoluminescence and Electroluminescence, Solid State***), circular dichroism (CD) (*see* ***Circular Dichroism (CD) Spectroscopy***), magnetic circular dichroism (MCD) (*see* ***Magnetic Circular Dichroism (MCD) Spectroscopy***) and Resonance Raman spectroscopies.

Any particular spectroscopic technique, once its theoretical and practical framework has been established, can be useful and adapted to relatively routine analytical or diagnostic purposes. The cornerstone analytical techniques of chemistry are perhaps increasingly Mass Spectrometry, nuclear magnetic resonance (NMR) (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Inorganic/Organometallic Molecules***; ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Metallobiomolecules***) and X-ray crystallography. It is often possible to identify the composition and provide the structure of a substance using these techniques alone. Electronic absorption spectra of solutions at room temperature do not usually exhibit the spectral resolution or distinctiveness required of an analytic technique. Most chemical species luminesce only weakly and in this respect electronic spectroscopies play a more specialized and relatively minor role. A *combination* of spectral techniques is often brought to bear on the complex and interesting systems now under study in modern chemistry. Multitechnique approaches are particularly important in biochemistry.

The large spectral width characteristically exhibited in electronic spectra is due to factors inherent to electronic excitations of the chromophore (homogeneous broadening) but is often dominated by factors due to variations in the local environment experienced by each individual chromophore in a sample (inhomogeneous broadening). We will point out that the vulnerability of electronic spectra to spectral broadening can sometimes be turned to advantage and important characteristics of a chromophore, such as its interaction with the local environment, can be understood by a study of broadening mechanisms. Metalloenzymes are systems that usually owe their unique abilities to interactions of metals with the protein environment.

Some electronic spectroscopies take particular advantage of the remarkable coherency, brightness, directionality, and spectral purity of laser sources or the extreme sensitivity and/or rapid response times of modern light detectors. Potent laser/detector combinations, when coupled to an

optical microscope, allow a single molecule to be detected and its spectra recorded in favorable cases.[1] Laser pulses that have a period as short as the fundamental electronic and nuclear reorganizational processes in molecules (picosecond-femtosecond) can be created, and by using such technology the most basic chemical processes can be directly monitored. We have discussed some aspects of these issues in a recent chapter.[2]

The current article does touch on laser-based spectroscopies but concentrates largely on important aspects of more conventional absorption spectroscopies. We pay particular attention to methods and developments in practical sample-handling techniques. These can be critical in the study of reactive samples or those that are sensitive to light, air, or moisture, for example. We also note the continuing revolution in light sources, spectrometers, filters, optics, and detectors, along with the developments in convenient and rapidly user-adaptable, computer-controlled instrumentation that allow potent and targeted experimental facilities to be relatively easily configured.

2 BASIC CONCEPTS

An effective understanding of electronic spectra does require a basic knowledge of a number of fundamental quantum mechanical principles. This section only briefly highlights, in a descriptive way, some important aspects. More complete and formal treatments are available in a wide range of texts.[3–7]

As a very basic description of the electronic absorption process, electromagnetic radiation (light) of wavelengths in the range from ∼180 nm to around ∼800 nm will interact, via its rapidly varying electric field, with the electronic charge distribution that defines the shape, size, and energy of a chromophore. The *magnetic* field of light can also interact with a chromophore and although this interaction is typically more than 10^6 times weaker than the interaction with the electric field, it has a critical role to play in CD spectra (*see* ***Circular Dichroism (CD) Spectroscopy***). Its influence can be seen directly in absorption spectra when the electric interaction is relatively weak. The parity of the electric and magnetic dipole operators are odd and even respectively, and this property can be used to distinguish them. In this chapter we refer to electric dipole processes unless stated otherwise.

If the frequency of the incident radiation is resonant with the energy difference between the ground state configuration and that of an excited state, then there is a well-defined increase in the probability of finding the chromophore in an electronically excited state after a given time. Another useful heuristic description is that the radiation field causes the eigenstates (stationary states) of the system to become ''mixed'' and thus there is the possibility of the ground state ''transforming'' to the excited state.

When the radiation field is sufficiently intense, such as in a high power pulse laser, the laser radiation field, ground, and excited states, all need to be considered as a coherent, interacting electromagnetic system. This is the fully quantum picture,[8,9] with the radiation field and the electronic excitations being entangled. A range of fascinating nonlinear and time dependent processes become enabled, including for example, optical analogues of NMR pulse techniques. A caveat is that a high power pulse laser may also induce unsuspected processes, particularly in the spectra of condensed phase systems. These may be associated with photochemical damage to the sample or unrecognized photophysical transformations. This article limits itself largely to more conventional (linear) studies.

All electronic states of a chromophore are *stationary* states and are the solutions to the quantum mechanical equations of motion (Hamiltonian) of a molecule defining nuclear and electronic kinetic energies together with all Coulomb (electrostatic) interactions between nuclei and electrons in a molecule. As electrons are far lighter than nuclei, purely electronic eigenstates can usually be calculated by assuming that nuclei are stationary. This is the basis of the Born–Oppenheimer separability of electronic and nuclear motions. Given that nuclei move slowly and electronic reorganization is rapid, electronic excited states are most likely to be created having the nuclear geometry of the *initial* state.

In general, electronic excited states have *different* equilibrium bond lengths and geometries to the ground electronic state. These differences lead to the possibility of excitation of *vibrational* quanta (in an excited state) along with the purely electronic component of the excitation. The degree of coupling to vibrational modes (*see* ***Vibrational Spectroscopy***) of an electronic excitation is defined by the appropriate overlap factors. Any excited (electronic + vibrational) state, although a stationary state of the Hamiltonian, has a limited lifetime. An excited state of a chromophore rapidly loses energy, either by emitting light or losing some or all of the excitation energy to the environment as heat. These processes are called radiative and nonradiative relaxation, respectively.

Under nearly all circumstances, with rare-earth ions and a few unusual electronic systems such as azulene being notable exceptions, nonradiative relaxation to the lowest electronic excited state is *extremely* rapid (typically $\ll$1 picosecond). Relaxation of vibrationally excited states, of either the ground electronic state or the excited electronic state, is also very rapid (∼picoseconds) even at low temperatures. These nonradiative relaxation processes are characteristically much faster than rates of radiative relaxation, leading to what is sometimes known as Kasha's rule. This notes that only the lowest energy electronically excited state of a chromophore will persist for long enough to give rise to easily measurable radiative emission (photoluminescence; *see* ***Photoluminescence and Electroluminescence, Solid State***). As a general rule, if the energy gap between the ground state and the lowest excited state is more than ∼5 quanta of

the highest frequency vibration in the system, then radiative relaxation from this state (luminescence) can compete with radiationless processes. Energy gaps between the manifold of higher excited states are rarely larger than the gap between the ground and first excited states and thus, in condensed phases, radiationless deactivation of these higher-lying states almost invariably outcompetes radiative pathways.

2.1 Excited State Energies

A simple yet fundamentally correct way of looking at the energy of an electronic state is by invoking the Hellman–Feynman theorem.[3] This result shows that the energy of any eigenstate is exactly that which one would calculate by an electrostatic calculation of Coulombic interactions of the charge cloud and the nuclei. The charge cloud is defined by the square of the electronic wavefunction. Each electronic state is described by its individual wavefunction and subsequent charge cloud. Excited states will in general involve a more spatially extended charge cloud than the ground state. Furthermore, for a transition to have optical intensity the two states involved must have opposite parity. Excited states are generally more electrically dipolar than the ground state. This dipole is the ‘‘handle’’ by which the light field grabs the molecule and mixes ground and excited states.

The independent electron approximation is central in the description of chemistry. Solutions to one-electron atomic or molecular Hamiltonians are taken as a starting point in developing the description of many-electron systems. Within this approximation, electronic excitations can be described as a particular electron jumping from one orbital to another. This approach, though useful, has no ultimate fundamental basis and fails in some situations. Additionally, in systems for which the electronic wavefunction itself is *strongly dependent* on the nuclear coordinate, such as Jahn–Teller active systems[10] and vibronically active mixed valence systems,[11] or the bacterial reaction center cation,[12,13] the Born–Oppenheimer approximation fails. In this situation some phenomena can become quite counterintuitive, such as the temperature dependence of the localization of charge.[11] More fundamentally precise methods[14] need to be invoked in dealing with these interesting systems.

Electronic excitations can be usefully classified as one-center excitations and those involving two or more centers. Intraconfigurational transitions such as d–d and f–f processes are examples of systems in which their energetics are well described as one-center (atomic) excitations, but as noted in a later section their optical intensity may be due entirely to contamination with two-center processes. A characteristic two-center excitation is an optical charge-transfer excitation between two identifiable subunits, the donor and acceptor. The electronic charge cloud of the donor will become smaller upon losing an electron while that of the acceptor, which gains an electron, will become larger. Consequently, multiple quanta of the vibrational modes accommodating the displacement will be induced. A large fraction of the overall excitation energy can become vibrational.

The importance of quantum computational methods in chemistry has increased significantly with advances in both the speed of computers and with improvements in code and software packages.[15] Methods in common use either approximate an electronic wavefunction to a (truncated) sum of Gaussian functions (which themselves are easy to integrate), or define an *effective* potential in which electrons move (density functional models). Although more effective in describing the properties of *ground* states, both approaches can, in many cases now provide useful, if limited, information on excited states. Each method has its advantages and limitations, but calculations are now widely used as a guide in the assignment and understanding of electronic spectra.

2.1.1 *Homogenous Broadening*

There is spectral broadening evident in the spectrum of each single molecule or chromophore. This is homogeneous broadening. The *minimal* such broadening of any eigenstate is determined by its radiative lifetime. This (lifetime) broadening gives rise to a Lorentzian lineshape (Figure 1). Its width is inversely dependent on the excited state lifetime. A radiative lifetime of 10 ns, which at 500 nm corresponds to a transition with an oscillator strength (see below) of $f = 0.375$, leads to a homogenous linewidth of $\sim 5.3 \times 10^{-4}$ cm^{-1} (16 MHz). The lowest excited state of a highly fluorescent dye molecule may have a linewidth close to the radiative limit at the lowest temperatures. At higher temperatures, although lifetimes

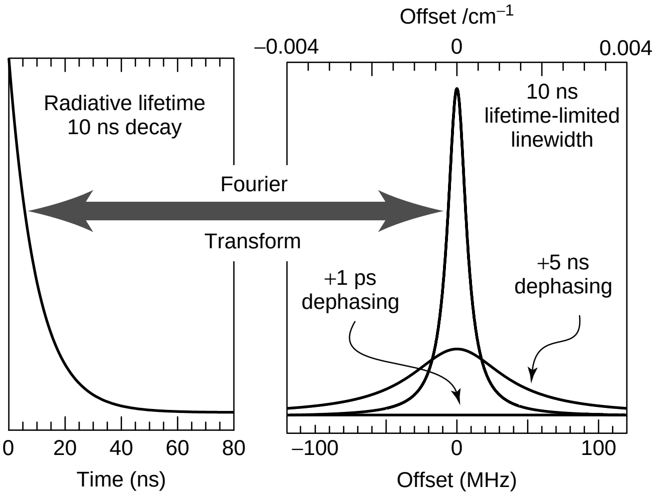

Figure 1 Schematic showing a chromophore with a radiative lifetime of 10 ns with its linewidth passing from the radiatively limited value of 5.3×10^{-4} cm^{-1} at cryogenic temperatures to the situation at higher temperatures where rapid dephasing induces a strong additional broadening, yet leaves the emission lifetime unaffected

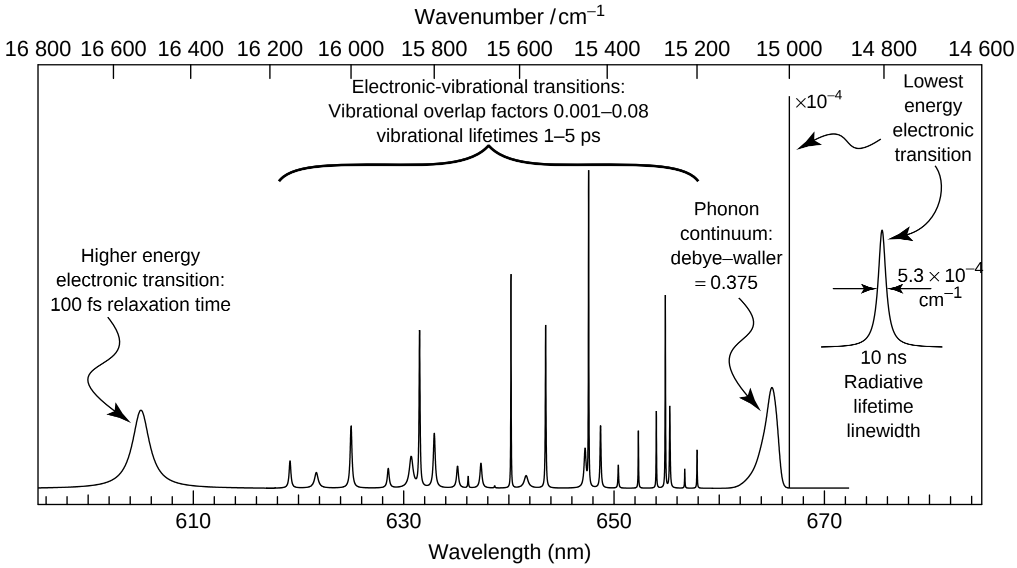

Figure 2 Schematic of the electronic absorption spectrum of a single chromophoric site in a condensed phase host environment at low temperatures. An extremely sharp electronic origin, exhibiting a radiatively limited linewidth is accompanied by a phonon sideband with vibrational sidelines. A second electronic excited state lies at higher energies. Vibrational sidelines and the second electronic excited state are lifetime broadened by rapid radiationless deactivation processes

may remain close to radiatively limited, thermally induced fluctuations of the environment cause the excitation energy to undergo rapid energy shifts. This process is called dephasing and leads to homogeneous widths of $100\,\text{cm}^{-1}$ or more at ambient temperatures (Figure 1).

Electronic states higher in energy than the lowest energy excited state almost always undergo rapid (<picosecond) radiationless deactivation (Figure 2). This rapid process will induce a homogeneous lifetime broadening in the range of $\sim 1-1000\,\text{cm}^{-1}$, even at the lowest temperatures. Along with the purely electronic excitations (also called zero phonon lines or origins), each electronic state is coupled, to a variable extent, to both phonon modes of the surrounding medium and vibrational modes of the chromophore (Figure 2). Phonon frequencies form a continuum in the $\sim 10-100\,\text{cm}^{-1}$ range, whereas molecular vibrations are discrete and have frequencies from the phonon range up to proton vibrational frequencies (if present) of $\sim 3500\,\text{cm}^{-1}$.

In chromophores containing even a modest number of atoms, a large number of vibrational frequencies may be coupled to an electronic origin. Each vibrational sideband has a Lorentzian width corresponding to its own particular vibrational relaxation rate. Increasing spectral congestion, due to a large number of vibrational modes, quickly leads to a weakly structured quasi-continuum. The overall shape of this continuum is variable, depending on the overlap factors of the various modes coupled to the electronic excitation. As the temperature increases, any remaining structure will diminish with the effects of rapidly increasing dephasing rates adding to homogeneous widths. Intensity also typically builds up on the low-energy edge due to absorption from thermally populated levels of the ground state.

When the difference between equilibrium geometries in ground and excited states is substantial, this will lead to the excitation of multiple vibrational quanta in the modes that accommodate such a displacement. When a large number of quanta of a particular mode are excited, the overall intensity distribution in the vibrational sideline will approach a Gaussian pattern. Thus, when vibrational sidelines dominate the spectrum, a homogeneously broadened electronic band can have an overall profile close to Gaussian (Figure 3).

2.1.2 Inhomogenous Broadening

Chromophores dissolved or embedded in any medium experience a range of nanoenvironments (Figure 4). This leads to their excitation energies being significantly modulated. The spectra of individual chromophores vary due to local variations in the positions of solvent molecules, charge compensating species, the proximity of other chromophores, strains, defects, or dislocations. These influences may indeed lead to a very significant spread in the energies of both ground and excited states and consequently to a range of electronic excitation energies. This ubiquitous phenomenon is called inhomogeneous broadening. Other spectroscopic techniques, such as IR (*see* ***Vibrational Spectroscopy***) and NMR (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Inorganic/Organometallic Molecules***) are less susceptible to inhomogeneous spectral broadening. In contrast to electronic excitation energies, which can vary significantly from a

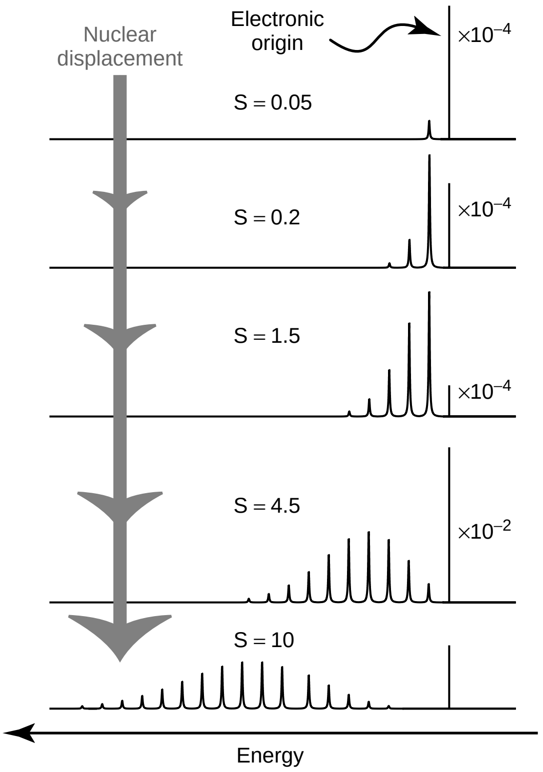

Figure 3 Schematic of the electronic spectrum of a single site coupled to one vibrational mode. A changing vibrational sideline pattern is seen upon increasing nuclear displacement between ground and excited states. This is quantified by the S (Huang–Rhys) parameter. With an S of 10, the peak in the vibrational pattern occurs with ~10 vibrational quanta being excited. The amplitudes of the sideline intensities then follow a profile that is close to Gaussian. The Lorenzian lineshapes of the individual transitions is determined by the Fourier transform of their lifetimes (Figure 1). The amplitude of the electronic origin feature is initially far larger than those of the vibrational sidelines but becomes comparable at high S values

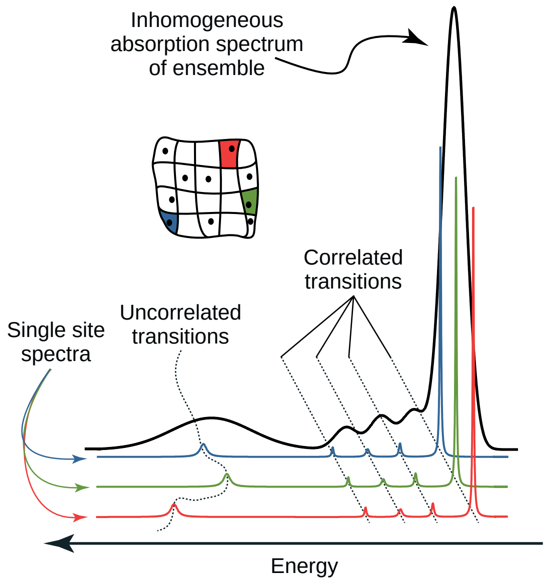

Figure 4 Schematic showing both correlated and uncorrelated transitions in an inhomogeneously broadened electronic spectrum. Each single site spectrum shows relatively narrow, homogeneously broadened features. Correlated features track with the energy of a narrow electronic origin. Noncorrelated sidelines appear at any energy within its full, inhomogeneously broadened band

single chromophore to the next, their vibrational and nuclear resonances are less affected by variations in local environments. In the case of IR spectra, vibrational frequencies are largely determined by local (bond) affects. In solution NMR, the slow timescale of the experiment leads to one well-defined resonance.

Inhomogeneous broadening is generally more extensive in solutions and glasses/polymers than in crystalline environments. Crystals usually have far better defined environments for a chromophore. Spectra of a particular chromophore that are measured when this chromophore is in a crystalline environment are usually better resolved even when taken at ambient temperatures. Proteins can exhibit well-defined binding sites for a chromophore. However, due to the inherent conformational flexibility of the protein medium, there can still be a wide variation in the configuration of this nanoenvironment, as there is in a glass.

Electronic excitations vary widely in their vulnerability to inhomogeneities. Intraconfigurational transitions such as some $d-d$ and $f-f$ transitions are examples of excitations that display relatively little inhomogeneous broadening, even in solution. The lineshape of an inhomogeneously broadened band can often be well represented as a Gaussian. This is understandable, as a Gaussian is the asymptotic shape expected when there are a number of distributive influences. There is however no particular reason why an inhomogeneously broadened band needs to have a Gaussian shape, especially when one influence dominates. There are examples[16] in which inhomogeneous distributions can even be bimodal, mimicking the presence of two separate electronic states.

One aspect of inhomogeneous broadening often not appreciated, relates to the *relative* energies of excited states. Relative energies can be strongly interdependent (correlated) or in the opposite extreme can be entirely nondependent (uncorrelated) (Figure 4). Electronic state energies are often found to be uncorrelated. This can be demonstrated via the line-narrowing techniques of laser-selective spectroscopy.[2,17,18] Spectral narrowing in the lowest excited state often leads to little energy selectivity of higher-lying states. Furthermore a noncorrelated distribution of excited state energies can lead to apparently anomalous behavior. For example, when noncorrelated excited state energy distributions overlap as in Figure 5, a fraction of the nominally identical chromophores in an inhomogeneous environment exhibit a reversed excited state energy order. This in turn can lead to a dramatic change of the emission and other characteristics of this subset.[19]

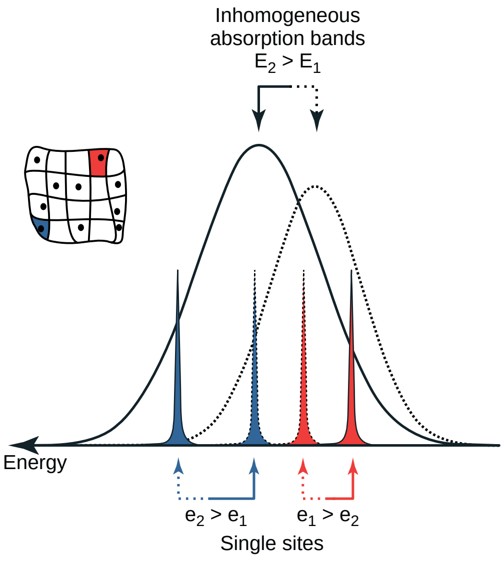

Figure 5 Schematic of overlapping, noncorrelated and inhomogeneously broadened bands E_1 and E_2. The system then has a wide range of single site energy splittings, $e_2 - e_1$. The average energy difference between the E_1 and E_2 peaks then loses much of its meaning. There becomes a substantial fraction of sites in which the relative order of the states is reversed

2.2 Transition Strengths

The probability of exciting an electronic transition with resonant light varies enormously with the nature of the ground and excited states. The rate of excitation is determined by the dipole strength, which is the square of the matrix element of the (electric dipole) operator between the ground and excited states (the dipole moment). The dipole moment reflects the change in charge distribution in passing from one state to the other. Another method of quantifying the transition strength is the oscillator strength, f. This dimensionless quantity is the ratio of the excitation rate of absorption by the chromophore compared to the excitation rate the same radiation field would induce in a free electron.

For transitions in the visible region, an excitation with $f = 1$ will arise from a transition dipole moment of magnitude ~2.5 Debye. An oscillator strength of $f = 1$ is the order of magnitude seen for an organic dye molecule. For a transition at 500 nm the radiative lifetime of such an excited state would be ~4 ns, leading to a Lorentzian linewidth of ~40 MHz or $\sim 1.3 \times 10^{-3}$ cm^{-1}. These values are appropriate to measurements in vacuo and need to be scaled by the dielectric constant of the medium in which the chromophore is embedded, in order to correct for the actual field experienced by the chromophore.

The Thomas–Reiche–Kuhn f-sum rule shows[3] that the summation of the oscillator strengths of *all transitions* in a chromophore is equal to the number of electrons. In this way, we could envisage an ‘‘electron count’’ in the same way NMR and electron paramagnetic resonance (EPR) (*see* ***Electron Paramagnetic Resonance (EPR) Spectroscopy***) techniques have a ‘‘spin count.’’ In these techniques, a very useful characteristic is that each nuclear or electron spin contributes a specific, well-defined, spectral intensity that is distributed by various couplings. In the same way, we could consider that each electron contributes specific electric dipole transition intensity. However, most electronic excitations in chromophores lie in the far UV and X-ray regions and are not practically accessible, whence the ability to ‘‘electron count’’ becomes moot.

The underlying idea that there is a specific electronic intensity that can be distributed amongst electronic excitations remains and one can refer to ‘‘intensity stealing’’ from one transition system to another. Excitations, such as nominally parity-forbidden $d-d$ transitions, may gain a small intensity ($f \sim 10^{-6}$) by mixing with allowed transitions ($f \sim 1$). The relatively high intensity of light sources, along with the high sensitivity of detectors allow excitations of $f < 10^{-6}$ to be measured with ease. In a sense one is ‘‘seeing’’ a very small fraction of an electron.

In order to determine the intensity of an electronic-vibrational sideline, the electronic transition moment must be multiplied by an appropriate vibrational overlap factor. These factors are nuclear displacement overlap integrals and are dependent on the number of vibrational quanta present in the in the initial (ground) state as well as in the final (excited) state. They reflect the probability that the (electronic + vibrational) combinations have the same nuclear geometry. When the equilibrium nuclear displacement between ground and excited electronic states becomes larger, the likelihood of exciting numerous vibrational quanta in the excited state increases. A lengthening vibrational progression will become apparent, with the absorption maximum moving to higher energy. The integrated area of the absorption is not dependent on the nuclear displacement parameter but as the band becomes broader, the peak intensity drops (Figure 3).

The situation is somewhat different when considering the charge-transfer process between two weakly coupled assemblies.[11] Optically induced charge transfer can occur between two distinct subunits (the donor and the acceptor) that have only a limited degree of electronic overlap. However, the integrated dipole strength of the charge-transfer excitation is then *strongly* dependent on the extent of nuclear displacement in the mode that accommodates the change in size in the electron donor and acceptor upon electron transfer. Large displacements lead to a dramatic drop in the integrated dipole strength from the asymptotic value for low displacements. The *asymptotic* value of the dipole moment is simply equal to the magnitude of charge transferred multiplied by the distance between the donor and the acceptor.

2.3 Transition Polarizations

Electronic transitions occur when light interacts with a chromophore via its transition dipole moment. The latter

is a vector quantity that has a specific direction. Light has directional properties, through both its propagation direction and the direction of its electric and magnetic fields. The fields are perpendicular to each other *and* to the propagation direction.

When light is linearly polarized, the direction of the oscillating electric field of the light is identified as its polarization direction. All electromagnetic radiation has a state of polarization, which may be linear, circular, (better described as helical) and more generally, elliptical. What is often called unpolarized light has a spatially or temporally modulated state of polarization. Processes of reflection by dielectric media and transmission through birefringent media change the state of polarization of light.

The transition dipole moments of a chromophore return different amplitudes of interaction when responding to light polarized in different directions with respect to the chromophore. In a chromophore with no symmetry, the direction of the transition moment associated with each excitation may take a different direction. When there is a two-fold axis, spectra that are taken with light that is polarized either parallel or perpendicular to the symmetry direction are unique. When there is a three-fold or higher axis of symmetry, the transition moment is independent of the direction of polarization in the symmetry plane.

Polarized spectra can be valuable in providing information on the symmetry of a species without requiring a detailed knowledge of their electronic structure. In crystalline environments, polarized information is inherently available, but its utility is dependent on knowing the orientation(s) of the chromophores with respect to the crystal axes. In general, it is only possible to measure polarized spectra along the symmetry axes of a crystal. These directions may differ from the directions of the transition moments of the chromophores and the spectra that are measured then need to be deconstructed into polarized spectra of the chromophores themselves.[20]

In solutions, glasses, and solubilized proteins, chromophores are usually randomly oriented. However, it is possible to obtain polarized information. This is done either by photo-selection of a subset of the chromophores, for example as can be done in spectral hole-burning,[17,18] or by orienting the chromophores. A degree of orientation of physically asymmetric chromophores may be achieved by stretching the polymer films in which they are embedded.[21] Similarly, asymmetric proteins embedded in gels can often be oriented by the creation of flows in the supporting gel medium. This process is called one or two dimensional *gel squeezing*.[22]

Vibrational sideline structure retains the polarization of the purely electronic excitation. Within the *crude* Born–Oppenheimer approximation, only totally symmetric vibrational modes are coupled to an electronic transition. Consequently, all vibrational sidelines have the same polarization as the purely electronic component (electronic origin or zero phonon line). There are two circumstances in which vibrational side-structure does not retain the same polarization as the purely electronic excitation.

Firstly, within the *full* Born–Oppenheimer (adiabatic) approximation,[7] the electronic wavefunction is not fixed but is allowed to be parametrically dependent on the nuclear coordinate. The process of Herzberg–Teller coupling can then lead to ‘‘intensity stealing’’ from other electronic states. The full symmetry of the excitation is defined by the ground and excited state symmetries *and* the symmetry of the ‘‘intensity stealing’’ vibrational mode. An example is the vibronically induced intensity of $d-d$ transitions in centrosymmetric chromophores. These intraconfigurational excitations are electric dipole (parity) forbidden, but gain intensity when there is coupling to a non totally symmetric odd parity mode, such as the e_u mode in a chromophore of D_{4h} symmetry. A non totally symmetric displacement of the nuclei leads to the electronic state in question being ‘‘mixed’’ with odd parity electronic excited states. Transitions to the latter from an even parity ground state are dipole allowed, leading to some intensity being induced in a nominally forbidden transition. More than one mode can lead to vibronically induced intensity and each sideband can have different polarization properties. When sidebands are not resolved this phenomenon often leads to the sideband region being less polarized than the electronic origin region.

Secondly, a breakdown of the Born–Oppenheimer separability occurs in systems with strong Jahn–Teller coupling.[10] Here, a degenerate electronic state is strongly affected by a degenerate vibration, leading to intimately coupled electronic and nuclear motions. This fully *vibronic* situation (vibronic = coupled nuclear and electronic motions) is very distinct from the more usual (electronic origin + vibrational sidebands) situation, which by the above definition is *not* vibronic. In the limiting vibronic case, there is no actual excitation that can be described as purely electronic. Each eigenstate of a manifold can then be described as a *combination* of *different* electronic and vibrational components. Consequently, each level can have different polarization properties and the usual (adiabatic) meaning of a potential surface is lost. Jahn–Teller coupling applies to systems with a *spatial* electronic degeneracy, such as the ^2E_g ground state in O_h Cu(II). Note that coupling does not necessarily give rise to a distortion of such a chromophore.[23] Chromophores such as square planar Cu(II), often described as Jahn–Teller distorted, do not then retain the degeneracy of the ^2E_g (cubic) ground state and are not necessarily Jahn–Teller active. In this case, polarizations of vibrational sidelines will follow those of the electronic origin.

2.4 Temperature-Dependent Spectra

The temperature dependence of spectra can be very useful in electronic spectroscopy. First, spectra at low temperatures are often, though not necessarily, better resolved. Inhomogeneous broadening factors may not change

but dephasing and vibrational relaxation processes become slower. Once the problems of low-temperature optical sample cells and the optically transparent supporting media for the chromophore are addressed, another distinct advantage in low-temperature spectroscopy of chemical systems is that unstable or reactive materials are far more stable once frozen in glass, protein, or crystal. Photochemical transformations at low temperature are also less likely, or at least slower, facilitating the possibility of the measurement of transient or metastable species. Spectroelectrochemistry is an example where the cooling of an optically transparent electrochemical cell can be of significant advantage[24] (*see also* ***Electrochemistry***).

Ambient temperatures of 300 K correspond to a Boltzmann energy of $\sim$209 cm^{-1}. The temperature of liquid nitrogen corresponds to $\sim$54 cm^{-1} and that of liquid helium only 3 cm^{-1}. Spectral features will be more noticeably changed by temperature when their width is comparable to the temperature change that is made. A relatively broad transition (300 cm^{-1} full width (at) half maximum (FWHM) at 300 K) may narrow slightly on cooling to 77 K but stay virtually unchanged on further cooling to 4 K. A band that shows some 50 cm^{-1} FWHM structure at 77 K is likely to become even better resolved at 4 K. Structure is most likely to be seen at the low-energy edge, where spectral congestion of vibrational sidelines is minimized.

Thermal contraction of the supporting medium of a chromophore becomes minimal below 100 K. This makes the temperature range between $\sim$2 K and 100 K particularly useful in both allowing good resolution in spectra along with relatively little change in the environment of a chromophore. At higher temperatures dimensional changes become significant, and these blur the more intrinsic changes in a chromophore with those changes that are induced by thermal effects of the supporting medium. This is of course particularly true when a glass softens and melts, or when a protein changes its conformation.

Besides changes in spectral widths, both the intensity and energy of electronic transitions can vary with temperature. Thermal population of vibrational excitations of the ground state will lead to increased intensity at the low-energy edge of an absorption (called *hot bands*) and a modest overall shift of the manifold to lower energies. A blue shift (to higher energy) with increasing temperature may indicate a charge-transfer excitation. When the donor and acceptor components move apart, the charge-transfer process requires more energy. In this case the intensity may also fall away as the intensity is dependent on the electronic overlap between donor and acceptor.

Interesting situations may occur when there are thermally accessible *electronic* excited states. In spin-crossover materials, low- and high-spin configurations of a *d* electron manifold are close to degenerate. However, besides different electron spin, these configurations have very different metal-ligand bond lengths. Consequently, interconversion between these configurations can be very slow. A synergy between the properties of the chromophore and its environment leads to interesting metastable states and thermal hysteresis.

There is considerable current interest in systems with optical functionality, such as optical switches, logic gates, or sensors. The utility of such devices depend critically on rather subtle balances of a range of influences, each of which ultimately needs to be addressed from a fundamental quantum mechanical perspective.

2.5 Electric Field-Dependent Spectra

It is natural to consider the effect of both applied electric fields (the Stark effect) and magnetic fields (the Zeeman effect) on electronic spectra. Chemistry is itself entirely an electromagnetic phenomenon. A basic limitation in regard to the application of the Stark effect in condensed phase samples is that the voltage which can be applied is practically limited to around 10^4 V across a sample thickness of around 0.01 cm. Beyond an applied field of $\sim 10^6$ V cm^{-1}, dielectric breakdown of the material occurs. This value of the external field is much smaller than the local electric fields experienced by chromophores. As a reference point, the field experienced at 10 Å from an electron in vacuo is $\sim 10^7$ V cm^{-1}. The electric field of 10^5 V cm^{-1} a magnitude typically achieved in an electrochromism experiment, acting on a dipole of 1 Debye ($\sim$0.2 e.Å invacuo) will experience a maximal energy shift of $\sim$1.7 cm^{-1}. This is small when compared to the inhomogeneous linewidths seen in typical spectra.

Electric field-induced effects can still be seen in condensed phase spectra by taking advantage of the high sensitivity and low noise characteristics available in optical spectroscopy. Field-induced absorption changes of $\Delta A < 10^{-6}$ can be seen in electrochromism experiments. Small changes in the transmission of a sample can be detected by a synchronous amplifier (lock-in). This is referenced to the frequency of an alternating applied electric field. These experiments are often done at low temperatures on a chromophore dissolved in a thin polymer film.[25] Both sides of the film are coated with an optically transparent electrode. Alternatively, samples such as proteins can be measured as a glassy film between two closely spaced optically transparent electrodes. A key piece of information obtainable is the value of $\Delta\mu$, which is the change in the permanent electric dipole moment of the chromophore in passing from the ground to excited states. This is extracted from the field-induced broadening of absorption bands. The magnitude of the broadening is quadratic in the applied field. When determining $\Delta\mu$ values, estimates of the dielectric constant of the medium containing the chromophore need to be made. The utility of $\Delta\mu$ as a distinctive characteristic of any excitation is of particular value in determining charge-transfer characteristics.

A novel extension to the electrochromic technique has recently been introduced.[26] This utilizes the exquisite ability of digital signal processors to measure harmonic distortion. When a purely sinusoidal modulation is made of the

electric field that is applied to a sample, the higher harmonics present in the optical transmission intensity signal provide valuable and relatively easily obtainable information on dipole moments and polarizabilities of the electronic states involved.

Studies on crystals have the advantage of both narrower inhomogeneous linewidths and the characteristic alignment of chromophores with respect to the crystal axes. Thus, rather than looking at spectral broadening, which is a consequence of the random orientation of chromophores in solution, there is the possibility of directly measuring Stark shifts. When combined with the laser-selective technique of transient hole-burning, it has been possible[27] to directly measure $\Delta\mu$ for the lowest energy metal-to-ligand charge-transfer (MLCT) transition of $[Ru(bpy)_3]^{2+}$ in a crystalline environment using an applied electric field of only $\sim$10 V cm^{-1}.

2.6 Magnetic Field-Dependent Spectra

In contrast to the difficulties with electric fields, it is possible to apply large magnetic fields, up to 8 T or more, to any sample relatively easily via the use of superconducting magnets. This ability to apply large fields is countered by the fact that magnetic interactions are intrinsically weaker. As a rule of thumb, degenerate electronic states may split by $\sim$1 cm^{-1}/T, with nondegenerate states being shifted by orders of magnitude less. The approach that is usually taken is *not* to directly measure energy shifts, but to monitor the magnetic field-induced optical polarization (the Faraday-effect) via MCD (*see* ***Magnetic Circular Dichroism (MCD) Spectroscopy***). At low temperatures, MCD can be extremely strong. Polarization modulation allows sensitivities up to $10^{-6}\Delta$A, providing the technique with a high dynamic range.

Again, when linewidths are narrow and/or when laser-selective techniques[2] can be utilized, it is possible to directly demonstrate Zeeman splittings. For example, accurate ground and excited state g-factors for the R1-line transition of $[Cr(ox)_3]^{3+}$ in crystalline $NaMgAl(ox)_3.9H_2O$:0.5%Cr(III) were determined using magnetic fields of only 2–16 mT.[28] Another example, presented in Section 4.3, is how the combination of spectral hole-burning upon the application of a magnetic field was able to quantify the distribution of low symmetry fields perturbing $[Cr(bpy)_3]^{2+}$ in a glassy medium by monitoring the interplay between zero field splittings and Zeeman interactions.[29]

2.7 Pressure-Dependent Spectra

The magnitude of pressure effects in electronic spectra can vary over a very wide range, depending critically on both the chromophore *and* its environment.[30] The most dramatic effects occur when there is a pressure-dependent phase-change whereby the nature of a chromophore may be completely changed. We present an example of pressure dependence of spin-crossover processes in an example in Section 4.1.

Technology exists to measure spectra at pressures higher than 10^6 bar using diamond anvil cells. Raman and IR techniques (*see* ***Vibrational Spectroscopy***) are most often brought into play in pressure-dependent spectroscopies.[30,31] Temperature-dependent spectroscopy at high pressures is also possible.[32,33]

2.8 Statistical Nature of Light and the Limits of Detection

Studies on complex systems, such as metalloenzymes, increasingly require the measurement of a minor spectral component in a far larger assembly. Basic aspects of optical spectroscopic techniques that make them particularly effective are the speed, sensitivity, and linearity of light detectors as well as the intensity, stability, and precision of conventional and laser light sources.

Photomultipliers, charge coupled devices (CCDs) and avalanche diode detectors are able to detect single photons over the visible to near-IR range with efficiencies approaching unity. The arrival of photons at a detector is not correlated, due to the quantum nature of electromagnetic radiation. Measurements of intensity as the averaged sum of photon events has a well-defined stochastic variance associated with a Poisson distribution. This variance scales as the square root of the number of photons.

For a light source of a specific power, there is a fundamental limit to the precision to which the intensity can be determined within a specific period. This is termed the *shot-noise limit*. If n photons are accumulated, the variance is $\sqrt{n}$ and the signal-to-noise ratio (S/N) is $\sqrt{n}/n$. Any *additional* noise source (due to the amplifier, interference or detector imperfections) will degrade this value. Theoretically, shot-noise in coherently squeezed light can be slightly lower than this limit, but ultimately only by a factor of $1/\sqrt{2}$.

A 1 mW source in the visible region (a modest power for a laser) corresponds to a photon flux of 10^{15}/s. This translates to a shot-noise-limited S/N of $\sim 3\times10^{-8}$ if the measurement is made for 1 s. Dispersed light from a relatively high bandwidth (nm) lamp/monochromator combination can have power of the order $\sim\mu$W in the visible and near UV leading to a limiting S/N of $\sim10^{-6}$ for a 1 s accumulation at each spectral point.

It is possible to approach shot-noise-limited performance in many optical experiments. When light levels are low, photomultipliers serve as noise-free ''quantum amplifiers'' with a gain of $\sim10^6$. For absorption measurements, detectors with the highest quantum efficiency and uniformity of response, such as ''end-on'' semitransparent photocathode styles, are better than the high gain, opaque photocathode, low dark count types that are used for luminescence measurements. If one needs to measure absorption with a precision of $\Delta A\sim10^{-3}$, then $\sim10^6$ photons need to be accumulated at each data point. At these light levels, the dark count usually may not contribute greatly to the S/N. However, in absorption

measurements, it is *essential* to accurately determine the zero or ''no light'' signal level. The logarithmic nature of absorption ($A = -\log_{10}(I/I_0)$) will induce large errors in A with only a small offset in I_0.

Although light sources of modest intensity promise excellent shot-noise-limited S/N, this can be difficult to achieve in practice. Laser sources are intrinsically unstable, and rarely achieve shot-noise-limited intensity stability. Even with sophisticated external stabilization techniques, stabilities better than $1{:}10^4$ are difficult to achieve. Arc lamps such as Xe or D_2 lamps are also intrinsically unstable at acoustic frequencies. It is however possible to stabilize an incandescent source such as a halogen lamp to $1{:}10^6$ through careful design.[34,35] When a chopper/lock-in amplifier combination is used for transmission measurements, it is important to recognize that the noise output of a light source can be very dependent on the modulation frequency at which the measurements are made. A chopper is used to determine the zero light value and/or to provide a reference beam, but its operating frequency should be chosen so that excess noise of the *source* at this frequency is minimal. Operation at electrical power frequencies or their harmonics should also be avoided. Signals at other frequencies may not actually distort the spectrum but they can add substantial noise. The rotational stability of many light choppers can also limit the available S/N.

Shot-noise-limited performance can be conveniently recognized by noting how the S/N of a system changes with light level. The S/N should vary quadratically with intensity if it is shot-noise-limited. Once a measurement is determined to be shot-noise-limited, the quantification of the noise[36] amplitude provides a simple, direct, and effective way to estimate the actinic flux experienced by a sample during a measurement.[37]

The use of an array detector bypasses some of the problems associated with the short-term stability of a source. An entire spectrum is accumulated in parallel and to first order, each wavelength is averaged in the same way. However, reference spectrum measurements may suffer due to longer-term stability issues. With array detectors, the precision of the analog-to-digital conversion process, often providing only 12 or 16 bits, will limit the S/N to 1×10^{-4} and $7 \times 10^{-6}\Delta A$ respectively.

When using photodiodes, the amplifier that is used in conjunction with the detector often adds excess noise. This can be reduced by the use of a low capacitance detector and a well designed detector/amplifier combination. Photodiodes are able to operate at far higher light levels than photomultipliers, and also have the advantage of higher quantum efficiencies. In addition, photodiodes operate over wider wavelength ranges than photomultipliers and are not as easily damaged. Consequently they are well placed to provide distinctly superior performance *unless* the amplifier noise exceeds the intrinsic shot-noise. In a conventional current-to-voltage amplifier circuit, shot-noise can only exceed the internal (Johnson) noise of the amplifier when the output

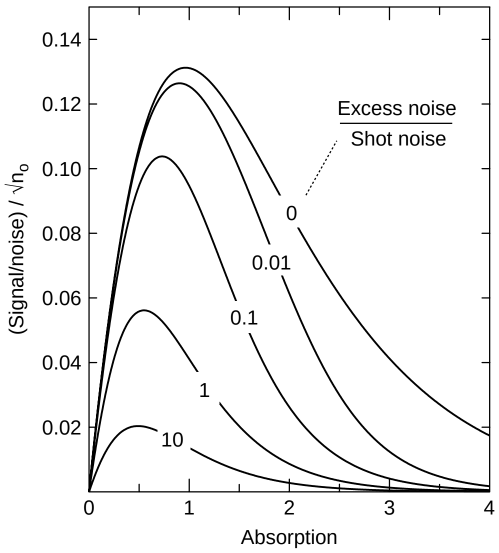

Figure 6 Signal-to-noise of a measurement provided as a function of the absorption of a chromophore. When excess electronic noise in the measurement system becomes comparable to the photon shot-noise, better data can be obtained by adjusting the absorption to lower values. (Drawn from data in Krausz[34])

of the amplifier is $>50\,\text{mV}$.[36] With diode detection, it is important that the signal output be kept above this level if possible. Again, a simple test of shot-noise performance is by the determination of the (quadratic) dependence of the S/N versus the light level.

When shot-noise is the limiting noise characteristic, the optimum S/N in an absorption measurement (and entirely equivalently in CD/MCD measurements of ΔA; *see* ***Circular Dichroism (CD) Spectroscopy***; ***Magnetic Circular Dichroism (MCD) Spectroscopy***) is obtained when the concentration and pathlength of a sample is adjusted to provide an absorption of $A \sim 0.9$.[34] The overall S/N then only degrades slowly as the absorption is increased, except that above $A \sim 3$, stray light often limits the accuracy of the measurement. When amplifier and other noise sources become significant, the optimal absorption is *always* lower than 0.9 (Figure 6). Not only does the optimal absorption reduce, but the S/N also degrades far more rapidly at higher absorptions compared to the shot-noise-limited situation. In circumstances in which shot-noise is *not* the limiting factor, better results may be obtained using a *lower* absorption sample, either by using a lower concentration or a shorter pathlength cell.

3 TECHNOLOGIES

3.1 Light Sources

The three most common conventional sources used in electronic spectroscopy are the quartz-halogen incandescent

source (Vis-Near IR), Xe (UV-Vis-Near IR), and D_2 (UV) arc. In spectroscopic applications, the power of a source is far less important than its brightness (spectral irradiance) and its stability. Halogen lamps are the most stable and also have the smoothest spectral output. They have comparable output to a xenon arc at wavelengths longer than 500 nm. A quartz-halogen lamp however, has far lower output than a xenon arc in the blue and UV regions. A deuterium lamp has comparable output to a xenon lamp near 200 nm but its output falls rapidly at lower energies and only puts out as much as a quartz-halogen lamp near 300 nm. Its utility is limited to the UV region and like the xenon arc suffers from intense emission lines in addition to the background continuum.

Laser sources[38] are essentially monochromatic and have enormously higher spectral irradiance than conventional sources. However, the tuning range of laser systems is usually limited and/or cumbersome. Their intensity stability is also problematic, as mentioned in previous sections. Lasers based on dyes dissolved in solvents may have a tuning range of ~20–50 nm before an alternative dye is required and laser diodes exhibit a narrower tuning range of 2–5 nm. Laser diodes operating at some wavelengths are not currently available. A uniquely versatile, widely tuneable laser source is the Ti:S (titanium sapphire) laser, which can operate over an exceptionally wide range from 700 nm to beyond 1000 nm. There are other broadly tuneable sources in the near-IR such as color center lasers.[38]

Broad tuning of a monochromatic source over an extended range has become possible by developments in optical parametric oscillators (OPOs). These devices are highly nonlinear, light-driven oscillators. They are not lasers themselves, but are powered by high intensity pulsed lasers of either nanosecond or femtosecond duration. OPOs can, with the interchange of some optical components, be tuned over a very wide wavelength range (<200 nm to >2000 nm). Operating as extremely intense nonlinear devices, they are prone to both instabilities and damage to their optical components. The extremely high intensities inevitable in such pulsed sources are likely to induce both unwanted nonlinear effects,[39] as well as photochemical damage in condensed phase samples, especially if the light is focussed on the sample. Experiments performed with such devices should be made with this caveat in mind.

Passing a femtosecond laser through a medium such as glass or sapphire can produce a collimated and very convenient (pulsed) continuum light source (400 nm to 16 000 nm) of high brightness via the optical Kerr effect. Alternatively, inserting such a pulse into a short length of highly nonlinear photonic fiber can also be used to enhance and tailor such a ‘‘super-continuum.’’ Using such sources, an entire broadband electronic spectrum can be accumulated, potentially from a single femtosecond pulse. This capacity greatly enhances ultrafast transient and excited state spectroscopies.[40]

A number of synchrotrons worldwide have been constructed to serve as light sources. They utilize the continuum radiation streaming from an accelerated electron beam in a large accelerator storage ring. Radiation appears in a broad continuum and can be optimized for operation in many segments of the electromagnetic spectrum from X-ray to IR regions. Light is typically delivered as nanosecond pulses. The repetition rate is widely variable, allowing time-resolved information to be gained. Selected beam lines are dedicated to electronic spectroscopy, particularly for use in the UV and IR regions (BESSY Berlin, Elettra Trieste, ALS Berkeley). A synchrotron source is indeed intense. Although it is nowhere near as intense as a laser, it is well collimated, polarized, and stable, providing a uniquely capable broadband source. Its advantages of intensity and wide tuneability make it especially useful in critical spectroscopic applications.

3.2 Light Detectors

Recent developments in light detectors over the entire region from UV-Vis to near-IR have been of significant benefit to electronic spectroscopy. There have been improvements and enhancements of more traditional single element detectors such as photodiodes and photomultipliers as well as more dramatic advances in multielement detectors such as CCDs.

Improvements in photomultipliers have been incremental, with the notable exception that photocathode materials have been developed that are sensitive to 1.6 µm. This is a very considerable extension to the previous limit of 1.1 µm. This means that the characteristics of high speed, high gain, and large sensitive area that are intrinsic to these devices are now available much further into the near-IR region. A parallel advancement has been in the development of InGaAs and related photodiodes and avalanche photodiodes. These have excellent quantum efficiencies into the 0.8–2.2 µm region. These devices also have excellent electrical characteristics, especially in speed when compared to previous near-IR detectors operating beyond the limit of Si diodes (~1 µm). They provide good performance even when operated at room temperature. Cooling such devices does however improve their electrical characteristics as well as lowering their dark current.

A key attribute of any detector, enabling it to have high sensitivity and high speed along with low noise is that it must have low electrical capacitance. This can often only be achieved by using a very small (<1 mm diameter) diode. This restriction makes it difficult to collect and utilize the entire measurement beam in many applications. Photomultipliers are inherently low capacitance devices, but it is much more difficult to minimize the junction capacitance of photodiodes. Some types of large area avalanche photodiodes can provide low noise along with a reasonable frequency response via manufacturing procedures that minimize the junction capacitance.

Dramatic improvements have occurred in the technological development of multisensor arrays. High

performance, cooled, back-illuminated silicon-based CCDs can have quantum efficiencies between 0.3 and 0.9 throughout the range from 200 nm to 1 μm. Dark counts are as low as 1 electron per pixel per h, making this effect practically negligible. The readout noise can also be engineered to be minimal, having a value of a few electrons. This allows CCDs to operate close to the shot-noise limit, even at low light levels. New devices have been developed that incorporate an avalanche diode structure before the CCD architecture. This allows higher gain, along with higher speed and essentially single-photon detection. Effective, cooled InGaAs-based cameras have also been developed to perform at a high level. These extend the spectral range of multielement sensor spectroscopies to 1.7–2.2 μm.

3.3 Light Discriminators and Systems

Traditionally, prisms and diffraction gratings have served as dispersive elements, with diffraction gratings being more versatile and providing higher resolution. Holographically generated diffraction gratings have advantages in producing lower stray light than conventionally ruled gratings and have the ability to be created on curved surfaces. Classically ruled gratings provide the highest efficiencies. For absorption experiments, especially those made in the UV, the presence of ‘‘stray light’’, that is, light in the measurement beam that is not at the wavelength specified by the discriminator, is an important limitation. Previous generation dual-beam spectrometers often used a combination of a prism monochromator linked with a grating monochromator. This combination provided exceptionally low stray light characteristics and allowed samples of very high absorption (up to ∼6) to be reliably measured. Except for CD spectrometers, which typically have two prism monochromators operating in tandem, grating-based spectrometers are now more common.

A Fourier Transform interferometer, often used in the infrared (the fourier transform infra-red (FTIR) technique; *see* ***Vibrational Spectroscopy***) does away with the need for a dispersive element, effectively measuring all wavelengths in parallel. Greater mechanical precision of the interferometric arm is needed to maintain good resolution in the UV-visible region compared with the IR region. The dynamic range of the instrument is determined by the precision of the analog-to-digital conversion of the light intensity and can be a limiting factor.

A very wide range of lasers, optical and electro-optic systems and components are becoming increasingly available and affordable through the ongoing revolution in photonics. For example, there is now a wide range of nonabsorptive filters, constructed using multilayer (interference) and holographic techniques that are able to reject or pass a particular wavelength or range of wavelengths with high efficiencies. There are also electro-optic tuneable filters, shutters, and intensity and polarization modulators.

Fiber optic-based systems can be readily configured and employed along with miniaturized spectrometer systems. Although such systems may not have the ultimate performance of a classical system they can be very useful and are particularly compact and transportable. Prototype systems and ‘‘virtual experiments’’ can be tested and optimized before construction by using commercial optics simulation packages. When these capacities are combined with the availability of flexible, high-level computer program packages with the capacity to intelligently control a rapidly assembled, multicomponent system, as well as display data in real time, a wide range of targeted ‘‘designer’’ optical experiments become imminently feasible. A further advantage of having a flexible system of this kind is that several types of measurements (absorption, excitation, or CD spectra, for example) can be performed, sometimes simultaneously, on one sample and taken under the same conditions. This is important for bioinorganic systems where there is often unavoidable sample variability or a limited amount of protein material.

3.4 The Optically Transparent Supporting Medium

When a chromophoric system can be dissolved in a transparent solvent and the absorption of interest adjusted to the optimal value of ∼0.9, optimal spectra can be readily obtained. Many proteins and other systems may be dispersed in a medium by detergent treatment or mulling when they are not sufficiently soluble. However, when the particle size of the dispersion becomes comparable to the wavelength of light used, there will be light scattering from the sample, evidenced by a degree of turbidity. This will give rise to characteristic apparent background absorption of the sample, increasing to shorter wavelengths. This scattering tail is sometimes modeled by the scattered light intensity provided by a Rayleigh ($1/\lambda^4$) functionality. However, apparent absorption due to scattering from either the supporting medium or the dopant chromophores will not, in general, follow this form precisely.

In addition to an apparent absorption background due to light scattering, the absorption spectrum of the dopant chromophore will be distorted by a ‘‘flattening’’ effect.[41] Regions of high optical absorption will display an apparent decrease in absorption, distorting the lineshape and creating deviations from Beer’s law. The scattering background and associated absorption artefacts in optical spectra can be reduced by collecting a maximal solid angle of the light transmitted through a sample. Essentially a large fraction of the scattered light is then detected and thus does not contribute to an apparent absorption of the sample. This is achieved either by placing a large area detector very close to the sample and/or installing appropriate collection optics. Residual ‘‘flattening’’ artefacts can be corrected when the size, shape and distribution of the scattering particles can be estimated.[41]

Chromophores can be supported in a wide range of solid solutions, microstructures and nanostructures.

Many transparent crystalline materials can incorporate chromophores, either substitutionally or interstitially. If sufficiently soluble, a chromophore may also be dissolved in a polymer film such as polyvinyl alcohol or polymethylmethacrylate. Incorporation of a chromophore can be achieved by dissolving the chromophore and polymer in a solvent. A suitable film is then quite simply created by evaporation of the solvent. Other types of supporting media are sol-gels. When a chromophore is present in the reaction medium, a rigid sol-gel embedded with the chromophore can be created.

Ionic polymers such as sulfonated teflons offer transparent media able to incorporate ionic species to very high concentrations.[42] The technique routinely used to make IR samples, where KCl and KBr discs are created by pressing a coground powder of the supporting material and compound at high pressures, can be extended to electronic spectroscopy. If the halide salt and material to be dispersed are kept particularly dry and are carefully ground, discs of good optical transparency in the UV-visible region can be created. With this grinding and pressing technique there is a danger that inadvertent solid-state chemistry occurs during the grinding and pressing procedures of sample preparation.

Condensed phase samples are useful in a range of experiments, especially for those performed at low temperatures. Perhaps the most common procedure is to use a solvent or mixture of solvents that form an optically transparent glass upon freezing. There is a range of solvents and mixtures that have found utility for different types of chromophores and some are presented in Table 1. Glassing mixtures are often freeze-thaw pumped to remove residual gases. Ethanol/methanol glasses benefit from being saturated with argon prior to freezing. The quality of the glasses that are obtained is strongly dependent on the rate of cooling, the purity (sometimes dryness) of the solvents, the concentration of the dopant, and the type of cell used. As well as creating background scatter, glass formation can also lead to cracks and/or severe strain in the sample. It is important to remember that glasses themselves are metastable and undergo transformations on a very wide range of timescales. This may lead to changes in their physical characteristics (scatter, strain), as well as spectral shifts and changes in the embedded chromophores, while experiments are being performed. The illumination of a glassy sample may itself lead to changes in the glass characteristics.

It is sometimes difficult to recognize if a sample is truly a solid solution or a fine dispersion of particles. If the solubility of the chromophore in the supporting medium is limited, it is important not to saturate the glassing mixture, as precipitation of the dopant will tend to occur upon cooling. It is not always apparent when this happens. If the precipitant is finely dispersed, its presence in a medium that by itself has substantial scatter may not be obvious.

A final caveat is with respect to any polarized experiments (linear or circular) that are contemplated on solid solutions. Many solid solutions such as polymer films or glassed solutions are prone to strain-induced birefringence. Birefringence modifies the polarization of the incident beam. This can seriously degrade the precision of a measurement, and furthermore the effect is neither spatially uniform nor necessarily constant during an experiment. A useful visual check is to view the sample between crossed polarizers. If there are no obvious bright areas in the field of the sample then useful polarized experiments can probably be performed.

3.5 Sample Cells and Sample Handling

Some of the more interesting systems studied in inorganic and bioinorganic spectroscopy may be unstable as well as air, heat, light, moisture or temperature sensitive. Procedures and protocols are required to accommodate for

Table 1 Table of some useful low temperature glass-forming solvents and solvent mixtures. Mixtures are specified by volume ratios

Glassing Medium	Quality	Typical Application
4:1 ethanol/methanol	Good	alcohol soluble
glycerol	Fair	alcohol soluble
polyethylene glycol	Fair/Poor	alcohol/polymer
polyamide	Good	protein gel medium
polysiloxane	Fair	inert medium
1:1 ethylene glycol/water	Medium	water soluble
3:2 glycerol/water	Fair	Proteins
1:1:3 ethylene glycol/glycerol/water	Good	Proteins
1:1 saturated sucrose/water	Good	Proteins
9M LiCl	Fair	high ionic strength
1:1 ethanol:ether	Fair	alcohol/ether soluble
2-methyl tetrahydrofuran	Fair	ether soluble
4:5 propionitrile/butyronitrile	Good	nitrile soluble
2:1:1 ether/ethanol/toluene	Good	mixed solvent soluble
3-methyl pentane	Good	hydrocarbon soluble
1:4 isopentane/methyl cyclohexane	Good	hydrocarbon soluble
5:2:2 ether/isopentane/ethanol (EPA)	Good	mixed solvent soluble

these characteristics and sensitivities to ensure reliability and quality of the electronic spectra that are recorded. It can be useful to construct a simple locking system in which a sensitive sample can be kept in a controlled environment while being transferred into and out of an apparatus. Samples such as photosynthetic reaction centers, which are extremely light sensitive, may need to be prepared and mounted under near-IR light (900 nm) using a night vision apparatus before being transferred to a light-tight lock and introduced into the spectrometer.

Measurement procedures using solutions in standard cuvettes are well developed. Some condensed phase samples such as large crystals and polymer films are relatively robust and easily mounted. Two areas of interest which have led to innovation are in the mounting of small, environmentally sensitive, single crystals and in the sample cells used for frozen glasses, particularly those having a substantial aqueous phase, such as proteins.

Electronic spectroscopy of single crystals often requires the use of small crystals, either because larger crystals are not available, or because larger ones are too optically dense. Crystals of proteins are characteristically soft, difficult to manipulate, and need to be kept in a humidity-controlled environment. It is however possible to measure polarized, well-resolved, low-temperature absorption spectra of small crystals while sealed in a small X-ray capillary as is exampled in Section 4.4. This approach can bypass both handling and sensitivity issues. A mask can be put above and below the capillary at the point at which the crystal is located, creating a light guide for the measurement beam. Although the overall throughput is small, the sensitivity of optical techniques allows the accumulation of good quality data, as the crystals themselves often have good optical transparency (i.e. low scatter).

Low-temperature glasses can place significant demands on the design of sample cells, especially when used with the aqueous media required by biological samples. Fused quartz cells, such as cuvettes, have excellent transmission characteristics, low thermal expansion, and are reasonably robust. However, attempts to freeze glasses with significant water content often leads to breakage of the cell. Another problem that arises is that small gaps can appear between the frozen glass and window material. This gives rises to wavelength dependence in transmitted light appearing as an oscillatory pattern, due to etaloning. This can severely limit the utility of the data.

The useful pathlength of aqueous glasses is limited to ~1–2 mm due to increasing scattering losses and uneven glassing through the sample. If a chromophore can be made more concentrated, significantly better data are obtainable from shorter pathlength cells, as scattering losses are reduced. Short pathlength (0.1–0.2 mm) cells are preferable but normal ‘‘single piece’’ designs (Figure 7) are difficult to fill and clean, often fracture, and are prone to strain birefringence. The ‘‘O-ring’’ design contains the glassing solution within a neoprene ring squeezed between two windows. Filling is accomplished by injecting the solution through the ring, while extracting the captive air with a second needle.

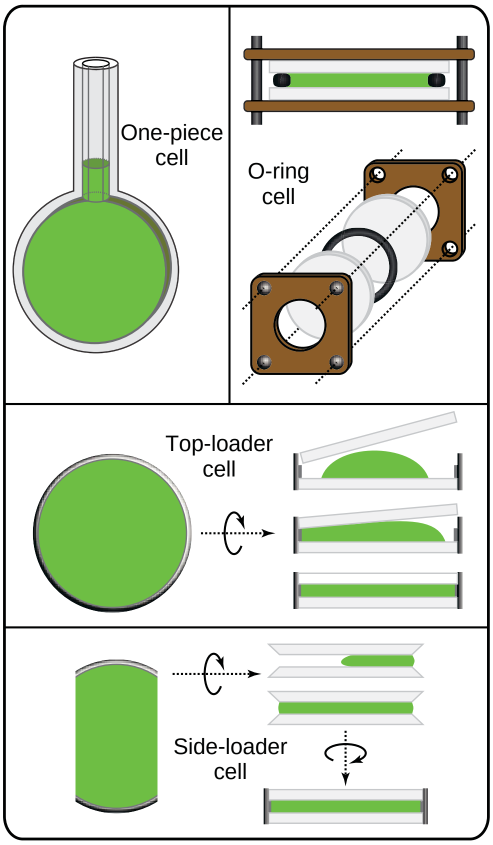

Figure 7 Designs of optical cells used in the low-temperature spectroscopy of glassy solutions

Alternative structures that largely eliminate the strain birefringence that is inherent in these designs are the ‘‘top-loading’’ and ‘‘side-loading’’ cells (Figure 7). In the top-loading cell, the bottom window is bonded to a metal ring and spacer. A calibrated volume of glassing solution is placed on it and the top window gradually angled on and fitted, excluding any air pockets. The top window effectively ‘‘floats’’ and this eliminates strain and breakages due to thermal expansion. The side-loading cell is constructed of two quartz windows, bonded to metal sections providing a fixed spacing and some strain relief. The glassing solution is wicked in from the side with a syringe and is held in the cell by surface tension. This design allows for rapid filling of a cell. This style cell can be thermally cycled to room temperature and re-glassed with good reproducibility. The metal spacers are sufficiently thin to allow strain associated with differential thermal expansion to be relieved.

When samples are unstable, or intermediates need to be studied, fast freeze techniques have been developed[43] to enable the study of reactive and unstable systems (*see* ***Freeze-Quench Kinetics***).

4 PRACTICAL EXAMPLES

4.1 Pressure Dependence of Fe(II) Spin-Crossover System

Fe(II) spin-crossover compounds are an interesting class of materials in which the low-spin $^1A_1$ state is close in energy to the high-spin $^5T_2$ state of the d^6 Fe(II) configuration. The spin-crossover process can be induced thermally or optically. The physical properties of the high-spin and low-spin states are very different. In particular, the change in volume between the two states is $\sim 25\,\text{Å}^3$. Consequently, a significant pressure dependence of the high-spin to low-spin conversion might be anticipated. The mixed crystal system $[Zn_{1-x}Fe_x(6\text{-mepy})_3tren](PF_6)_2$ ($x = 0.0005$) was studied[44,45] at 6 K in the pressure range from 1 bar to 27 kbar (Figure 8). The spin-crossover rate was found to change by the very large factor of $\sim 10^9$. These data, as well as temperature-dependent data on the spin-crossover rate allowed a number of thermodynamic properties to be determined.

The experiment was performed with one laser used to excite the conversion to the high-spin state and a second to monitor the relaxation back to the low-spin state. This approach allowed measurements over the wide dynamic range from nanoseconds to seconds. Pressures up to ~ 1 kbar were performed with a helium pressure cell and those at higher pressures with a diamond anvil apparatus.

4.2 Electroabsorption in $[Ru(bpy)_3]^{2+}$

The emitting levels of Ru(II) and Os(II) tris-immine complexes are relatively long lived metal-to-ligand charge-transfer (MLCT) states. These complexes, and their derivatives, exhibit a wide range of fascinating photophysical, photochemical, and spectroscopic[46,47] phenomena and consequently are of continuing interest and utility. A question that has often been raised is that of delocalization. Are the MLCT excited states best described as involving electron donation to a single immine ligand or all three ligands?

The electrochromism spectrum of the visible absorption region of $[Ru(bpy)_3]^{2+}$ recorded in a PVA polymer film exhibits a second derivative pattern (Figure 9) indicative of an excitation with a substantial $\Delta\mu$. A symmetric excitation of all three ligands leads to no excited state dipole moment. Electrochromism spectra of mono-immine complexes were also found to be similar to the tris-immine parent complex.[48] These results were taken as evidence for localization in the symmetric complexes.

It was later shown[49] that the E state of a degenerate MLCT in D_3 point symmetry will however show a second derivative pattern of electrochromism of comparable magnitude to that observed for the localized case. This is

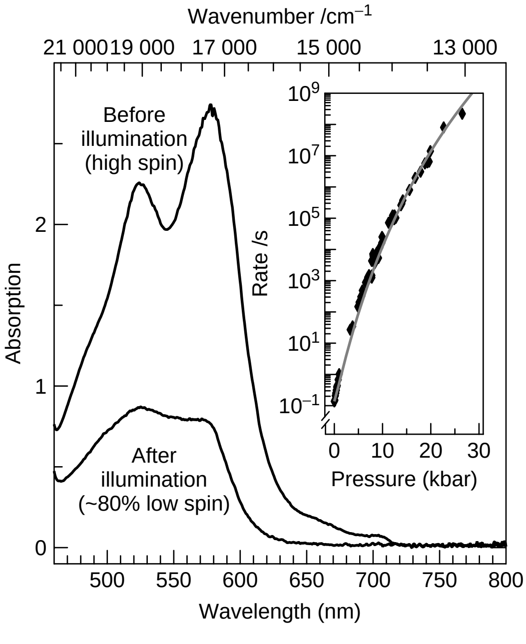

Figure 8 Absorption spectra at 6 K of $[Zn_{1-x}Fe_x(6\text{-mepy})_3tren](PF_6)_2$ ($x = 0.0005$) crystal taken before and after illumination with 514 nm light, leading to $\sim 80\%$ of Fe(II) centers being converted to the low-spin state. The inset shows the pressure dependence of the high-spin to low-spin conversion rate as a function of pressure (points) and a modeled dependence using the Grüniesen approximation (Drawn from data in Wang *et al.*[44] and Hauser *et al.*[45])

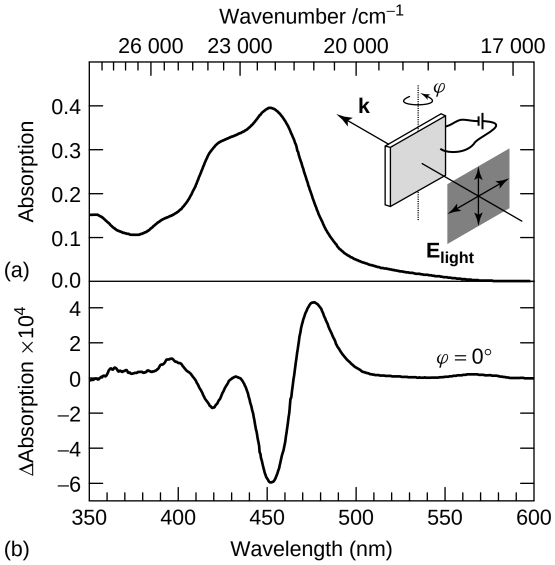

Figure 9 Absorption spectrum (a) and electrochromism (b) of $[Ru(bpy)_3]^{2+}$ dissolved in a thin polymer film at 77 K. Absorption and electrochromism spectra are taken through semitransparent conducting electrodes. Electrochromism is usually measured with the externally applied electric field parallel to the propagation direction **k** of light ($\varphi = 0°$). Experiments can also be made with the film tilted away from the normal to the propagation direction (Drawn from data in Oh and Boxer[48])

because the degenerate charge-transfer E state splits in an applied electric field. Although both delocalized and localized descriptions of the MLCT excitations give rise to comparable electrochromism, its magnitude as a function of the angle between the applied electric field and the plane of the electric field of the light, is distinctly different. The data here suggest that the intense ^{1}MLCT excitations seen in absorption are best described as delocalized. This conclusion agrees with polarized single crystal absorption data.[50] The far weaker ^{3}MLCT emitting states are widely accepted as being localized.[47]

4.3 Zeeman Hole-Spreading in $[Cr(bpy)_3]^{3+}$

Although Cr(III) systems typically show sharp $^4A_2 \rightarrow {}^2E$ intraconfigurational R-line transitions, the nominally trigonal complex $[Cr(bpy)_3]^{3+}$ dissolved in glycerol exhibits unresolved R-line structure near 730 nm.[29] Persistent spectral holes burnt in the R1 component at low temperatures establish that the correlation between R1 and R2 components of the ^2E excited state is weak. The average splitting is 67 cm^{-1}, but there is clear evidence for a significant spread in local fields that determine the R1-R2 splitting. Spectral holes burnt into the R1-line show a distinctive ''hole-spreading'' and apparent splitting in an applied magnetic field of only 0.1–0.2 T (Figure 10). Under these conditions the zero field splitting of the $^4A_2$ state and the Zeeman splittings are comparable.

By analyzing the Zeeman pattern at various field strengths, it was possible to establish that the nominal trigonal field in this D_3 complex was perturbed by lower symmetry components due to the local environment. A major influence was attributed as most likely arising from a tipping of the bpy ligands.

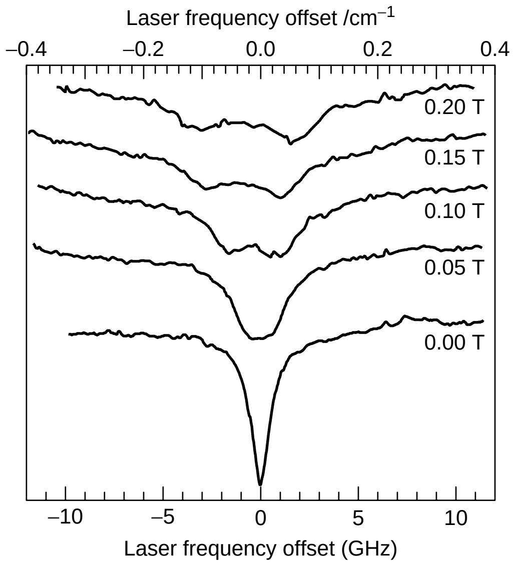

Figure 10 High-resolution excitation spectra of a persistent spectral hole burnt near 730 nm into the R1 line of $[Cr(bpy)_3]^{2+}$ dissolved in glycerol, recorded at 2 K. Spectra are shown as energy shifts with respect to the wavelength at which the hole was burnt and as a function of applied magnetic field in a range in which zero field splittings and Zeeman splittings of the ground state are of comparable magnitude. An analysis of this ''hole-spreading'' provides information on the low-symmetry fields acting in an amorphous environment (Drawn from data in Riesen *et al.*[29])

4.4 The Blastochloris viridis Reaction Center

Bacterial reaction centers crystallize readily, providing high-resolution X-ray data and structural information. Photoactivation of these crystals leads to structural changes that can be monitored in time-resolved X-ray experiments. In order to be able interpret these changes, it is important to know the actual extent and kinetics of photoactivation of the *crystallized* reaction center. It has been possible[51] to measure polarized single crystal data in the near-IR region on crystals of the same size (~200 µm) and contained within the same 1 mm capillary tubes as were used in the X-ray experiments.

The spectrum of the photogenerated cation P^+, absorbing near 1.2 µm, is shown in Figure 11. Measurements were made utilizing a small area InGaAs diode. Although the peak OD is <0.2, good sensitivity was obtained. The amplitude of this signal, as a function of both illumination and time, provided quantitative yields and kinetics of photoactivation processes. Measurement of the P^+ band in the near-IR region (which is itself not photoactive) had a significant advantage

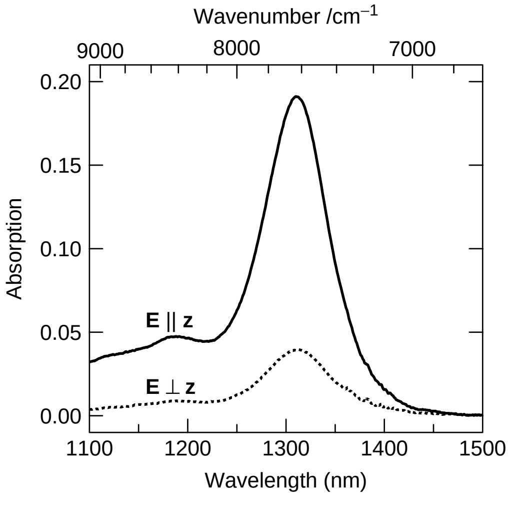

Figure 11 Polarized room temperature near-IR absorption spectra of a *Blastochloris viridis* bacterial reaction center single crystal of ~200 µm thickness. Spectra were taken with the crystal encapsulated and preserved in a thin-walled capillary while illuminated with a 633 nm HeNe laser. The spectral band seen near 1300 nm is of the photogenerated bacteriochlorophyll special pair cation P^+. The amplitude of this peak allows the extent of photoconversion of the sample and its kinetics to be directly monitored (Drawn from data in Baxter *et al.*[51])

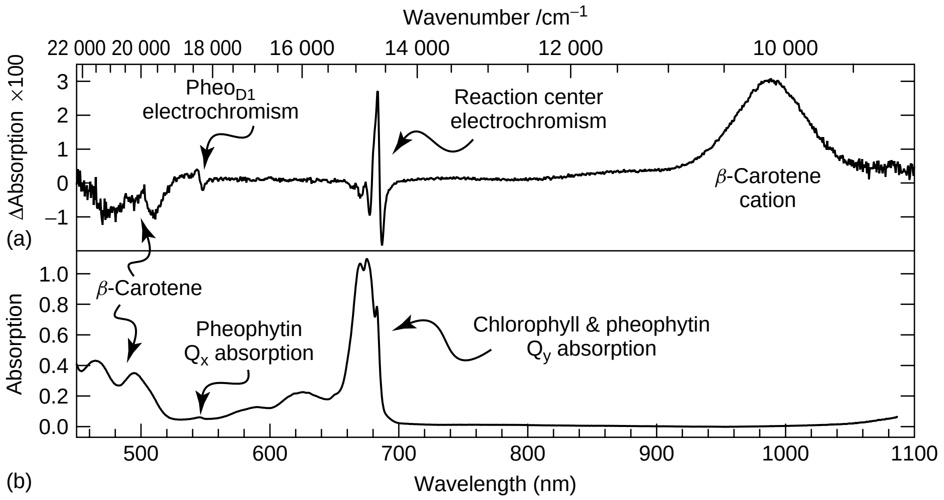

Figure 12 (a) is the absorption spectrum, taken with a single 100 ms frame on a CCD spectrograph, of an oxygen-evolving PSII core complex[52,53] at 5 K in a 40% 1:1 ethylene glycol/glycerol glass. This spectrum was taken before any illumination of the sample, leaving the plastoquinone in its neutral configuration. Also presented (b) is the difference between this spectrum and one taken immediately after illumination of the sample. This illumination served to quantitatively convert the plastoquinone to its anion. Electrochromic shifts induced on the active pheophytin$_a$ (Pheo$_{D1}$) transitions near 685 nm and 556 nm due to the electric field of the anion are accompanied by oxidation of β-carotene to its cation. (Drawn from data provided by Dr. Ronald Steffen)

compared to measurements of depletions in the P band absorption near 970 nm. Such measurements are prone to actinic effects associated with the measurement beam itself, due to the high quantum efficiency of the photoconversion process.

4.5 Low-Temperature Photochemistry in Photosystem II

Photosystem II (PSII) is a complex metallo-enzyme responsible for the light-induced oxidation of water and reduction of plastoquinone. Through its unique ability to extract electrons from water, it powers almost all life on earth. The minimal assembly able to oxidize water is a PSII core complex. This assembly incorporates a large number of interactive redox active pigments and metal centers, as well as two integral proximal antenna proteins CP47 and CP43. Attempts to simplify this minimal assembly affect its basic functionality. The multiple electron pathways that are available, combined with considerable spectral congestion and photoconversion quantum efficiencies that approach unity makes a PSII core an extremely demanding system to investigate spectroscopically.[52,53]

Figure 12 shows low-temperature absorption spectra of a PSII core complex prepared from spinach. These spectra cover a wide spectral range with good resolution, and were recorded using a single 100 ms exposure on a spectrograph based on a high performance back-illuminated and cooled CCD. Incident light levels were such that photochemical processes with yields close to unity were not significantly advanced. Spectra taken before and after a deliberate (but low intensity) illumination reveal depletions of the absorption of centers undergoing photoinduced redox transformations and also identify their photoproduct absorptions. Electrochromic shifts on pigments close to the photo-reduced plastoquinone are clearly identifiable.[37,52,53] The wide spectral range, high speed and high sensitivity of this apparatus allow the quantitative determination of the yields of redox processes, and the ability to track electron transfer pathways in PSII.

5 ABBREVIATIONS AND ACRONYMS

CD = circular dichroism; CCD = charge coupled device; EPR = electron paramagnetic resonance; FTIR = fourier transform infra-red; FWHM = full width (at) half maximum; MCD = magnetic circular dichroism; MLCT = metal-to-ligand charge-transfer; NMR = nuclear magnetic resonance; OPOs = optical parametric oscillators; PSII = photosystem II.

METHOD SUMMARY

Acronyms, Synonyms

- Electron-Nuclear DOuble Resonance
- EPR-detected NMR.

Measured physical quantities

- EPR signal intensity (CW or pulsed) as a function of applied radiofrequency (rf).

Information available

- nuclear hyperfine coupling (A) in paramagnetic systems
- nuclear quadrupole coupling (P or Q) in paramagnetic systems
- nuclear magnetic resonance (Larmor frequency, ν) in paramagnetic systems.

Information not available, limitations

- applicable only to EPR-active systems
- quantitative comparison of magnetically coupled nuclei is difficult
- analysis of overlapping signals can be difficult.

Examples of questions that can be answered

- Is there a nitrogen ligand in the paramagnetic active site?
- What is the orientation of a water molecule bound to the paramagnetic active site?
- How many iron sites are minimally in a paramagnetic FeS cluster?
- How much spin density is on a nitrogen ligand?

Major advantages

- Nuclei distant from the paramagnetic site are not detected or easily disregarded.
- All magnetically active ($I \neq 0$) nuclei in the vicinity of the paramagnetic site are detected, including nuclei unfavorable for NMR (e.g., ^{14}N, ^{57}Fe).

- Provides quantitative measure of parameters not resolved in the EPR spectrum itself.
- Isotopolog/isotopomeric samples allow identification of specific interactions.
- Can obtain ‘‘single-crystal-like’’ directional information from frozen solution samples.

Major disadvantages

- requires an EPR-active sample
- isotopic enrichment is necessary for low-abundance magnetic nuclei (e.g., ^{13}C, ^{15}N, ^{57}Fe).

Sample constraints

- Sample volume is ∼50−250 μL (volume inversely dependent on EPR microwave frequency).
- Concentration is 0.1 mM or higher (dependent on EPR signal).
- Multiple EPR-active species can complicate matters, but they can be distinguished by ENDOR and studied selectively.
- Samples must be magnetically dilute: doped powders, doped crystals, or solutions.
- Deoxygenated solutions are desirable, but not required.
- Aqueous or organic solvents are suitable and should form decent, but not optical quality, glasses.

1 INTRODUCTION

1.1 Background for Electron Magnetic Resonance in General

Magnetic resonance dates from the 1940s, with the discovery of electron paramagnetic resonance (EPR, also known as electron spin resonance (ESR) or electron magnetic resonance (EMR)) by E. K. Zavoisky in 1944 in Kazan, USSR (now Kazan, Tatarstan, Russia) preceding that of nuclear magnetic resonance by E. M. Purcell and by F. Bloch and their coworkers in 1946 in the USA.[1] This discovery of EPR was not recognized by the Nobel Prize, only that of nuclear magnetic resonance NMR was (Physics, 1952). Subsequent Nobel Prizes have been awarded for work related to NMR (Chemistry, 1991, 2002; Medicine, 2003), but none for work related to EPR.

By the early 1950s, EPR had already proved to be a powerful tool in the study of inorganic complexes, especially those of transition metal ions. Much of this early work is summarized in a review by McGarvey[2] and in the monumental text by A. Abragam and B. Bleaney (A^2B^2),[3] as well as in references to EPR in general, e.g., by Weil, Wertz, and Bolton (WWB),[1] Gordy,[4] and Pake.[5] The usefulness of EPR stems from its providing information on electronic structure as revealed by the g values of an EPR signal of a system with a single unpaired electron ($S = 1/2$) and by the fine structure (zero-field splitting (zfs); D, E values; *see* ***Magnetic Circular Dichroism (MCD) Spectroscopy***) for a system with multiple unpaired electrons ($S \geq 1$; *see* Section 3.5 in A^2B^2).[3] In addition, in cases where there are magnetically active nuclei ($I > 0$), there can be hyperfine structure. Hyperfine coupling is readily observable in the EPR spectra of organic radicals for which the EPR linewidths are narrow and there is usually a variety of magnetically inequivalent protons (^1H, $I = 1/2$) that are magnetically coupled to the radical spin. This phenomenon is analogous to the spin−spin coupling observed in NMR of diamagnetic systems. In the case of inorganic systems, hyperfine coupling can sometimes be observed when the paramagnetic metal ion has magnetically active nuclei. Classic examples are $3d^{1,9}$ ($S = 1/2$) systems such as Cu^{II} with 100% natural abundance of the two isotopes ^{63}Cu and ^{65}Cu (both $I = 3/2$ with very similar g_N values) and V^{IV} (e.g., as vanadyl) with 100% natural abundance ^{51}V ($I = 7/2$). These two ions yield, respectively, four-line and eight-line (number of lines $= 2nI + 1$, where $n = 1$ for the sole metal ion) hyperfine-split EPR spectra. In many cases, however, the metal ion has no nonzero spin nuclei of significant natural abundance. For example, iron has only ^{57}Fe ($I = 1/2$) with only 2.15% natural abundance.

In addition to hyperfine coupling between the unpaired electrons and the transition metal ion nucleus, there can be hyperfine coupling to magnetically active nuclei directly coordinated to the metal ion. Examples include ligands such as fluoride (^{19}F, $I = 1/2$, 100% natural abundance), phosphines (^{31}P, $I = 1/2$, 100% natural abundance), and various nitrogen donors (^{14}N, $I = 1$, 99.63% natural abundance; *see* ***Nuclear Quadrupole Resonance (NQR) Spectroscopy***). For example, porphyrin complexes of Cu^{II} often exhibit resolved hyperfine splitting from the four pyrrole nitrogen ligands.[6] The ^{14}N hyperfine coupling, combined with that for $^{63,65}Cu$ can be analyzed to provide a complete description of the semi-occupied molecular orbital (SOMO) in the complex.[6] However, in many cases, hyperfine coupling information from neither the metal ion nor any ligands is available by EPR. This is the result not only of the absence of magnetically active nuclei in sufficient abundance (e.g., Fe^{III} with oxygen and/or sulfur-donor ligands), but also from a lack of spectral resolution. If the hyperfine couplings are small in magnitude but large in number (i.e., a large number of closely spaced lines resulting from $\sum(2n_i I_i + 1)$, where i is a given set of magnetically equivalent nuclei), then

resolution of the splitting is often impossible due to spectral overlap. Of more relevance to inorganic, and especially metalloprotein systems, the natural EPR linewidths may be too broad to allow resolution of individual hyperfine splittings. Proteins can exhibit conformational distribution,[7] and such distributions can affect the coordination environment of the paramagnetic center in a metalloprotein, leading to broad EPR linewidths in frozen solution for what is nominally a single paramagnetic center.

An example of the type of EPR spectrum with which one is often confronted in metallobiochemistry is shown in Figure 1, which presents the 35 GHz EPR spectrum recorded at 2 K under rapid-passage conditions[8–10] of an oxidized heme protein. The signal is due to a low-spin ($S = 1/2$) Fe^{III} porphyrin axially coordinated by cysteine-75 as the proximal ligand and most likely proline-2 as the distal ligand, as found in the CO-sensing transcription factor CooA isolated from *Rhodospirillum rubrum*.[11] The EPR signal exhibits several features that are often found in studies of metalloproteins. The signal is rhombic (i.e., it shows three distinct g values: g_{min}, g_{mid}, and g_{max}), which is indicative of the lower symmetry often found in metalloprotein systems. The specific g values are typical for many low-spin Fe^{III} systems,[12] but are not particularly useful in themselves. There is no observable metal hyperfine coupling, given that the metal is iron. Although there are nitrogen-donor axial and equatorial ligands, none yields resolvable hyperfine coupling. This lack of resolution is not surprising given that the EPR linewidths are relatively broad and anisotropic (single-crystal Gaussian linewidths range from 200–500 MHz; ca. 7–18 mT), which is indicative of local conformational heterogeneity. Lastly, the sample is globally heterogeneous in that there are two resolvable components, in roughly a 2:1 ratio. This heterogeneity is proposed to be the result of pH effects on the axial ligation,[11] but is not germane to the present discussion. What is important is that this paramagnetic metalloprotein, like many others, exhibits a broad, low symmetry, heterogeneous EPR spectrum that provides generic information about the metalloprotein, but provides little detailed information. Such systems are good candidates for electron-nuclear double resonance (ENDOR) spectroscopic investigation, which can extract information on the metal ion coordination environment and ideally even provide mechanistic information that is simply not obtainable from EPR alone, nor from other techniques. A specific case study demonstrating this success will be described below (Section 4.1).

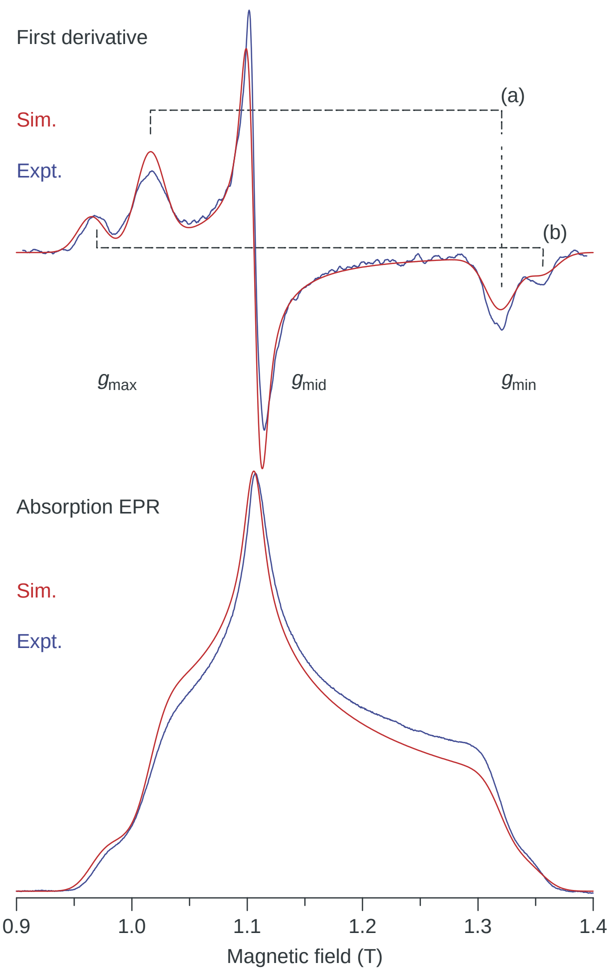

Figure 1 Experimental and simulated EPR spectra of oxidized CooA at pH 7.4. Experimental conditions: temperature, 2 K; microwave frequency, 35.106 GHz; microwave power, 20 µW; 100 kHz field modulation amplitude, 0.4 mT; time constant, 128 ms; scan time, 4 min. Lower traces, in absorption lineshape (due to rapid-passage conditions), are the experimental spectrum (blue) and a digital integration of the simulated spectrum (red). Upper traces in first-derivative lineshape are a digital derivative of the experimental spectrum (blue) and the simulated spectrum (red). Simulation parameters: component (a) $\mathbf{g} = [2.60, 2.268, 1.85]$, (b) $\mathbf{g} = [2.47, 2.268, 1.90]$; Gaussian single-crystal linewidths (half-width at half-maximum): $W = [500, 200, 400]$ MHz. Simulated spectra for (a) and (b) are added in the ratio 2:1 to give the summed spectrum shown

1.2 Historical Background for ENDOR

The above discussion defines the problem in that EPR-active metalloprotein systems often exhibit readily observable but relatively uninformative spectra, with broad linewidths and unresolved hyperfine splitting. In contrast, NMR exhibits narrow lines and nuclear-specific signals with chemical shift and spin coupling information, but is inherently insensitive due to the tiny size of nuclear magnetic moments relative to that of an electron. It would therefore be desirable to combine the signal sensitivity of EPR with the nuclear information of NMR. This was first achieved not in bioinorganic chemistry, or even in chemistry at all, but in the area of solid state physics by George Feher at Bell Telephone Laboratories in the 1950s,[13–16] only a decade after EPR and NMR were themselves discovered. The technique was the ‘‘observation of NMRs via the electron spin resonance line’’, as Feher entitled his first paper.[13] This phrase describes better than anything else the essence of the technique to which Feher

soon gave the appealing acronym of ENDOR,[15] for ''*e*lectron-*n*uclear *do*uble *r*esonance''. [The word ''Endor'' first appears in the Old Testament, Joshua 17:11, and refers to a place name (http://en.wikipedia.org/wiki/Endor_%28village%29; accessed 02/28/2007).] The initial systems studied were paramagnetic centers (defects/dopants) in solid state semiconductor materials (e.g., silicon), with relevance to the work on transistors going on at Bell Laboratories at the time. The rationale for ENDOR and some of Feher's early work is summarized in Sections 4.1–4.4 of A^2B^2.[3] After moving to the newly established University of California at San Diego, Feher pioneered the application of ENDOR to metalloproteins, such as hemoglobin and myoglobin,[17–19] and later in the area of photosynthetic reaction centers.[20,21]

1.3 Overview of Current Status of ENDOR in Bioinorganic Chemistry

ENDOR is not a technique widely practiced in chemistry, as it requires specialized EPR instrumentation, however the use of ENDOR has led to significant advances in the area of bioinorganic chemistry. Among the current practitioners of ENDOR are two former students of Feher, Charles P. Scholes at SUNY-Albany and Wolfgang Lubitz at the Max Planck Institute for Bioinorganic Chemistry, Mülheim/Ruhr, Germany. Among the systems studied by Scholes and coworkers are heme proteins[22] and multicopper enzymes.[23] Among the systems studied by Lubitz and coworkers are photosynthetic reaction centers[24,25] and nickel hydrogenases.[26] David J. Lowe at the John Innes Center, Norwich, UK, is also active in the area of metallobiomolecule ENDOR.[27] The contributions of the late Arthur Schweiger, ETH-Zürich, must also be noted, recently in cobalt and nickel bioinorganic systems.[28,29] Other workers such as R. D. Britt, D. Goldfarb, and A. M. Raitsimring focus more on electron spin echo modulation (ESEEM) techniques (*see* ***Electron Spin Echo Envelope Modulation (ESEEM) Spectroscopy***). Brian M. Hoffman at Northwestern University is best known to the author. His group has made contributions in many areas of bioinorganic chemistry by use of ENDOR spectroscopy.[30–35] One case study, which has several components, is selected from among the many such examples for illustration of the application of ENDOR toward bioinorganic systems: nitrogenase.

2 TECHNICAL BACKGROUND

2.1 General Theory Background for ENDOR Spectroscopy

As mentioned above, ENDOR is the detection of NMR resonances by observing their effect on an EPR signal, whether in continuous wave (CW) or pulsed mode. The NMR transitions are effected by application of radiofrequency (rf) energy, as with NMR. In NMR (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Inorganic/Organometallic Molecules*** and ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Metallobiomolecules***), the selection of signals is determined by the rf energy being specific for the resonant (Larmor) frequency of a particular nucleus (e.g., 300 MHz for ^{1}H with an external magnetic field of $\sim$7 T) and the frequency range of signals is very narrow (at least in diamagnetic NMR: typically $<$1 kHz total, ppm). Signals from other NMR active nuclei appear at other (lower) rf energies, which might also involve the use of different NMR probes, and are also in relatively narrow ranges. Thus one records a ^{1}H NMR spectrum, or a ^{13}C NMR spectrum, and so forth.

In ENDOR, one records, at least in principle if not in practice, a spectrum that exhibits resonances from *all* magnetically active nuclei (nuclear spins) that are hyperfine coupled to the paramagnetic center (electron spin(s)). The position of these resonances can vary greatly, depending on the nature of their interaction with the paramagnetic center. A given scan might exhibit ENDOR signals due only to ^{1}H nuclei coupled to the center, as these might appear at rf energies well separated from other coupled nuclei, and experimental parameters might favor ^{1}H NMR transitions as opposed to those of other nuclei, but there is no such thing as a ^{1}H ENDOR spectrum in the same way as there is a ^{1}H NMR spectrum. Nevertheless, terms such as ^{1}H ENDOR, ^{13}C ENDOR, are extremely useful at indicating the nucleus of interest in a given experiment.

2.2 ENDOR Transitions for a Simple Spin System

2.2.1 *First-Order ENDOR Transitions for an $S = 1/2, I = 1/2$ System*

Where do these ENDOR transitions appear? The answer can be seen by consideration of the simplest system relevant to ENDOR: a single unpaired electron ($S = 1/2$) interacting with a single nucleus with $I = 1/2$ (e.g., ^{1}H, ^{13}C, etc.). The energy level diagram of such a system is shown in Figure 2. If we ignore any anisotropy in g values (e.g. for an unpaired electron in an s orbital, any orbital angular momentum effects will be absent), then there would be a single EPR signal observed (at $g_e = 2.0023$; a resonant field of 0.339 T at 9.50 GHz microwave frequency—X-band). If the NMR signal of the nucleus could be observed, then it would show a single line as well. However, if there is a hyperfine interaction (here assumed isotropic[36]) between the electronic and nuclear spins, then this effect would lead to a splitting of the EPR signal into two peaks (''doublet''). There would likewise be a splitting of the NMR signal, which in this case would be observed by ENDOR. The electronic Zeeman interaction (given by the spin Hamiltonian: $\boldsymbol{H} = \beta_e B{\cdot}\mathbf{g}{\cdot}S$, where β_e is the Bohr magneton (9.2740×10^{-24} J/T), B is the magnetic field (T), and **g** is a matrix—relevant for anisotropy)

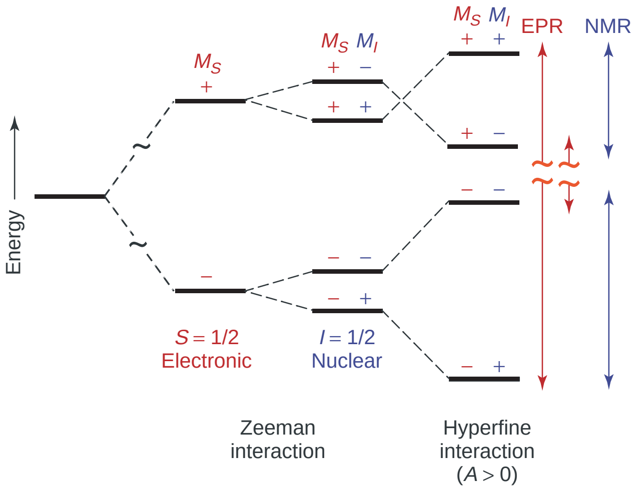

Figure 2 Energy level diagram for system of $S = 1/2$ and $I = 1/2$. The M_S, M_I values are shown (rather than use of α, β). The assignment of these values is based on g_N, $A^N > 0$, with the magnetic field along z. The EPR transitions are indicated in red and the NMR (ENDOR) transitions in blue. The transition energies are not to scale; at X-band the EPR transition energies are ~9 GHz (~0.3 cm^{-1}), while the NMR transition energies are ~15 MHz (for ^{1}H)

is almost always larger than the hyperfine interaction (given by the spin Hamiltonian: $\boldsymbol{H} = S{\cdot}\mathbf{A}{\cdot}I$, where **A** is the hyperfine coupling matrix—relevant for anisotropy). Thus the EPR signal would be centered at its resonant field determined by its g value (0.339 T) and split by the hyperfine coupling, **A**, which could vary greatly in magnitude but typically is in the field range of mT (MHz in energy), thus ~1% of the electronic Zeeman effect. In contrast, the nuclear Zeeman interaction (given by the spin Hamiltonian: $\boldsymbol{H} = -\beta_N g_N B{\cdot}I$, where β_N is the nuclear magneton (5.0508×10^{-27} J T^{-1}), and g_N is the nuclear g value, which is treated as isotropic for EPR and ENDOR) is small and is on the same order of magnitude as the hyperfine coupling. Thus, the ENDOR transition can either remain at the NMR (Larmor) transition and be split by the hyperfine interaction, or be dominated by the hyperfine interaction and be split by the Larmor energy. The following equation defines these two situations:

$$\nu_{\pm}^{N} = \left| \frac{\nu^N \pm A^N}{2} \right| \quad (1)$$

where $\nu_{\pm}^{N}$ is the resonant frequency of the pair of ENDOR signals for a given nucleus N (separately, ν_{+}^{N} and ν_{-}^{N}), ν^N is the NMR (Larmor) frequency of N, and A^N is the hyperfine splitting (all parameters are typically in MHz). In the case of dominant nuclear Zeeman splitting, the $\nu_{\pm}^{N}$ signals are centered at the Larmor frequency and split by the hyperfine coupling. In the case of dominant hyperfine splitting, the $\nu_{\pm}^{N}$ signals are centered at half the hyperfine coupling constant and split by twice the Larmor frequency. The former situation, a Larmor-centered hyperfine-split doublet, is typically found for ^{1}H, which has a very large g_N value, and yields, e.g., $\nu_- \approx$ 14 MHz, $\nu_+ \approx$ 16 MHz at X-band (where $\nu^{1\text{H}} \approx$ 15 MHz, $A^{1\text{H}} \approx$ 2 MHz). The corresponding figure is often presented with the abscissa given as a difference frequency ($\nu - \nu^N$; in MHz) so that spectra at multiple magnetic fields can be easily compared to show hyperfine coupling. The latter situation, a Larmor-split hyperfine-centered doublet, is typically found for ^{57}Fe, which has a very small g_N value but large hyperfine coupling since the nucleus is usually an intrinsic part of the paramagnetic center. Such a situation at X-band would yield, for example, $\nu_- \approx$ 14.5 MHz, $\nu_+ \approx$ 15.5 MHz at X-band (where $\nu^{57\text{Fe}} \approx$ 0.5 MHz, $A^{57\text{Fe}} \approx$ 30 MHz). The abscissa of the corresponding figure would simply be rf (ν; in MHz). Actual examples of these types of spectra will be shown below in the case study on nitrogenase (Section 4.1).

2.2.2 *Microwave Frequency Effects in ENDOR*

The above example also illustrates a potential difficulty with ENDOR, namely that since different nuclei can simultaneously contribute to an ENDOR spectrum, signals from different nuclei can overlap (at the commonly used X-band microwave frequency). Such signals cannot always be readily analyzed or even distinguished. Pulsed ENDOR methods can address this problem (*see* Section 3.3.4), but the most effective method to overcome this problem is by use of higher microwave frequencies (and correspondingly higher resonant magnetic fields). This development has occurred much as NMR has progressed to ever higher rf energies in the quest for greater spectral (chemical shift) dispersion (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Inorganic/Organometallic Molecules*** and ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Metallobiomolecules***). In the case of ENDOR, a shift from X-band (9–10 GHz) to 35 GHz (commonly referred to as Q-band), is usually sufficient to move the field-dependent (Larmor) component, while the field-independent (hyperfine) component is unaffected. In the above example, use of 35 GHz would shift the ^{1}H ENDOR signals to $\nu_- \approx$ 52 MHz, $\nu_+ \approx$ 54 MHz (since now $\nu^{1\text{H}} \approx$ 53 MHz) while the ^{57}Fe signals would remain relatively unaffected: $\nu_- \approx$ 13.3 MHz, $\nu_+ \approx$ 16.7 MHz (since now $\nu^{57\text{Fe}} \approx$ 1.7 MHz).

This use of 35 GHz ENDOR in bioinorganic chemistry was pioneered by Hoffman in the late 1980s[33] and is now widely used in this area.[22,25] More recently, ENDOR at W-band (95 GHz)[37–40] and even higher frequencies (140 GHz)[41,42] have been successfully applied to bioinorganic systems.

2.3 ENDOR Transitions for More Complicated Spin Systems

2.3.1 *General Background*

The above example is for the case of a *single* nucleus with $I = 1/2$. In a typical metalloprotein system, there

are multiple nuclei, magnetically and chemically distinct, coupled to the paramagnetic center. Such a situation could lead to complex hyperfine splitting patterns, if actually resolved, in an EPR spectrum. The ENDOR spectrum, in contrast, would have only a single pair of $\nu_{\pm}^{N}$ signals for each magnetically inequivalent set of nuclei, which could be analyzed individually. In the case of ^{1}H, a typical metalloprotein exhibits overlapping signals from numerous hydrogen atoms associated with the cofactor(s), protein residues, and solvent in the vicinity of the paramagnetic site, usually a metal ion or cluster. In this case, assignment of ENDOR signals to individual hydrogen sites is difficult, except when the coupling is large relative to that of the bulk. Use of isotopic labeling can also assist greatly, as discussed below (*see* Section 4.1). For magnetically active nuclei that are common, but less ubiquitous than ^{1}H, such as ^{14}N, it is often possible to identify and analyze individual signals, even within a group of several signals. Examples include heme pyrrole nitrogen ligands in peroxidases,[43,44] corrinoid pyrrole/pyrrolidine nitrogen ligands in Ni-F_{430},[45] or histidine nitrogen ligands in Rieske iron–sulfur proteins.[46,47]

2.3.2 ENDOR Signal Quantification

One caveat that must be made is that ENDOR signal intensities, in contrast to those in diamagnetic NMR, are not reliable indicators of the relative numbers of magnetically equivalent nuclei. The process by which an NMR transition affects the EPR signal intensity that is being monitored to yield a given ENDOR signal is complicated.[14,48] Many relaxation factors are involved, both nuclear and electronic (*see* Sections 4.5–4.6 in A^2B^2)[3] in addition to simply numbers of nuclei. Thus ENDOR can identify sets of magnetically equivalent nuclei, but generally cannot provide the relative numbers of each of these sets. Because of anisotropy of electronic Zeeman (i.e., g value) and hyperfine coupling (i.e., **A** value) effects, magnetic equivalence among ENDOR-active nuclei in a metalloprotein system is relatively uncommon, so that this drawback is usually not a great concern. Furthermore, in certain cases it is possible to combine the hyperfine information accurately determined by ENDOR with EPR linewidth information to assist in quantification. To state this more elegantly: ''ENDOR can measure, EPR can count.''[48] A specific example is the combined multifrequency EPR and 35 GHz ENDOR study of the di-iron center in the R2 subunit of *Escherichia coli* ribonucleotide reductase (RNR).[49] Samples in natural isotopic abundance (0.038% ^{17}O) and using $H_2^{17}O$ (34.9% ^{17}O) or $^{17}O_2$ (85.5% ^{17}O) were prepared. ENDOR provided ^{17}O ($I = 5/2$) hyperfine coupling constants and these values were used to quantify the line broadening seen in ^{17}O-enriched versus natural abundance samples, which showed that the intermediate X contained two oxygen atoms, initially derived from dioxygen, as opposed to an alternate model with only one such oxygen atom.

2.3.3 ENDOR of Electronic High-Spin (S > 1/2) EPR Systems

Other caveats are related to equation (1) being appropriate only for nuclei with $S = 1/2$ (''low-spin'') and $I = 1/2$, as opposed to $S > 1/2$ (''high-spin''). The term ''high-spin'' in the sense of EPR spectroscopy means simply $S > 1/2$ (i.e., a system with more than one unpaired electron), but this term in the sense of ligand-field theory[50] means the electronic configuration with higher S in an idealized octahedral coordination environment, e.g., high-spin d^5 is the configuration $^6A_{1g}$ and low-spin d^5 is $^2T_{2g}$. When $S = 1/2$, there is only one EPR transition: $-1/2 \leftrightarrow +1/2$, however, systems with $S > 1/2$ have the added complication that there are multiple EPR (fine structure) transitions, e.g., $\langle S, M_S| = \langle 3/2, -3/2| \leftrightarrow \langle 3/2, -1/2| \leftrightarrow \langle 3/2, +1/2| \leftrightarrow \langle 3/2, +3/2|$. Each of these can in principle be monitored under the application of rf energy to yield ENDOR signals. If these fine structure transitions overlap, then all can contribute to a given observed ENDOR signal, but the different M_S manifolds will scale the ENDOR transitions proportionately.[51]

$$\nu_{\pm}^{N} = \left| \frac{\nu^N \pm (2|M_S|)A^N}{2} \right| \tag{2}$$

Equation (2) is a first-order generalization of equation (1) wherein the M_S scaling factor has been explicitly included ($2|M_S| = 1$ for $S = 1/2$).

Such a situation can occur for Mn^{II} ($S = 5/2$) where the zfs is often small (relative to the microwave energy, e.g., $|D| < 0.1\,\text{cm}^{-1}$, where the zfs Hamiltonian is given as: $\boldsymbol{H} = S{\cdot}\mathbf{D}{\cdot}S = D[S_z^2 - (1/3)S(S+1)]$ for a uniaxial system) and the fine structure peaks overlap. With careful computer simulation analysis, it is possible to unravel such potentially complex spectra.[25,52] In cases where the zfs is large relative to the microwave energy (e.g., $|D| > 1\,\text{cm}^{-1}$), then only the $\langle S, M_S| = \langle\, 5/2, -1/2| \leftrightarrow \langle 5/2, +1/2|$ transition is observed (for $D > 0$) and the EPR spectrum can be treated as a ''fictitious spin'', $S' = 1/2$, system and lacks multiple fine structure transitions. Such a situation can obtain for Fe^{III} ($S = 5/2$) with relatively strong-field ligands such as heme. In this case, the ENDOR spectrum for a given nucleus would appear to be exactly the same as that in a true $S = 1/2$ system.

However, this appearance can be misleading because the apparent hyperfine coupling of a given nucleus, A^N given in equation (1), would not correspond to the actual hyperfine coupling of that nucleus. This is because of the ''g-over-g effect'', which results from use of the fictitious spin $S' = 1/2$, rather than the real spin $S = 3/2$, 5/2. The relation between the actual and observed hyperfine coupling matrices is given as follows:

$$\mathbf{A}' =^{g} \mathbf{A}{\cdot}\mathbf{g}' \tag{3}$$

where $\mathbf{A}'$ is the hyperfine coupling matrix in the fictitious spin representation (i.e., as observed using equation (1)),

${}^{g}\mathbf{A}$ is the hyperfine coupling matrix in the true spin representation and in the electronic (**g**) frame of reference (i.e., the actual hyperfine coupling collinear with **g**), and $\mathbf{g}'$ is the g matrix in the fictitious spin representation.[53,54] The following equations represent the individual elements of these matrices.

$$A'_{ij} = \frac{{}^{g}A_{ij}g'_j}{g_j} \quad g'_{ij} = \frac{\delta_{ij}g'_j}{g_j} \tag{4}$$

where i refers to the elements of the operator $\hat{I}$, j to the elements of the operator S, $A^{(\prime)}_{ij}$, $g^{(\prime)}_j$ are the individual elements of the matrices in equation (3) and δ_{ij} is related to the coordinate transformation from the real electronic to the fictitious nuclear spin system, which is relevant for noncollinearity. To put this in practical terms, the elements of **g** (i.e., g_j) are usually close to 2.00 (g_e), especially for high-spin d^5 systems, while the values of g'_{ij} are equal to $(2S-1)$ for $g_{x,y}$ and equal to 1 for g_z (D along z), giving $g'_{x,y}$ ($g_\perp$) ≈ 6 (for $S = 5/2$; $g'_{x,y} \approx 4$ for $S = 3/2$) and g_z ($g_{||}$) ≈ 2. Thus, for an $S = 5/2$ system, ENDOR observed at $g_\perp$ would appear to be three times larger than the actual value, and for an $S = 3/2$ system, twice as large. As an example we consider ^{57}Fe ENDOR at X-band of the resting state of the ^{57}Fe-enriched iron–molybdenum cofactor (FeMo-cofactor) of *Azotobacter vinelandii* (*Av*) nitrogenase, which has $g_\perp = 2.005$, $g_{||} = 2.01$ as the intrinsic g values in the true, $S = 3/2$ representation.[53,54] ENDOR signals from five distinct iron centers were observed. Among these we select two sites, denoted B^1 and B^2, which at $g'_y = 4.32$ (the low field edge of the EPR signal) each gave $\nu_\pm$ signals centered respectively at ~12.5 MHz and at ~9 MHz. By equation (1), these would be interpreted as corresponding to $A_y(\mathrm{B}^1) \approx 25$ MHz and $A_y(\mathrm{B}^2) \approx 18$ MHz, but this interpretation is wrong! These observations are actually of A'_y values and in the true spin representation (by equation 4) correspond to $A_y(\mathrm{B}^1) = 11.34$ MHz and $A_y(\mathrm{B}^2) = 8.86$ MHz. Next consider two ^{57}Fe ENDOR $\nu_\pm$ signals observed at $g'_z = 2.01$ (the high field edge of the EPR spectrum): one centered at ~6 MHz denoted b^1, and another centered at ~5 MHz denoted b^2. In this field, $g'_j \approx g_j$, so that now the observed couplings do correspond directly to $A_z(\mathrm{b}^1) = 11.58$ MHz and $A_z(\mathrm{b}^2) = 9.84$ MHz.[53,54] Thus the B^{1,2} and b^{1,2} sites are likely the same, which is reasonable given that ^{57}Fe hyperfine coupling in FeS clusters is generally rather isotropic.[55]

The above discussion is a major concern in ENDOR of high-spin systems with large zfs. In addition, the experimental Larmor frequency (ν^N) might differ from that expected for nucleus N at the magnetic field of observation. This discrepancy is due to the pseudonuclear Zeeman (pnZ) effect (see A^{2}B^2, Section 1.8(e)),[3] which results from mixing of the higher M_S manifold(s) (e.g., $\langle S, M_S| = \langle 5/2, \pm 3/2|$) into the ground state $\langle S, M_S| = \langle 5/2, \pm 1/2|$) leading to an effect similar to that seen for ENDOR transitions actually within these higher M_S manifolds. The pnZ effect was observed and analyzed in the ^{57}Fe ENDOR studies of *Av*-nitrogenase FeMo-cofactor mentioned above.[53,54] Another example is in the ^{19}F ENDOR of fluorometmyoglobin,[56] which has $S = 5/2$, but is treated as $S = 3/2$ in terms of the pnZ because the $\langle S, M_S| = \langle 5/2, \pm 5/2|$ manifold is so much higher in energy (>30 cm^{-1}) than the ground state so as to have insignificant mixing.

The pnZ effect acts to convert the isotropic g_N into a (essentially axial) tensor with the following components:[54]

$$g_{Nij} = g_N\left[\delta_{ij} + \left(\frac{3}{2}\right)\left(\frac{g_e\beta_e}{g_N\beta_N}\right)\left(\frac{{}^{g}A_{ij}}{\Delta}\right)(1-\delta_{i3})\right] \tag{5}$$

where the terms are as defined above and $\Delta = 2D[1 + 3(E/D)^2]^{1/2} \approx 2D$ for nearly axial systems. Assuming collinear **A** and **g** (so that: $\delta_{ij} = 1, i = j$; $\delta_{ij} = 0, i \neq j$), $g_{N(3(z))} = g_N$, thus, there is no pnZ effect at $g_{||}$ (g_z), but at $g_\perp$ ($g_{x,y}$), $g_{N(2,3(x,y))} = g^N[1 + (3/2)(g_e\beta_e/g_N\beta_N)({}^{g}A_{ij}/\Delta)]$, and the effect can be large, particularly when the zfs is small and/or when the hyperfine coupling is large (and g_N is small). All of these criteria are met for ^{57}Fe in resting state nitrogenase FeMo-cofactor. For rhombic systems, mixing of the $\langle S, M_S| = \langle 3/2, \pm 3/2|$ and $\langle S, M_S| = \langle 3/2, \mp 1/2|$ manifolds (via the zfs Hamiltonian: $\boldsymbol{H} = S\cdot\mathbf{D}\cdot S = D[\hat{S}_z^2 - (1/3)S(S+1)] + E(\hat{S}_x^2 - \hat{S}_y^2)$ for a rhombic system) leads to a small pnZ effect at g_z as well as a slight divergence between $g_{N(2(x))}$ and $g_{N(3(y))}$.

2.3.4 ENDOR of Nuclear High-Spin ($I > 1/2$) (Quadrupolar) Systems

Equation (1) is the ''fundamental equation of ENDOR'', however it is applicable only to nuclei with $I = 1/2$. The energy levels of quadrupolar nuclei ($I \geq 1$) are affected not only by the nuclear Zeeman interaction and hyperfine coupling with the paramagnetic center, but also by the electric field gradient at the nucleus. This effect is nuclear electric quadrupole coupling (*see* ***Nuclear Quadrupole Resonance (NQR) Spectroscopy***), which has spin Hamiltonian $\boldsymbol{H} = I\cdot\mathbf{P}\cdot I$, where **P** (also sometimes given as **Q**) is the traceless quadrupole coupling tensor. The diagonal components of this tensor are often given as $P_{||} = (3/2)P_z$, $\eta = (P_x - P_y)/P_z$ ($\eta = 0$ for axial systems), and $P_{||} = [3e^2Qq/4I(2I-1)]$, where Q is the quadrupole moment of a given nucleus and q is the electric field gradient at the nucleus (*see* A^{2}B^2, Section 3.7).[3] The first-order ENDOR resonance positions must then be modified to include this interaction as follows:

$$\nu_\pm^N = \left|\frac{A^N}{2 \pm \nu^N} + \frac{3P^N(2m-1)}{2}\right| \tag{6}$$

where $m = (-I+1), \ldots, (I-1), I$. As a result, for $I = 1$, the simplest case, there are two doublets (in general, each peak splits into $2I$ lines) each separated by $3P^N$ with the doublets separated by twice the Larmor frequency and the entire pattern centered at half the hyperfine coupling,

assuming $P^N < \nu^N < A^N/2$. For bioinorganic systems, the most important quadrupolar nucleus is ^{14}N, followed in importance by ^2H (D), the latter in isotopically enriched samples. Both of these have $I = 1$. A distant third in importance is ^{17}O, again in enriched samples, for which resolved, first-order spectra are seldom observed, due in part to the large nuclear spin ($I = 5/2$) and corresponding number of lines, as well as noncollinearity of nuclear and electronic coordinate systems.

2.4 Anisotropy in ENDOR

A nuclear quadrupole interaction is by definition anisotropic (parameters: $P_{||}$, η) as is an electronic quadrupole interaction (i.e., zfs; parameters: D, E), since these are described by a nonzero field gradient. Both of these effects have been briefly mentioned above, but the most important manifestation of anisotropy in ENDOR is with respect to g values and to hyperfine coupling interactions.

2.4.1 Electronic (g value) Anisotropy

Anisotropy in g values results from the contribution of orbital angular momentum to electron spin energy levels, which can provide valuable information on the orbitals involved.[2–4] From the point of view of ENDOR spectroscopy, g value anisotropy provides a mechanism whereby a powder pattern EPR signal can provide orientational information.[57–60] The details of this are described in the literature, of which the recent exposition by Doan is the most readable.[60] Very briefly, a powder pattern (whether as an actual powder or a frozen solution, as is usually the case in bioinorganic systems) EPR spectrum can be thought of as the superposition of single-crystal spectra, which give rise to the ''Pake'' pattern,[5] as seen in Figure 1. A given g value of observation (i.e., magnetic field at the resonant microwave frequency, g_{obs}) thus corresponds to some set of single-crystal orientations that make up the powder pattern at that g_{obs}. At the field extrema of the pattern, relatively few orientations contribute and these g_{obs} values yield ''single-crystal-like'' spectra,[57] i.e., ENDOR spectra appear as if the sample were oriented with all molecules aligned in that orientation in the **g** frame of reference. However, intermediate fields can also be analyzed since the contributions of different orientations at any g_{obs} value can be quantitatively determined.[60]

The ''orientation selection''[58] that results as g_{obs} values are varied across the EPR powder pattern envelope would be of little interest were it not for the fact that this procedure reveals anisotropy in the hyperfine coupling. This is shown in cartoon fashion in Figure 3. The analysis of such a field-dependent ''2-D'' ENDOR pattern can be challenging, even when there are no overlapping signals from different nuclei. The quantitative analysis of such complex patterns is a hallmark of many recent ENDOR studies of bioinorganic systems.[30,35,43,46,61]

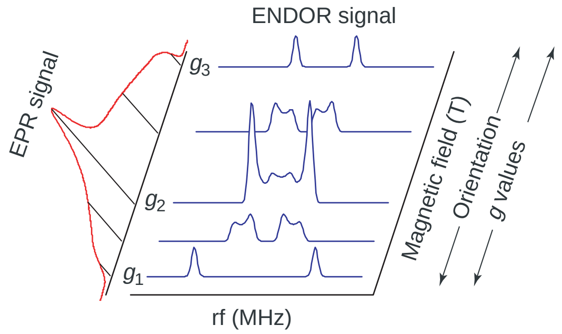

Figure 3 EPR powder pattern for a rhombic $S = 1/2$ system with ENDOR spectra recorded at multiple field positions (g_{obs} values). The ENDOR pattern depicted is for illustrative purposes only. The g_{obs} values select a set of orientations of the paramagnetic center with respect to the external magnetic field (i.e., θ, ϕ values)

This challenge obtains because the hyperfine anisotropy can be very large, and can be combined with quadrupole coupling (for ^{14}N or ^2H), and the coordinate systems that diagonalize the nuclear coupling matrices (hyperfine and quadrupole—which in turn need not be collinear) need not be collinear with the electronic (**g**) matrix. Noncollinearity of **g** and **A** means that the hyperfine coupling observed at, e.g., a ''single-crystal-like'' g_{obs} value (i.e., at a canonical g value, whether denoted as g_z, g_{max}, or simply g_1) does not correspond directly to A_z (or A_1), but to a combination of components of **A**, as determined by the Euler angle rotations[62] of the nuclear (**A**) and electronic (**g**) coordinate systems (assignment of **A** and **g** components to molecular directions x, y, z would require knowledge of the relation between the molecular and electronic coordinate systems, which could be obtained from single-crystal EPR). How could this noncollinearity arise? One scenario is when a nucleus is relatively distant from the paramagnetic site and the coupling is entirely through space (*see* Section 2.4.2). However, even when the nucleus of interest is an integral part of the paramagnetic center (i.e., a ligand) there could well be noncollinearity. For example, in heme systems, π-bonding effects can lead to **g** matrix directions differing from hyperfine coupling directions.[63] Another scenario is in spin-coupled systems, such as the mixed oxidation state of di-iron proteins ($Fe^{II}Fe^{III}$, ground state total spin, $S_{tot} = 1/2$). The **g** matrix of the coupled system need not have any correspondence with the **A** matrices of individual ligands, particularly for those to Fe^{III}, since the **g** anisotropy is largely determined by Fe^{II}.[64]

2.4.2 Hyperfine Anisotropy—Dipolar Coupling

The physical origin of hyperfine coupling is discussed in many other places,[1–4] and dates back to the work of Fermi in 1930. Very briefly, there are two contributions to hyperfine coupling, an isotropic contribution, A_{iso}, and an anisotropic or dipolar contribution, A_{dip} or T. The isotropic contribution

results from unpaired spin in s orbitals, since only s orbitals have finite electron density at the nucleus (in SI units, *see* Section 2.6 in WWB[1]):

$$A_{\rm iso} = \left(\frac{2\mu_0}{3}\right)(g_e\beta_e g_N\beta_N)\langle\rho_s\rangle \quad (7)$$

where the constants $\beta_{e,N}$ are in J T^{-1}, the vacuum permeability, μ_0, in T^2 m^3 J^{-1}, and s electron spin density at the nucleus from all relevant electron spins, $\langle\rho_s\rangle$, is in m^{-3}, to give $A_{\rm iso}$ in J (which value for normal usage would be converted by division by h in J MHz^{-1} to give $A_{\rm iso}$ in MHz). Values for the isotropic coupling for an unpaired ns electron, assuming unit total spin density in s orbitals as a_0 (in mT; since $a_0 = [A_{\rm iso}]/g_e\beta_e$), are tabulated in appendix G of WWB.[1] Such s unpaired spin density at the nucleus can result from the direct contact (i.e., a metal ns (e.g., $n = 4$ for Cu$^{\rm II}$) component in the SOMO being probed by EPR/ENDOR, which can include sp^n ligand orbitals ($n = 1$–3) and from polarization of all ns electrons ($n = 1$–4) by unpaired spin density in other orbitals (e.g., 3d orbitals for Cu$^{\rm II}$). This type of spin polarization that affects s electrons should not be confused with the direct dipolar coupling described in the following.

The anisotropic contribution can result from both direct (local) and indirect (nonlocal) dipolar coupling. Dipolar coupling is averaged to zero in fluid solution (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Inorganic/Organometallic Molecules***), but essentially all (bio)inorganic ENDOR is performed in frozen solutions, so that dipolar interactions are present and can be the dominant effect in hyperfine coupling. The indirect dipolar coupling is usually treated via a classical through-space electron point-dipole–nuclear point-dipole approximation. A cartoon of this type of dipolar interaction is shown in Figure 4, which is appropriate, e.g., for the H atom of a coordinated hydroxo ligand (X=O) to a paramagnetic site (M). Equally appropriate would be the case of hydrogen-bonding to X from, e.g., an endogenous (nearby protein residue) or exogenous (solvent) H atom, which is still close enough to M to give a measurable indirect dipolar coupling. The external magnetic field that aligns the dipoles is along the z axis, which is defined along the M–X bond. The metrical parameters d (M–X bond length), r (H–X bond length), and γ (H–X–M bond angle) are either known from specific structural information or can be assumed by analogy with related systems. From these parameters, the angle θ for this interaction is determined, for use in the equation, originally due to Breit and Rabi (in SI units; *see* Section 2.2 in WWB[1]):

$$T = \left(\frac{-\mu_0}{4\pi}\right)(g_e\beta_e g_N\beta_N)\frac{(3\cos^2\theta - 1)}{R^3} \quad (8)$$

where the constants μ_0, $(g,\beta)_{e,N}$, are as in equation (7) and the distance R is in meter, to give the dipolar coupling T in joule (thence normally converted to MHz), which gives the components $\mathbf{T} = [-T/2, -T/2, T]$. This simplified equation uses the isotropic g_e value, rather than taking into account anisotropy in the **g** matrix of the actual electronic system. The dipolar coupling matrix **T** can deviate greatly from the classical form given above if there is significant g anisotropy.[65] More recently, the point-dipole model has been modified to include both this effect and the spatial characteristics of d orbitals, so that the electron is treated realistically and not merely as a point-dipole.[66] This work by Snetsinger *et al.*[66] has been incorporated by the author into a simple computer program (DIPOLE), which allows estimation of the maximum distance between the metal center and a nucleus of interest (R) that would give an observable ENDOR signal. This estimate is crude because spin delocalization onto ligands is ignored (i.e. only a 3d orbital is considered here), but suggests that for ^{1}H, a distance of ~800 pm (~8 Å) is easily achieved: $T \approx 0.3$ MHz. For ^{13}C, a distance of ~500 pm yields the same coupling. In general, hyperfine coupling of ~0.1 MHz might be considered the experimental lower limit. Such an estimate might be complicated in the case of ^{1}H by ‘‘distant’’ (matrix) ^{1}H signals from this ubiquitous isotope. Even for ^{13}C, an ENDOR signal from natural abundance (1.1%) isotope can often be observed at the Larmor frequency. An example is the very thorough study of a series of FeS proteins,[67] for which only ^{1}H ENDOR would be expected, yet natural abundance ^{13}C and even ^{57}Fe (due in part to the increased probability of isotopologs, relative to the mononuclear center, e.g., $[^{57}FeFe_3S_4]^{+,3+}$ in the active site). Signals from ^{14}N from the protein residues (H-bonded to FeS cluster cysteinyl ligands and/or sulfide ions) were also observed.[67] Thus, a nucleus such as ^{19}F, which has a large g_N (94% that of ^{1}H), 100% natural isotopic abundance, but with no natural occurrence of fluorine/fluoride in bioinorganic systems and hence no background signal, might be the best scenario for observation of a chemically relevant, dipolar coupled nucleus at a maximal distance.

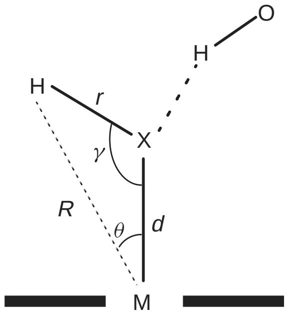

Figure 4 Diagram of the metrical parameters involved in a simple model for electron-point dipole—nuclear point-dipole hyperfine coupling, where the nucleus of interest is hydrogen. The paramagnetic metal center is indicated by M, with the ligand (e.g., a porphyrin) indicated by the dark horizontal line, X is a donor atom such as F, O, S, N, etc. Also shown is a second H, hydrogen-bonded to X, which can also be coupled to M (but with metrical parameters omitted for clarity)

An additional anisotropic interaction is a direct (local) dipolar one. It has its origin in unpaired electron density in, for example, p orbitals, which are by definition anisotropic, in contrast to s orbitals, although they have no density at the nucleus (hence no contact contribution to hyperfine coupling). As a result, there is direct (local) dipolar coupling between the unpaired electron spin in a p orbital (or sp^n hybrid MO) and the nucleus associated with that MO. Such a situation is especially relevant for the analysis of hyperfine coupling in organic radicals (*see* Section 5.3 in WWB[1]). However, it is also relevant to (bio)inorganic systems. The SOMO of a paramagnetic metal center is usually not a pure d orbital, but has ligand orbital contributions. There is thus unpaired spin density in ligand sp^n orbitals that can directly couple to the ligand nucleus (^{14}N, or ^{13}C—as part of a π-conjugated ligand more likely than as a C-donor ligand itself). The importance of including both indirect (nonlocal) and direct (local) dipolar contributions was recently demonstrated in an ENDOR study of the ''very rapid'' intermediate in the pyranopterin Mo enzyme xanthine oxidase, which was probed by use of a ^{13}C-labelled purine substrate.[61] This intermediate contains Mo^{V}, 4d^1, which has extensive covalency with ligands.

The most general form of the equation for dipole–dipole coupling ($\boldsymbol{H} = S\cdot\mathbf{T}\cdot I$), that is, without quantization along the z axis, is given in Section 5.2 of WWB,[1] which also tabulates in Appendix G the hyperfine coupling for an unpaired electron in an np orbital, b_0, (in mT; since $b_0 = T/(g_e\beta_e)$).

2.4.3 Signs of Hyperfine Couplings

The final consideration is the sign of hyperfine coupling. The sign of g_N, which is related to the pairing of the nucleons themselves, affects the sign of $A_{\rm iso}$ as seen from equation (7), however, the nature of the core (s) electron polarization can lead to a net positive or negative spin at the nucleus (*see* Section 17.6 in A^{2}B^2).[3] It is thus difficult to predict the actual sign of $A_{\rm iso}$. Furthermore, it is normally not possible to determine the sign of an isotropic hyperfine coupling from EPR, although the relative signs of two resolved couplings can be determined from higher-order analysis of the spectra (*see* Sections 2.6 and 3.6 of WWB[1]), which is much more likely the case for organic radicals, typically with their multiple, well-resolved couplings from ^{1}H (primarily), than for inorganic complexes. ENDOR likewise does not normally provide the sign of $A_{\rm iso}$. Specifically, for $A_{\rm iso} > 0$ (and $g_N > 0$, with the hyperfine interaction larger than the nuclear Zeeman interaction), the assignment of $\nu_\pm$ signals would be: $\langle M_S, M_I| = \langle -1/2, +1/2| \leftrightarrow \langle -1/2, -1/2|$ as ν_+ (i.e., the higher energy ENDOR signal) and $\langle +1/2, -1/2| \leftrightarrow \langle +1/2, +1/2|$ as ν_- (the lower energy partner), while for $A_{\rm iso} < 0$, the assignments would be: $\langle M_S, M_I| = \langle +1/2, +1/2| \leftrightarrow \langle +1/2, -1/2|$ as ν_+ and $\langle -1/2, -1/2| \leftrightarrow \langle -1/2, +1/2|$ as ν_-. One might imagine that in the former case, the signal intensity of the ν_+ partners would be larger as the population of the $M_S = +1/2$ state is larger than that of the $-1/2$ state, while for the latter case, the intensities would be reversed. Unfortunately, as mentioned above (*see* Section 2.3.2), ENDOR signal intensities are very unpredictable and rely on many relaxation factors,[48] and not simply on Boltzmann population differences. However, it is possible, in analogy to the comparison of two separate hyperfine coupled nuclei in EPR, to use two separate rf energies to give the technique known as TRIPLE,[68,69] which can provide relative signs of two hyperfine couplings. This technique will be discussed later in this text (*see* Section 3.3.7).

Much more important than the sign of $A_{\rm iso}$ is the sign of the dipolar coupling as this is related to spatial parameters. As seen in equation (8), there is necessarily a change of sign as a result of dipolar coupling. As described above (*see* Section 2.4.2), analysis of the field-dependent ENDOR spectra can provide the components of the hyperfine coupling matrix, **A**, including the Euler angle relation with **g**, and the relative signs of these components. Designating the largest magnitude hyperfine coupling component as A_1 and the smallest as A_3, $A_{\rm iso} = (A_1 + A_2 + A_3)/3$, and the dipolar (anisotropic) components, $T_i(A_{\rm dip}) = [A_i - A_{\rm iso},\ i = 1\text{–}3]$. By analogy with electronic and nuclear quadrupole coupling, the hyperfine matrix can also be used to derive an axial (uniaxiality) parameter B (analogous to $D, P_{||}$) and an asymmetry (rhombicity) parameter C, (analogous to E, η), where $B = [A_1 - (A_2 + A_3)/2]/3$, $C = (|A_2| - |A_3|)/2$ (these are a_0, b_0, c_0 in magnetic field units; see Section 5.2 in WWB[1]).

3 EXPERIMENTAL ASPECTS

3.1 Computer Simulation of ENDOR Spectra

It is clear from the above that analysis of ENDOR spectra is not trivial. A variety of computer programs exist for the simulation of ENDOR spectra. A convenient program is that written (now in C; earlier versions, known as GENDOR, were in BASIC) by Hoffman and coworkers, GENSIM, which is widely used in their work (http://www.chem.northwestern.edu/~bmh/endor.htm; accessed 03/01/2007). This program simulates ENDOR spectra of nuclei with arbitrary orientation with respect to **g**. In its later versions, GENSIM directly incorporates the distance (R) into dipolar coupling calculations of the type described above (*see* Section 2.4).[60] Another program, DDPOWHE, written in Fortran (now g77 Fortran) generates ENDOR spectra for a single nucleus ($I \le 9/2$) coupled to an electronic spin ($S \le 9/2$). This program is more cumbersome than GENSIM, but has the advantage that the ''g-over-g'' and pnZ effects described above for $S > 1/2$ are automatically incorporated since there is no use of fictitious spin, although an estimate of the zfs parameters is needed. The exact calculation methods included in DDPOWHE are also relevant with $S = 1/2$ systems, for analysis of ENDOR signals from

quadrupolar ($I > 1/2$) nuclei. When the quadrupole splitting is similar in magnitude either to the Larmor splitting (for signals centered at $A^N/2$) or to the hyperfine splitting (for signals centered at ν^N), the readily interpreted, first-order situation (equation 6) does not obtain and exact calculation methods are needed.

Arguably the best software currently available is the EasySpin package written by Stefan Stoll at the ETH-Zürich.(http://www.easyspin.ethz.ch/main.html; accessed 03/01/2007). This package covers every possible situation one might encounter in ENDOR, as well as other areas of EPR, but does require access to MathCad® software. Nevertheless, the old adage ''garbage in—garbage out'' applies, and no sophistication of software can compensate for a lack of understanding by the user.

3.2 Background on Sample Requirements for ENDOR

The sample requirements for ENDOR are essentially the same as for EPR, given that an EPR signal is monitored. Fused silica tubes of diameter appropriate for the microwave cavity dimensions are used: typically, 3 mm inner diameter (i.d.) for X-band, 2–2.5 mm i.d. for 35 GHz, capillary tubes for W-band (95 GHz). Fused silica is in the absence of paramagnetic impurities (as opposed to borosilicate glass) and has the appropriate dielectric properties for microwave transmission. These tube sizes result in sample volumes of ~50 and ~250 µL for 35 GHz and X-band, respectively, so that the sample volume is rarely an issue, even for metalloproteins. Single crystals can also be studied by ENDOR, as with EPR. For metalloproteins, ENDOR at higher frequencies is preferable, where the small sample size is not a drawback. An example is the W-band ENDOR study on azurin.[37] However, for the vast majority of bioinorganic systems (metalloproteins and model compounds), solutions are generally used. So far as metalloproteins in aqueous solution are concerned, the high dielectric constant of water makes EPR of aqueous solutions difficult at room temperature; however, the fast electronic relaxation times of bioinorganic systems precludes their study by EPR at room temperature in most cases (and makes ENDOR impossible). Ice, in contrast, has a low dielectric constant and is perfectly suitable for low temperature EPR measurements; however, purely aqueous solvents are not recommended. Although optical quality glasses are not required, it is generally necessary to include some glassing agent, typically ethylene glycol or glycerol (~10% v/v; for a sample in D_2O, ethylene glycol-d_2 and glycerol-d_3 are needed). These glassing agents break up the spin–spin communication in the aqueous solvent that contributes to the faster relaxation times of ENDOR signals, which particularly affect pulsed experiments. Methanol or ethanol or mixtures of the two or aqueous alcohols are also suitable. Bioinorganic model compounds can also be studied by ENDOR and purely organic solvents are generally suitable. Neat toluene or 1:1 v/v toluene–acetonitrile are recommended solvents. One organic solvent that is often used in EPR, but has proved problematic in the author's experience in terms of explosive thawing is neat 2-methyltetrahydrofuran (2-Me-THF). However, THF with as little as ~2% v/v 2-Me-THF has the glassing properties of 2-Me-THF without its destructive properties.

Furthermore, the complex relaxation requirements of a double resonance technique mean that low temperatures are required in all cases. In general, temperatures below that of liquid nitrogen are needed. These are obtained either with a variable temperature flow cryostat using liquid helium (~4–40 K) or with a liquid helium immersion dewar (~4 K, or ~2 K for pumped (superfluid) helium).

An EPR signal of reasonable signal-to-noise (S/N) is necessary, but not sufficient for successful ENDOR spectroscopy, again due to the relaxation properties, that is, good EPR does not necessarily mean good ENDOR, but the reverse (i.e., weak EPR signal giving strong ENDOR signals) is very unlikely. In general, most bioinorganic (i.e., metal centered paramagnetic) systems with $S = 1/2$ that are available in concentrations of at least 0.1 mM (with the range 0.5–1 mM being preferable) have the potential for providing useful ENDOR spectra, assuming nuclei of interest are present, whether naturally (^{1}H is always present, but not necessarily informative) present or artificially (organism growth on isotopically enriched media or use of isotopically labeled substrate) introduced. Such systems could be mononuclear, i.e., authentic $S = 1/2$, such as d^9 (Cu^{II}, Ni^{I}), low-spin d^7 (Fe^{I}, Co^{II}, Ni^{III}), low-spin d^5 (Fe^{III}), and d^1 (Mo^{V}, V^{IV}), to list metal ions with which the author is personally familiar, or the systems could be multinuclear, but with total spin 1/2 ground states, such as in di-iron enzymes ($Fe^{II}Fe^{III}$) and various iron–sulfur proteins (e.g., 3Fe-ox ($[Fe_3S_4]^+$) cluster-containing proteins). High-spin ($S > 1/2$) EPR systems can be more problematic, perhaps because of faster relaxation processes due to the multiplicity of electronic states. Nevertheless, certain high-spin systems have proved amenable to ENDOR, such as the mononuclear high-spin Fe^{III} in fluorometmyoglobin ($S = 5/2$),[56] and multinuclear system resting state of nitrogenase FeMo-cofactor ($S = 3/2$).[54] The characteristic of these two systems is that they are nearly uniaxial (i.e., generally $|E/D| < 0.1$; here, $|E/D| = 0.053$ for nitrogenase;[54] $|E/D| \leq 0.002$ for fluorometmyoglobin[56]) with very well-defined EPR spectra (i.e., narrow lines, ''Pake pattern'') observable up to relatively high temperatures (liquid nitrogen temperatures for fluorometmyoglobin). Other high-spin systems have been partly successful, in that ENDOR signals from some, but not all, nuclei of interest were observable. These include high-spin Co^{II} ($S = 3/2$) in a Co-substituted zinc finger protein, TFIIIA,[70] and high-spin Mn^{II} ($S = 5/2$) in a mononuclear enzyme, FosA.[51] In both cases, ENDOR signals from ^{31}P associated with substrate (for FosA; ^{31}P from DNA in the case of TFIIIA) were observed, but not ^{14}N from coordinating residues (other Co-substituted proteins with histidine ligands have been investigated by

ENDOR). The EPR characteristics of these two systems were that they were relatively more rhombic, with broader EPR linewidths and observable only at lower temperatures, all relative to the axial systems listed above. Yet another spin system of interest is high-spin d^5 with very large rhombicity (the maximum is $|E/D| = 1/3$; a larger value simply corresponds to a change in principal axis), which is the case for mononuclear Fe^{III} in many cases such as oxidized rubredoxin and other mononuclear nonheme Fe proteins. In the author's experience, such systems have not been fruitful. Apparently, the relaxation properties and ill-defined EPR spectra make such systems generally unsuccessful candidates for investigation by ENDOR. A final class that one might also imagine to be unsuitable for ENDOR is the rhombic systems with $S = 2$ (or higher integer values), which include mononuclear high-spin Fe^{II} and certain multinuclear systems such as reduced di-iron proteins ($Fe^{II}Fe^{II}$)[71] and various iron–sulfur proteins (e.g., 3Fe-red ($[Fe_3S_4]^0$) cluster-containing proteins).[72,73] These systems exhibit the so-called ''non-Kramers'' signal at very low magnetic fields (very high g_{obs}).[74] It is possible to record ^{1}H ENDOR spectra of such systems,[75–77] although attempts by the author to record ^{57}Fe ENDOR spectra of $S = 2$ FeS proteins have proved unsuccessful.

3.3 Instrumental Requirements for ENDOR

The instrumental aspects of EPR have been summarized elsewhere,[1,4,5] although the text by Poole is especially noted for instrumental details and parameters.[78] Obviously, to perform ENDOR experiments, one must have an EPR spectrometer, of which Bruker Biospin is the sole viable vendor at present (http://www.bruker-biospin.com/brukerepr/index.html; accessed 03/01/2007). ENDOR accessories include the rf synthesizer and amplifiers and a microwave resonant cavity that includes rf coils in addition to the normal structure with field modulation coils. Locally constructed ENDOR spectrometers were more common in the past, with that of the late Clyde A. Hutchison Jr being a notable example, particularly for single-crystal studies.[65] Such spectrometers still exist; the author is familiar with those at Northwestern University.[79–81]

3.3.1 Continuous Wave (CW) ENDOR Spectroscopy Employing Radiofrequency Modulation Detection (RFMD-ENDOR)

In such a spectrometer, the magnetic field modulation (typically at 100 kHz, and at amplitudes of 0.1–1 mT) used to record a typical EPR spectrum is turned off. The microwave power is usually set to saturating conditions. The rf is swept through the desired range, but is modulated during this process, much as the magnetic field is modulated to record an EPR spectrum. The phase sensitive detection used in this method yields first-derivative lineshape ENDOR signals, just as field-modulated EPR yields first-derivative EPR signals (when under slow passage conditions[8–10]). This experimental protocol is what is employed in commercial Bruker spectrometers (http://www.bruker-biospin.com/brukerepr/continuous waveendor.html; accessed 03/01/2007).

3.3.2 CW ENDOR Spectroscopy Employing Magnetic Field Modulation Detection (FMD-ENDOR)

In such a spectrometer, there is no modulation of the rf while it is swept, however, the magnetic field modulation is left on. The resulting ENDOR spectra exhibit absorption lineshapes (when under rapid-passage conditions, as are typically the cases here). The appearance of ENDOR spectra can be quite sensitive to the field modulation amplitude because of its effect on this type of ''packet shifting'' ENDOR. This means that the NMR transition removes a ''packet'' of spins from the EPR envelope, which would in principle reduce the EPR signal and lead to negative pointing ENDOR signals. In practice, ENDOR signals recorded by this method can be either negative or positive and this behavior can be the case not only for different nuclei (i.e., ^{57}Fe versus ^{1}H), and for magnetically inequivalent nuclei of the same isotope, but even for the ν_+ and ν_- partners of a given ENDOR signal from a single nucleus (or a set of magnetically equivalent nuclei).[48] This type of ENDOR was that originally developed by Feher fifty years ago[13] and is still a tremendously effective technique. A further, relatively recent improvement was the use of rf bandwidth broadening, effected by a white noise generator (normally used for communications equipment testing).[82] It might seem paradoxical that use of a broader, rather than narrower bandwidth would be beneficial in any type of spectroscopy. The reason is that CW ENDOR lines are relatively broad (often 500 kHz half-width half-maximum (hwhm)) so that linewidth is not bandwidth limited, while the use of a broader rf bandwidth leads to shifting of a larger spin packet and thus significantly larger S/N.[82] The white noise source can broaden rf up to 500 kHz, however, the range of 50–200 kHz is normally employed.

In addition to the positive and negative directions of ENDOR signals, there are also rf sweep effects, which are related to nuclear spin relaxation effects. These effects can be manifest in ''tailing'' in the sweep direction, giving an appearance coincidentally like that in high performance liquid chromatography (HPLC). There can also be a slight frequency shift in the rf sweep direction as well. Both of these effects can be mitigated by use of slower rf sweep rates and by comparison of forward (i.e., low to high rf) and reverse (high to low) sweeps. These effects appear to be more significant for nuclei, which are directly part of the paramagnetic center, for example, ^{57}Fe, ^{63}Cu, and in some cases ligand ^{14}N, rather than nuclei that are more indirectly coupled.

3.3.3 CW Stochastic ENDOR Spectroscopy Employing Magnetic Field Modulation Detection (FMDST-ENDOR)

A recent and very promising effort in CW ENDOR to alleviate these effects is the use of FMD-ENDOR with stochastic application of rf (FMDST-ENDOR). This technique was first developed by Brueggeman and Niklas,[83] and was refined by Doan, working in the Hoffman laboratory, for use with field-modulated CW ENDOR for application to bioinorganic systems.[84] The concept is a simple one: rather than sweeping the rf linearly, whether forward or reverse, over a given frequency range, one samples individual radiofrequencies in a random fashion and then constructs the spectrum from these. The individual frequency points are determined by dividing the desired rf range by the number of spectral points (e.g., 1000 points over the range 1–21 MHz gives random points every 20 kHz, with e.g., $\nu_{rf}^{k} = 13.12$ MHz, $\nu_{rf}^{k+1} = 9.12$ MHz, $\nu_{rf}^{k+2} = 19.58$ MHz, $\ldots$; $k = 1-1000$). Note that the resolution of the rf synthesizer is not a limitation because such a synthesizer is ''overengineered'', in that it is designed for NMR applications (high resolution kHz frequencies) rather than lower resolution MHz frequencies needed for ENDOR. Because the rf application is not continuously swept, FMDST-ENDOR is a sort of ''poor man's'' pulsed ENDOR (*see* Section 3.3.4) in that no pulsed microwave (i.e., EPR) generation is involved—only rf (i.e., NMR). The time constant (analog averaging function) that is used in normal EPR and CW ENDOR must not be used in FMDST-ENDOR as all averaging is done via the point by point data acquisition method.

The FMDST-ENDOR pulse sequence is shown in Figure 5. A key feature is the sampling of a baseline (i.e., rf off) before every sample point to ensure any baseline drift is compensated for. The baseline and sampling periods are generally fixed, but the time during which the k^{th} rf is applied (rf ''pulse'') and the delay time can each be varied to achieve optimal results. The delay time can range from zero (sampling concurrent with rf pulse) to a time immediately after completion of the rf (or even later), as well as intermediate values (as shown in Figure 5). FDMST-ENDOR has great promise for application to systems for which the lineshapes of standard CW ENDOR are severely distorted. Furthermore, the parameters of the FDMST-ENDOR sequence allow discrimination among overlapping samples and their quantification (*see* Section 4.1.5).[84]

3.3.4 Pulsed Mims ENDOR Spectroscopy

We next consider actual pulsed techniques. The definitive reference work in this area is the text by Schweiger and Jeschke.[29] Also notable is the much earlier review by Gemperle and Schweiger,[85] and the Bruker web site, which is extremely thorough (http://www.bruker-biospin.com/brukerepr/pulseeprtheory.html; accessed 03/01/2007).

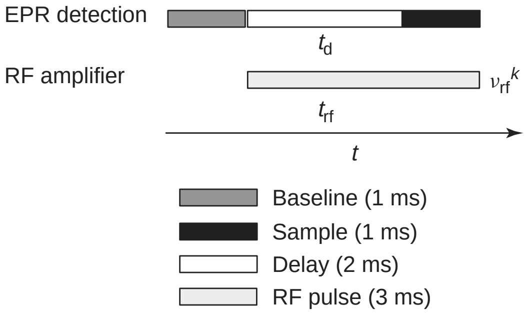

Figure 5 Field modulation detected stochastic (FMDST) ENDOR sequence. The upper level indicates monitoring of the EPR signal prior (baseline) and (usually) after (signal) application of the k^{th} rf pulse. This pulse is applied for time t_{rf}, and at frequency ν_{rf}^{k}, which is a randomly selected frequency among the total number of possible values determined by the rf range and number of spectral points. There is also a delay time, t_d, that can range from zero (sample concurrent with application of the k^{th} rf pulse) to $t_d \geq t_{rf}$ (sample immediately after application of the k^{th} rf pulse, or later); this example has an intermediate delay time: $0 < t_d < t_{rf}$. The timings of the baseline and sample periods are rarely altered, but the rf and delay times can be altered to optimize spectral appearance of a given sample. Typical times are given. (Adapted from Figure 2 in Lee, Igarashi, Laryukhin, Doan, Dos Santos, Dean, Seefeldt and Hoffman.[84] Reprinted with permission, © 2004 American Chemical Society)

Following their lead, it is worth beginning with a historical perspective. As mentioned earlier (*see* Section 1.2), EPR was discovered by Zavoisky in the mid 1940s, and ENDOR was discovered by Feher in the mid 1950s. Shortly after the discovery of NMR in the mid 1940s, the first pulsed NMR experiments, specifically the observation of a nuclear spin echo, were performed by Erwin L. Hahn, in 1950 at the University of Illinois-Urbana.[86] The electron spin echo (ESE) was first observed in 1958, independently by Blume at IBM (studying Na in $NH_{3(l)}$) and by Gordon and Bowers at Bell Telephone Laboratories (studying Si, presumably for the same reasons as Feher was).[87] This has led to electron spin echo envelope modulation (ESEEM) techniques (*see* ***Electron Spin Echo Envelope Modulation (ESEEM) Spectroscopy***). Pulsed ENDOR was discovered soon thereafter, by William B. Mims, also at Bell Telephone Laboratories, in the mid 1960s.[88] Mims and Peisach later pioneered the application of ESEEM to bioinorganic systems[89] and ENDOR. It is interesting to note how many crucial developments were made in corporate research laboratories in the USA. The author has come across excellent papers from the pre-1980 era on EPR of inorganic complexes from groups employed at not only Bell Telephone Laboratories and IBM, but at DuPont, Ford Motor, GE, Lockheed, RCA, Shell Oil, and others. That was truly a different era from today.

The method invented by Mims that bears his name was the first and is still the ''workhorse'' technique in pulsed ENDOR as it is ideal for providing high resolution spectra of nuclei with small hyperfine couplings, generally less than

2 MHz, and under ideal conditions, as low as 0.1 MHz. Nuclei such as ^{2}H, ^{13}C, ^{15}N, ^{19}F, and ^{31}P, generally from specifically labeled molecules interacting with the paramagnetic site via longer range dipolar coupling are typical targets as will be described in specific examples (*see* Section 4.1.3). Mims ENDOR also provides the best sensitivity among the pulsed ENDOR techniques. However, in the author's experience, pulsed ENDOR is normally less sensitive than CW ENDOR, so that a given system should always first be investigated (''screened'') by CW ENDOR to see what signals are available, and then examined by pulsed ENDOR for higher resolution and/or observation of weaker couplings.

The Mims pulse sequence is shown in Figure 6. It is based on a stimulated ESE sequence, in which there are three $\pi/2$ (90°) microwave pulses, with the first two (the preparation pulses) separated by a delay time τ. This is followed by a mixing period and then the third $\pi/2$ microwave pulse generates (stimulates) the ESE, observed during the detection period. To make this three-pulse ESE sequence into an ENDOR sequence, an rf pulse is applied during the mixing period, which causes polarization transfer between electronic and nuclear transitions.[29] The rf is stepped through the desired range, with the steps derived from the range and number of spectral points, as described earlier for FMDST-ENDOR (*see* Section 3.3.3). Normally, a number of ''shots'' (i.e., pulse sequences) are averaged at each rf point (e.g., 20 shots/point) and further signal averaging obtains by recording a number of spectra as a running total. There is a delay in time between each shot during which time (ideally) equilibrium magnetization is restored. Typical timings for each aspect of the sequence are given in Figure 6. For those familiar with NMR, note the much shorter times that occur in EPR (ns pulse widths, ms delay times) especially given that these experiments are done in frozen solution at liquid helium temperatures for bioinorganic systems. The specific timings in Figure 6 are based on routine use of the 35 GHz pulsed ENDOR spectrometer at Northwestern University constructed by Clark E. Davoust in the Hoffman laboratory. The microwave pulse power is also important and this is usually adjusted (with rf off) to maximize the ESE height. The rf power is relatively less important and experience has yielded standard settings for typical experiments. Instrumental details are outside the scope of this discussion, but are available elsewhere.[79] An X-band pulsed spectrometer was also constructed earlier,[80] however, for the reasons described above (*see* Section 2.2.2), use of the higher microwave frequency is generally preferable. For example, ^{2}H has $\nu^N \approx 2.3$ MHz at X-band, which is approaching the difficult region of very low rf (the baseline signal generally deteriorates as ν approaches $\sim$0 MHz), but $\nu^N \approx 8.2$ MHz at 35 GHz, well into an easily observable rf region.

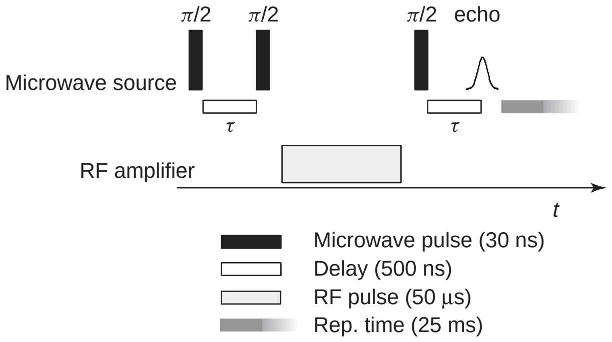

Figure 6 Mims ENDOR pulse sequence.[88] The upper level indicates the microwave pulses and immediately below delay times are indicated. The lowest level indicates the rf pulse. The timing is defined as pulse edge-to-edge, as depicted by Schweiger and Jeschke,[29] however, the timing can also be defined as pulse center-to-center.[90] Typical times are given based on a 35 GHz spectrometer.[79] The timing of the microwave and rf pulses is less commonly altered, but the delay time τ and the repetition time need significant adjustment to optimize spectral appearance of a given sample. Microwave phase cycling is also employed, but is not indicated in the figure

The above point is related to the Larmor-centered frequencies at which Mims ENDOR signals appear. It must be made clear, however, that this technique is not applicable irrespective of hyperfine coupling. Mims ENDOR is not really suitable for larger hyperfine couplings ($A^N > \sim$2 MHz, although this value should not be accepted blindly). This limitation is due in part to the ''blind spots'' or ''holes'' that occur in Mims ENDOR as given by the following equation:[88]

$$I_{\text{Mims}} \propto \left(\frac{1}{4}\right)[1 - \cos(2\pi A_{\text{iso}}\tau)] \tag{9}$$

where τ is the delay time as defined above (A_{iso} can be replaced by the effective coupling at the given g_{obs} value), and I_{Mims} is the ENDOR signal intensity. This can be defined as the change in ESE intensity (measured as a voltage), V_{echo}, between resonant rf off and on. This measurement is useful in quantitative comparison of ENDOR signals across the EPR envelope of a given sample. One can also define the ENDOR fractional efficiency or effect, F_{ENDOR}, that is, the change in *normalized* ESE intensity between resonant rf off and on:

$$F_{\text{ENDOR}} = \left|\frac{[V_{\text{echo}}(\text{rf off}) - V_{\text{echo}}(\text{rf on})]}{V_{\text{echo}}(\text{rf off})}\right| * 100\% \tag{10}$$

so that elimination of the echo yields an ENDOR effect of 100%, while no effect is obviously zero. If the echo were actually inverted by the rf polarization transfer, then the effect would be 200%, which is an almost unknown occurrence in our experience. Note that equation (10) as given by Schweiger and Jeschke has a factor of (1/2),[29] so that the elimination of an ESE via ENDOR gives an effect of only 50%. This parameter is useful in comparing different samples and different experimental runs on the same sample.[68]

As a result of equation (9), the Mims ENDOR signal is minimal (''blind'') at $\tau = (n/A_{\text{iso}})$, $n = 0$ (which is experimentally meaningless), 1, 2, ..., and is maximum at $\tau = [(2n+1)/2A_{\text{iso}}]$.[29] Mims ENDOR spectra of a broad ^{1}H pattern can clearly show the oscillating ''blind spot'' pattern

experimentally and the software developed by Doan can include this effect in simulation by inclusion of equation (9) and the user entry of the τ value.[60] The distortions in a Mims ENDOR pattern caused by ''blind spots'' can greatly complicate interpretation by suppressing peaks (which might actually be useful at times[91]) and/or making a single peak appear a doublet. Therefore, one would prefer to record an undistorted Mims ENDOR spectrum, that is, where the first holes appear outside the $\nu_{\pm}$ partners. For practical purposes, the maximum undistorted A_{iso} (MHz) is $\sim 1/(2\tau\ (\mu s))$,[29] so that $A_{\text{iso}} \approx 2$ MHz would require $\tau \approx 0.25\,\mu s$ (250 ns). Is this reasonable? Figure 6 would seem to indicate that any value can be used until the $\pi/2$ pulses overlap. This is not the case in reality. A microwave pulse does not simply go from maximum power to zero instantaneously; there is a ''deadtime'', which is highly variable from one sample to the next and even from one day to the next with a given sample. This ''cavity ringdown'' from the microwave pulse can severely distort the ESE and lead to very high noise and/or temporal instability. A value for $\tau = 0.5\,\mu s$ free of distortion is readily achievable (so the maximum $A_{\text{iso}} \approx 1$ MHz), but much shorter τ values can be a challenge. In any case it is desirable to record Mims spectra with varying τ values to monitor such behavior. A method to overcome this limitation will be discussed in Section 3.3.6.

For readers interested in the quantitative description of the time-dependent magnetization processes, the magnetization ''grating'', that occurs in Mims ENDOR using the density operator formalism, which leads to the experimental behavior described earlier, the reader is referred to other sources by authors infinitely more qualified than the present one.[29,48,91]

3.3.5 Pulsed Davies ENDOR Spectroscopy

The other major form of pulsed ENDOR spectroscopy is known as Davies ENDOR, after its discoverer, E. R. Davies at the Clarendon Laboratory, Oxford, UK.[92] Davies ENDOR is in many ways complementary to Mims ENDOR in that the former is more suited for larger couplings and the latter for smaller couplings, as described earlier (Section 3.3.4).

The Davies pulse sequence is shown in Figure 7. In this sequence, an initial π microwave pulse is applied, inverting the magnetization, followed by the mixing period in which an rf pulse is applied and ENDOR transitions occur. These are observed by application of a primary ESE sequence, a $\pi/2$ pulse followed by a delay time τ during which dephasing occurs, followed by a second π pulse and delay time τ during which rephasing occurs with observation of an ESE. For tuning purposes, the first (π) pulse is switched off and the standard ESE signal can be optimized. This first pulse ''burns a hole'' in the magnetization that is then ''filled in'' by ENDOR shifting of spin packets. As a result, in Davies ENDOR the signals are usually observed as an increase in the echo voltage, i.e., $[V_{\text{echo}}(\text{rf off}) - V_{\text{echo}}(\text{rf on})]$ is positive, while in Mims ENDOR there is usually a

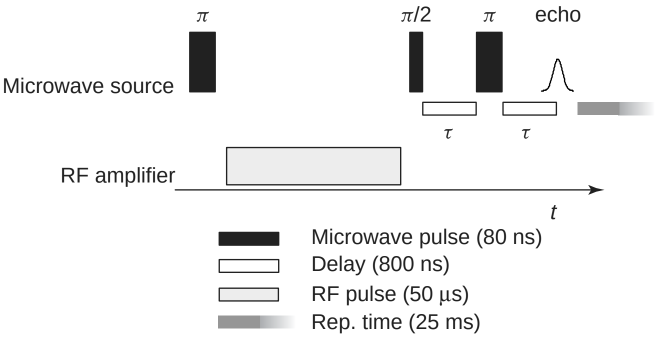

Figure 7 Davies ENDOR pulse sequence.[92] The upper level indicates the microwave pulses and immediately below delay times are indicated. The lowest level indicates the rf pulse. Typical times are given based on a 35 GHz spectrometer.[79] The timing of the microwave and rf pulses is less commonly altered, but the delay time τ and the repetition time need significant adjustment to optimize spectral appearance of a given sample. Microwave phase cycling is also employed, but is not indicated in the figure

decrease, i.e., $[V_{\text{echo}}(\text{rf off}) - V_{\text{echo}}(\text{rf on})]$ is negative. In practice, the complex nature of relaxation phenomena means that, particularly in Davies ENDOR, the direction of ENDOR signals is not totally predictable.

The important difference between the Mims and Davies experiments, however, is that in Davies ENDOR there are no ''blind spots'', although the minimum hyperfine coupling observable is generally less than in Mims ENDOR and the sensitivity is usually lower, since Davies ENDOR is more sensitive to the phase memory of the ESE. Thus a Davies ENDOR spectrum would be expected to provide the same information as a CW spectrum, often with a better baseline and resolution, albeit with longer acquisition time. The true advantage of Davies ENDOR is that it offers a form of hyperfine selection, analogous to the use of Mims holes to suppress signals. This ability was shown by Doan *et al.* using a pulsed X-band spectrometer and only the standard Davies sequence,[91] as opposed to earlier, more elaborate selection methods that required additional equipment to modify the EPR signal during the ENDOR experiment. A Davies ENDOR signal is dependent on the magnitude of the hyperfine coupling (at the particular g_{obs} value), A^N (MHz; over which there is no control), and on the microwave π (preparation) pulse length (t_p, μs, which value can be user selected, within instrumental limitations). The product gives a selectivity parameter, $\eta^N = (A^N t_p)$. As a rule of thumb for the longer t_p values traditionally employed in Davies ENDOR, when $\eta^N > 1$, the ENDOR response will be observed; when $\eta^N < 1$, ENDOR will be suppressed. For ^1H, the hyperfine couplings are typically small while for other nuclei (e.g., ^{57}Fe, ligand ^{14}N), the couplings are large, yet, as described earlier (Section 2.2.2) these signals are often overlapping at X-band. Davies ENDOR, however, allows discrimination amongst these signals. Use of a ''hard'' pulse ($t_p = 30$ ns) effectively suppresses all signals with

$A^N < \sim 6$ MHz ($\eta^N < \sim 0.2$), which would cover much of the ^{1}H ENDOR pattern in many metalloprotein systems, while for nuclei with $A^N > \sim 30$ MHz (e.g., ^{57}Fe, ligand ^{14}N), ENDOR would be readily observable ($\eta^N > \sim 1$). Use of a very ''soft'' pulse ($t_p = 600$ ns) allows observation of weak couplings ($A^N > \sim 1$ MHz; $\eta^N > \sim 0.6$). This method was thus dubbed ''POSHE'' (for *pro*ton *s*uppression and *h*eteronuclear *e*nhancement).[91]

Use of very short preparation pulses, however, is not ideal since the size of the spin packet that potentially gives an ENDOR signal is small (i.e., a longer pulse affects more spins). There is a trade off between selectivity and signal intensity of the hyperfine selected nucleus. As shown by Fan *et al*., who give numerous quantitative examples on metalloproteins, the ideal situation actually obtains for $\eta^N = 0.7$.[80]

3.3.6 Pulsed ReMims (Doan) ENDOR Spectroscopy

A final development in pulsed ENDOR using standard instrumentation is that discovered by Doan and Hoffman, which they called ReMims ENDOR, for refocused (or remote-echo) Mims ENDOR.[90] By analogy with the eponymous nomenclature of other pulsed ENDOR techniques, the author will also refer to this technique as Doan ENDOR. ReMims (Doan) ENDOR is a four-pulse variation of Mims ENDOR. The pulse sequence is shown in Figure 8. The preparation and mixing portions of the sequence are identical to that described above for Mims ENDOR (*see* Figure 6). Furthermore, comparison of Figure 7 with Figure 8 shows that the Davies sequence is simply a special case of the ReMims (Doan) ENDOR sequence in which $\tau_1 = 0$ ($\tau_2 \equiv \tau$), so that the first two $\pi/2$ pulses collapse into one π pulse and all of the echoes described below are one and the same.

The key feature of ReMims (Doan) ENDOR is that τ_1 can be less than the ''deadtime'' of the spectrometer. This is because, in contrast to Mims ENDOR, the stimulated spin echo (which would be distorted by cavity ringdown) is not detected. Instead, an additional π pulse is applied after time τ_2, which leads to a ''standard'' spin echo at time τ_2 (Hahn echo, since it results from the original Hahn sequence; here from the third $\pi/2$ pulse and the following π pulse). More important, there are two additional spin echoes formed: one at time $(\tau_2 + \tau_1)$, which is observable for all values of τ_1 and τ_2, and is denoted the RME, which is detected, and one at time $(\tau_2 - \tau_1)$, which is observable only for values of $\tau_2 > \tau_1$, and is denoted the refocused stimulated echo (RSE). The deadtime for the ReMims (Doan) sequence is thus the minimum feasible value of $(\tau_2 + \tau_1)$, rather than the minimum value of τ_1 in a Mims sequence (Figure 6). As mentioned earlier (Section 3.3.4), the maximum undistorted A_{iso} (MHz) is $\sim 1/(2\tau_1$ (µs)). The deadtime in the X-band pulsed spectrometer is $t_d \approx 0.1$ µs (100 ns), thus $\tau_1 > 0.1$ µs in a Mims sequence and the maximum coupling is $\sim$5 MHz; however, in a ReMims (Doan) sequence, $\tau_1 \approx 0.05$ µs (combined with $\tau_2 \approx 0.1$ µs), therefore couplings up to $\sim$10 MHz can be observed without distortion. A ReMims (Doan) experiment requires more acquisition time than a Mims experiment (due to loss of phase memory over the overall lengthier sequence). However, a relatively low S/N ReMims experiment can be performed at $\tau_1 < t_d$ and then compared to a Mims experiment at $\tau \approx t_d$. Are there any distortions in the Mims ENDOR spectrum? If not, then the (more efficient) Mims experiments are sufficient and spectra can be averaged to achieve publishable S/N. But what about comparison with Davies or CW ENDOR? Davies ENDOR is

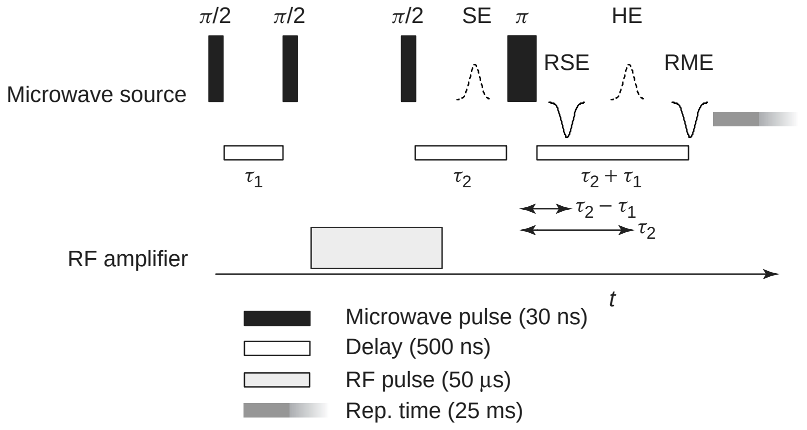

Figure 8 ReMims (Doan) ENDOR pulse sequence.[90] The upper level indicates the microwave pulses and immediately below delay times are indicated. The lowest level indicates the rf pulse. SE is the stimulated echo that is not detected, RSE is the refocused stimulated echo that can be detected (for $\tau_2 > \tau_1$; as shown here), and RME is the refocused Mims echo that is normally detected (at time $\tau_2 + \tau_1$). HE is the Hahn echo that is not detected and normally eliminated by microwave phase cycling. Typical times are given based on an X-band ($\sim$9.6 GHz) spectrometer,[80] but are also applicable at 35 GHz. The timing of both delay times τ_1 and τ_2 are adjusted to optimize spectral appearance as desired. Other aspects are similar to standard Mims ENDOR

often unsuitable for a sample with poor phase memory (i.e., a weak ESE, despite a large CW EPR signal). CW ENDOR often simply does not have the resolution of pulsed methods and often has more distorted lineshapes due to relaxation effects absent in pulsed experiments.

3.3.7 Pulsed TRIPLE Spectroscopy

As discussed earlier (Section 2.4.3), simulation of field-dependent ENDOR spectra for a given nucleus (or set of magnetically equivalent nuclei) allows determination of the *relative* signs of the components of a hyperfine matrix, which is crucial in understanding dipolar coupling, although it is not possible to determine the *absolute* signs. However, it is possible via a modification (augmentation) of standard ENDOR, known as *double ENDOR* or TRIPLE (which does not apparently stand for anything) to determine the relative signs of hyperfine couplings among different nuclei. If the absolute sign of any one of these can be determined by theoretical prediction or by some other experimental technique (e.g., paramagnetic NMR (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Metallobiomolecules*** or ***Mössbauer Spectroscopy***), then absolute sign determination is possible.

TRIPLE was first demonstrated as a CW technique applied to organic radicals in fluid solution,[93] for which the signs of coupling constants could provide important information on the nature of the SOMO. For bioinorganic systems, their inherently broad linewidths mean that maximum resolution is needed, thus the most meaningful form of TRIPLE is as a pulsed technique. A Davies pulse sequence is shown for TRIPLE in Figure 9. All aspects of the pulse sequence are the same as for a standard (i.e., single ENDOR) Davies experiment (*see* Figure 7), except that there are now two rf channels. The first, rf_1, is fixed to correspond to a specific nuclear transition (e.g., ν_+ of specific nucleus) and is thus the ‘‘pump’’. The second, rf_2, is swept as described for a standard Davies experiment and is thus the ‘‘probe’’. The reader is directed elsewhere for a more detailed description,[29] but the main point is that if two NMR transitions have the same origin, then irradiation of one will affect the intensity of the other. For example, in an $S = 1/2$ system with two nuclear spins ($I_1 = I_2 = 1/2$; $A_{iso} > 0$ for *both*, $g_N > 0$), then the NMR transitions $|M_S, M_{I1}, M_{I2}\rangle = |-1/2, +1/2, +1/2\rangle \leftrightarrow |-1/2, -1/2, +1/2\rangle$ and $|-1/2, +1/2, +1/2\rangle \leftrightarrow |-1/2, +1/2, -1/2\rangle$, which correspond to ν_+ for both I_1 and I_2, are coupled so that irradiation of the $\Delta M_{I1} = \pm 1$ transition at ν_{1+} will affect the ENDOR intensity of the $\Delta M_{I2} = \pm 1$ transition at ν_{2+} and *vice versa*. The ENDOR spectra of the ν_- transitions for I_1 and I_2, $|M_S, M_{I1}, M_{I2}\rangle = |+1/2, -1/2, -1/2\rangle \leftrightarrow |+1/2, +1/2, -1/2\rangle$ and $|+1/2, -1/2, -1/2\rangle \leftrightarrow |+1/2, -1/2, +1/2\rangle$, respectively, will be unaffected by the irradiation at ν_{1+} (or at ν_{2+}). The difference between a standard ENDOR spectrum and a TRIPLE spectrum (i.e., the difference between rf_1 off and rf_1 on) is best to demonstrate the TRIPLE effect. In this example, the difference spectrum would cancel out the ν_{1-} and ν_{2-} transitions, since neither is affected by rf_1, but the signals of the ν_{1+} and ν_{2+} transitions would both change and clearly appear in the difference spectrum. If the sign of A_{iso} for I_2 were opposite to that for I_1, then ν_{1+} and ν_{2-} transitions would show up most strongly in the difference spectrum.

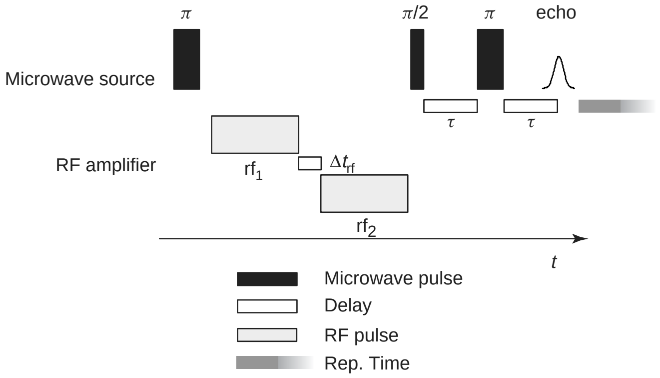

Figure 9 Davies TRIPLE pulse sequence.[29] The uppermost level indicates the microwave pulses and immediately below, delay times are indicated. The two lower levels indicate the rf pulses. The first rf energy (rf_1) is fixed and corresponds to a resonant nuclear transition and the second rf (rf_2) is swept over a range of frequencies to yield an ENDOR spectrum. The rf_1 pulse would be omitted to provide the control for a difference TRIPLE spectrum. The timing would be similar to a standard Davies sequence (*see* Figure 7). A Mims TRIPLE pulse sequence likewise would be the same as in Figure 6, except with two rf pulses as shown here

An example of the use of TRIPLE in a bioinorganic system is its application to the $[Fe_3S_4]^+$ ($S = 1/2$) cluster of *Desulfovibrio gigas* hydrogenase.[68] The protein was exchanged in D_2O buffer and the ^2H ENDOR signals of interest derived from solvent-derived molecules H-bonded to the cluster. Such H-bonding can affect the redox and other properties of FeS clusters. TRIPLE experiments demonstrated two points, the first that a given pair of ^2H signals was due to the same form of the cluster. The second point was that pumping on a $\nu_\pm$ signal of one ^2H affected the $\nu_\mp$ signal of the other ^2H, which indicated the opposite signs of A for these two hydrogen atoms (the relationship for ^1H is the same as for ^2H).[68] Such information is useful for the development of models of spin delocalization in an FeS cluster.

3.3.8 Pulsed ‘‘Implicit TRIPLE’’ Spectroscopy

The above description is of standard TRIPLE, i.e., explicit TRIPLE, employing two rf energies. Pulsed ENDOR can also exhibit relative sign information, in the absence of an additional rf energy. This phenomenon has been called ‘‘implicit TRIPLE’’,[69] and was demonstrated for nitrile hydratase, a nonheme iron enzyme (low-spin Fe^{III}, $S = 1/2$). Standard Mims ENDOR experiments were performed and the intensities of $\nu_\pm$ signals for ^1H were compared for natural

abundance enzyme (i.e., ^{14}N, $I = 1$) and enzyme globally enriched in ^{15}N ($I = 1/2$). The latter sample exhibited the expected roughly equal intensities for $\nu_{\pm}$ partners of ^{1}H Mims ENDOR signals, while the natural abundance sample exhibited anomalous intensities. These anomalous intensities arose because the ESEEM provided by the ^{14}N nuclei (which is absent for ^{15}N) coupled to the paramagnetic site (as ligands) in effect provided the second rf energy, normally provided by a second rf pulse in explicit TRIPLE.[69] A detailed explanation for this process is given by Doan *et al*., however, the consequence is that when the ^{1}H and ^{14}N hyperfine couplings have the same sign, then the ν_{-} partner of a given ^{1}H Mims ENDOR signal is suppressed, while ν_{+} is suppressed when the two have opposite signs. Thus, the same information is obtained as from a TRIPLE experiment, but with standard ENDOR equipment. The disadvantage is that without comparison to samples in the absence of this ESEEM effect, assignment of signs might be overly optimistic since there might be other factors leading to $\nu_{\pm}$ partner intensity differences.

Another advantage of ReMims (Doan) ENDOR is the ability to observe this implicit-TRIPLE effect for a wider range of hyperfine couplings.[90] A given hyperfine coupling could be deleteriously affected by Mims blind spots, which would prevent observation of implicit TRIPLE. However, use of ReMims (Doan) ENDOR would allow selection of τ value(s) that do not cause troublesome blind spots while simultaneously suppressing ESEEM, so that the presence of the implicit TRIPLE effect could be explored.

4 APPLICATIONS

4.1 Nitrogenase

4.1.1 Background on Molybdenum Nitrogenase

The enzyme nitrogenase is found in a number of anaerobic microorganisms, such as *Azotobacter vinelandii* and *Clostridium pasteurianum*.[94,95] Nitrogenase catalyzes the ambient temperature and pressure reduction (‘‘fixation’’) of dinitrogen to ammonia by the following reaction:

$$N_2 + 8H^+ + 8e^- \longrightarrow 2\,NH_3 + H_2 \qquad (11)$$

Owing to both the biological importance and the chemical difficulty of this reaction, nitrogenase enzymes have been very widely studied by biological and chemical techniques.[94–98] Extensive synthetic modeling efforts have also been made.[99] The active site of nitrogenase, referred to as FeMo-cofactor, resides within the MoFe protein, and comprises an unusual $MoFe_7S_9$ cluster that contains a single Mo (bound to the cluster and also coordinated by homocitrate, and possibly another atom, ‘‘X’’, as yet unidentified[100]). The MoFe protein also contains another unusual $[Fe_8S_7]$ cluster, referred to as the P-cluster. Here we merely highlight selected recent studies on the FeMo-cofactor that made use of ENDOR spectroscopy.[97,98]

4.1.2 ENDOR Studies on the Resting State of Nitrogenase FeMo-cofactor

Much of this work has been discussed earlier (Section 2.3.3) in the context of ENDOR spectroscopy of high-spin ($S > 1/2$) systems, as the electronic spin ground state of nitrogenase FeMo-cofactor has $S = 3/2$. From a historical perspective, this work was one of the earlier applications of ENDOR to metalloprotein systems by the Hoffman laboratory,[53,54] and owed a great deal of its success to the biochemical expertise of the late William H. Orme-Johnson, one of the pioneers not only of nitrogenase research but of bioinorganic chemistry in general.[101]

Analysis of the ^{57}Fe ENDOR spectra of isotopically enriched FeMo-cofactor indicated the number of magnetically distinct Fe sites in the cluster,[53,54,102] which, well before the crystal structure of nitrogenase was determined,[103] was important in understanding the unusual structure of the FeMo-cofactor. Specifically, five Fe sites were identified and characterized by their hyperfine coupling tensors. This information, in combination with studies on model compounds and other FeS proteins can provide information on the oxidation state of the Fe ions and the nature of their coupling. Other experimental techniques, in particular Mössbauer spectroscopy, were applied to analyzing the Fe sites in this system, but ENDOR has the advantage that only those Fe ions that are associated with the paramagnetic center under interrogation (i.e., contributing to the EPR signal at a particular g_{obs} value) will give rise to ENDOR signals. In contrast, Mössbauer spectroscopy simultaneously observes all Fe atoms. This lack of specificity is a particular problem for understanding nitrogenase since the enzyme has two component proteins, the MoFe protein of interest here, and an Fe protein involved in electron transfer that will not be discussed here, so that the total number of Fe sites is very large.

What ENDOR was also able to accomplish with regard to the resting state FeMo-cofactor, which was not possible for Mössbauer spectroscopy, was to elucidate the nature of the Mo site.[53,104] This result represented a remarkable collaboration between spectroscopy and enzymology. Enzyme samples enriched in several Mo isotopes were prepared by microbe growth on a medium containing the following molybdate isotopologs: ^{100}Mo (97.4%, $I = 0$), ^{97}Mo (94.2% (9.6% natural abundance), $I = 5/2$), and ^{95}Mo (96.5%, (15.9% natural abundance), $I = 5/2$). The ^{100}Mo-enriched sample was needed as a zero-spin baseline control since the natural abundance of the nonzero spin Mo isotopes (as indicated) is sufficiently high so that a natural isotopic abundance sample would not be a convincing ENDOR control. Careful comparison of CW X-band ENDOR spectra of these

samples indicated that the FeMo-cofactor contained a single Mo site, and the small magnitude of the observed hyperfine coupling, $A^{95\mathrm{Mo}} \approx 5-8$ MHz, indicated a diamagnetic Mo ion, either $\mathrm{Mo^{IV}}$ or $\mathrm{Mo^{VI}}$, as opposed to paramagnetic $\mathrm{Mo^{III}}$ or $\mathrm{Mo^{V}}$. ENDOR also provided ^{95}Mo quadrupole coupling information, which allowed assignment of the formal oxidation state of the Mo site to $\mathrm{Mo^{IV}}$. This assignment was based on information from ^{95}Mo NMR studies of model compounds and on the qualitative consideration that $\mathrm{Mo^{VI}}$, a d^0 ion, would be expected to show very small quadrupole coupling.

Enzyme samples from microbes grown on ^{33}S enriched medium (0.75% natural abundance, $I = 3/2$) allowed observation of ^{33}S ENDOR[53] results that were also useful in characterizing the inorganic sulfide sites in the FeMo-cofactor, as at that time, the cluster was indeed a ''black box''.

4.1.3 *ENDOR Studies on Inhibitor States of the Nitrogenase FeMo-cofactor—Carbon Monoxide*

A major biochemical breakthrough in the biochemical investigation of nitrogenase was the ability to prepare EPR-active inhibitor states of the enzyme. Under traditional turnover conditions (i.e., N_2, ATP, Fe protein, etc., all present), the resting state EPR signal disappears, rendering any ENDOR studies useless. However, it was found that turnover in the presence of the inhibitor CO led to the observation of two new EPR signals, both of $S = 1/2$ species: lo-CO, observed under low CO concentration (partial pressure, 0.08 atm), rhombic with $g_{\mathrm{av}} < 2$: $\mathbf{g} = [2.09, 1.97, 1.93]$, and hi-CO, observed under high CO concentration (0.5 atm), axial with $g_{\mathrm{av}} > 2$: $\mathbf{g} = [2.17, 2.06, 2.06]$.[105,106] These EPR results were the first evidence of a small molecule interacting with the MoFe protein, but no direct information on the nature of the CO interaction was obtainable.

Such information was provided by ENDOR studies of both the lo-CO and hi-CO inhibitor forms of the FeMo-cofactor prepared with isotopically enriched ^{13}CO[105,107,108] and ^{57}Fe (*see* subsequent text).[107,109] The combination of CW and pulsed 35 GHz ^{13}C ENDOR demonstrated that there is a single CO molecule bound to the FeMo-cofactor in the lo-CO state and at least two CO molecules bound in the hi-CO state. Representative ENDOR spectra of the ^{13}CO signals are shown in Figure 10. The hyperfine couplings for the ^{13}CO bound in lo-CO and for one of the two molecules in hi-CO are quite small: $A_{\mathrm{iso}} = 1.2$, 0.7 MHz, respectively.[108] The measurement of these small couplings was an excellent example of the use of Mims and ReMims (Doan) ENDOR. The ^{13}C hyperfine coupling tensors, in combination with information from EPR and ENDOR studies on iron carbonyl compounds and other model compound and metalloprotein systems, as well as spin delocalization studies of nitrogenase, led to a proposed geometry of CO binding to the FeMo-cofactor. This structure is shown in Figure 11, in which the CO that binds initially bridges two Fe ions (μ_2 geometry),

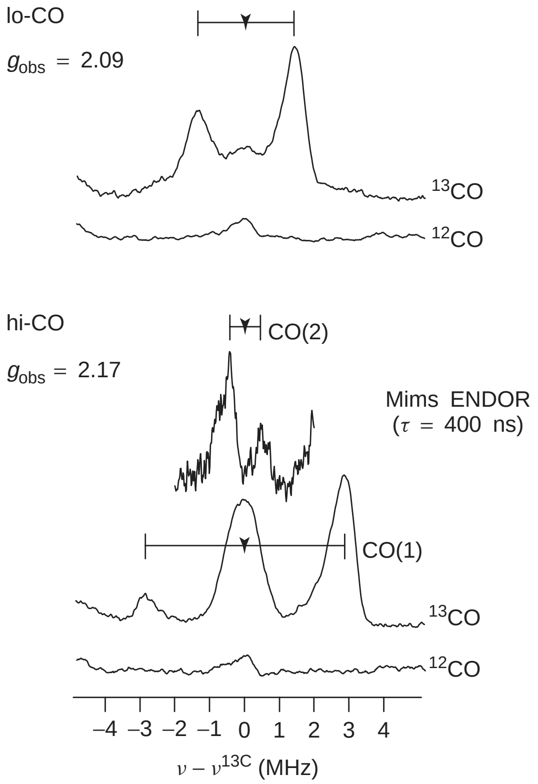

Figure 10 35 GHz CW ^{13}C ENDOR (except for Mims ENDOR as indicated) of lo-CO and hi-CO inhibitor forms of nitrogenase FeMo-cofactor, prepared with both ^{13}CO and ^{12}CO. The spectra were recorded at g_{max} of each species, as indicated. The spectra are centered at the ^{13}C Larmor frequency ($\nu^{13\mathrm{C}} \approx 12.3$ MHz at $g_{\mathrm{max}} = 2.17$ for hi-CO). The ^{13}C ENDOR signals from the cluster-bound CO molecules are indicated. The spectra of samples prepared with ^{12}CO show weak signals from natural abundance ^{13}C, most likely from protein residues in the cluster vicinity. (Adapted from Figure 5 in Pollock, Lee, Cameron, DeRose, Hales, Orme-Johnson and Hoffman.[105] Reprinted with permission, © 1995 American Chemical Society)

while the two CO molecules in the hi-CO form bind terminally to each of two different Fe ions.

In parallel with this work using ^{13}C isotopologs, extensive work was done on the CO-inhibited turnover states using ^{57}Fe-enrichment.[107,109] One of the first studies employed MoFe protein in which, through beautiful biochemical work, its two inorganic constituents, the FeMo-cofactor and the P-cluster, were each labeled with ^{57}Fe to yield specifically labeled [(Mo^{57}Fe)(P-Fe)] and [(MoFe)(P-^{57}Fe)], as well as both globally enriched and natural abundance MoFe protein.[107] Representative 35 GHz CW ^{57}Fe ENDOR spectra of all of these isotopolog samples are shown in Figure 12, which clearly shows that the signals are due only to the FeMo-cofactor. Thus the EPR signal that results under turnover conditions in the presence of CO arises *only* from the active site of the MoFe protein. With this established, the next step was a detailed quantitative analysis, primarily by field-dependent

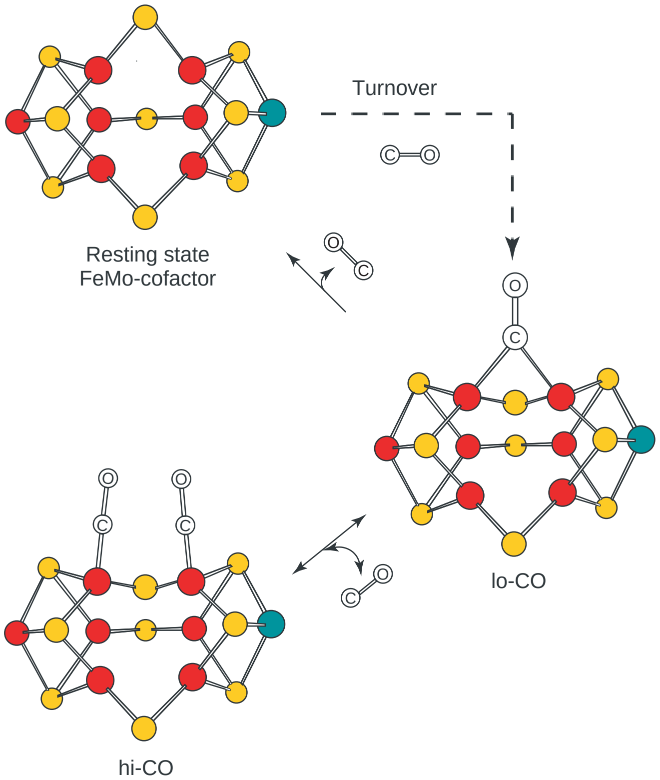

Figure 11 Cartoon showing CO binding to the FeMo-cofactor of nitrogenase FeMo protein. The S atoms are shown in yellow, the Fe atoms in red, and the Mo atom in blue-green. At lower CO partial pressure, the lo-CO form exists with a single, bound, bridging CO. At higher CO partial pressure, the hi-CO form exists, with two CO molecules bound to the cluster

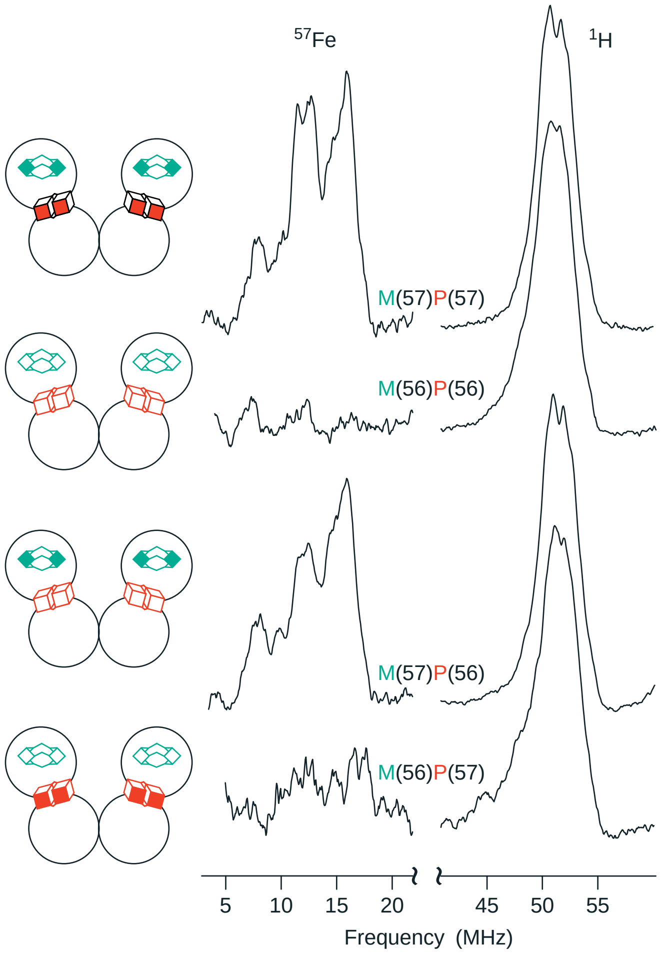

Figure 12 35 GHz ^{57}Fe and ^{1}H CW ENDOR spectra of the hi-CO form of nitrogenase MoFe protein with varying types of ^{57}Fe-enrichment. The ^{1}H signals are included as intensity standards since the natural abundance samples contain observable amounts of ^{57}Fe. The spectra were recorded at $g_{obs} = 2.06$ ($g_{\perp}$). Cartoons on the left indicate the specific sample, wherein the FeMo-cofactor is indicated by the diamond shape (in green), and the P-cluster is indicated by the two cubes (in red). These shapes roughly represent the clusters' actual structures. ^{57}Fe-enriched sites are indicated as colored blocks. The abbreviations used are as follows: M(56)P(56) is natural abundance FeMo-cofactor and P-cluster; M(56)P(57) is natural abundance FeMo-cofactor and enriched P-cluster; M(57)P(56) is enriched FeMo-cofactor and natural abundance P-cluster; M(57)P(57) is enriched FeMo-cofactor and P-cluster (i.e., globally enriched MoFe protein). (Adapted from Figure 1 in Christie, Lee, Cameron, Hales, Orme-Johnson and Hoffman.[107] Reprinted with permission, © 1996 American Chemical Society)

CW 35 GHz ENDOR, of the individual Fe sites in the CO-inhibited forms,[109] much as had been done earlier for resting state FeMo-cofactor.[54] Hyperfine coupling constants were determined for four Fe sites in the lo-CO and three in the high-CO forms. The signs and magnitudes of the A_{iso}^{57}Fe values, in comparison with those of other FeS proteins and with extensive computational studies,[55] allowed a proposal as to the formal oxidation state assignments of the metal ions in the FeMo-cofactor as: $[Fe_7S_9Mo]^+ = [(Fe^{2.5+})_2, Fe_5^{2+}, S_9^{2-}, Mo^{4+}]^+$, where $(Fe^{2.5+})_2$ is the delocalized $Fe^{II}Fe^{III}$ pair.[109]

4.1.4 *ENDOR Studies on Substrate Analogue Turnover States of the Nitrogenase FeMo-cofactor—Ethyne*

Another molecule isoelectronic with the substrate dinitrogen and the inhibitor carbon monoxide is ethyne (acetylene), which is a substrate for nitrogenase (producing ethene, a process used as an assay for nitrogenase activity).[110] Hales and coworkers showed that a site-directed mutant of wild-type nitrogenase, in which the α-subunit histidine-195 residue was substituted by glutamine (denoted α-H195Q-FeMo-cofactor), was not active in N_2 reduction, but did reduce C_2H_2 at the rate similar to wild-type enzyme. Of relevance here is that this mutant, under turnover conditions with ethyne, allowed observation of three different $S = 1/2$ EPR signals ($S_{EPR1,2,3}$, of which S_{EPR3} was very minor), presumably arising from the interaction of ethyne with the FeMo-cofactor.[111]

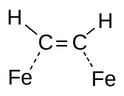
As above with the CO-inhibited forms, only by means of ENDOR spectroscopy was it possible to demonstrate that

the substrate was indeed interacting with the active site cluster. As with CO, ^{13}C labeling was employed, although in this case there are two labeled atoms: $^{13}C_2H_2$. However, there is an additional, convenient isotopic label, not available with CO, namely C_2D_2. Thus, α-H195Q-FeMo-cofactor under turnover conditions in the presence (0.1 atm) of natural isotopic abundance ethyne, $^{13}C_2H_2$, and C_2D_2 were investigated by 35 GHz CW ENDOR.[110] The major species, S_{EPR1}, exhibited signals assignable to both ^{13}C atoms of ethyne, which were nearly equivalent ($A_{iso}^{13}C = 2.5$ and 2.3 MHz, respectively), and to an additional, very weakly coupled ^{13}C (the other two, minor EPR signals did not give observable ^{13}C couplings). The experiments with ^{1,2}H isotopologs were more sophisticated than might be naively thought, since there is also the consideration of buffer composition. Thus, there were four cases to be investigated by ^{1,2}H ENDOR: C_2D_2 in D_2O buffer, C_2D_2 in H_2O buffer, C_2H_2 in D_2O buffer, and C_2H_2 in H_2O buffer. The primary result from comparisons among these spectra was that samples prepared with C_2H_2 exhibited a strongly coupled (maximum $A^{1H} \sim 13$ MHz) ^{1}H signal that is absent for samples prepared with C_2D_2, even in H_2O buffer. Thus, this hydrogen must be associated with ethyne substrate and is not solvent exchangeable.[110] Unfortunately, it was not possible to determine whether this signal was due to one or two hydrogen atoms, which is related to the limitations of ENDOR (Section 2.3.2). Enzymological studies showed that reduction of C_2H_2 in D_2O yields primarily *cis*-CHDCHD. It was therefore proposed that the model for ethyne binding consistent with spectroscopic data, organometallic models, computational and structural studies of cluster spin density and structure, and biochemical results, was that S_{EPR1} arises from ethyne bound to two cluster Fe ions as shown in Scheme 1.[110]

The bonding depicted is deliberately vague and could be described either as π-bound alkyne or as a σ-bound alkene dianion. This model will be expanded on and revised in Section 4.1.6.

4.1.5 ENDOR Studies on Substrate Analogue Turnover States of the Nitrogenase FeMo-cofactor—Propargyl Alcohol (Prop-2-yn-1-ol)

The molecules described above, CO and C_2H_2 (Sections 4.1.3 and 4.1.4, respectively), are obvious choices for probes of nitrogenase. Less obvious is a molecule used very recently and successfully, propargyl alcohol (PA, prop-2-yn-1-ol, HC≡C–CH_2OH).[84] What was also critical in this project was the preparation of another site-directed mutant



Scheme 1 Bonding of ethyne to FeMo-cofactor as originally proposed[110]

of nitrogenase, in which the α-subunit valine-70 residue was substituted by alanine (denoted α-V70A-FeMo-cofactor). In this mutant, the enzyme can reduce larger alkynes, such as PA, which are nearly inactive with wild-type nitrogenase. Not only did this expand the range of substrate probes available, but the mutation also showed the location of substrate binding onto the cluster.[112]

Trapping of a reaction intermediate of α-V70A-FeMo-cofactor under turnover conditions with PA yields a species with $S = 1/2$ and $\mathbf{g} = [2.123, 1.998, 1.986]$.[84] Use of the globally labeled isotopolog H^{13}C≡^{13}C–^{13}CH$_2$OH yielded ^{13}C ENDOR spectra indicating three types of carbon signals.[112] Further refinement was possible through use of commercially available PA-^{13}C3 (H^{13}C≡C–CH$_2$OH) and a series of ^{1,2}H samples analogous to those described above for ethyne: DC≡C–CH$_2$OD in D_2O buffer, DC≡C–CH$_2$OH in H_2O buffer, HC≡C–CH$_2$OD in D_2O buffer, and HC≡C–CH$_2$OH in H_2O buffer. The 35 GHz CW and ReMims (Doan) ^{13}C ENDOR spectra are shown in Figure 13. The higher resolution (albeit with lower S/N) of the ReMims (Doan) ENDOR spectra relative to CW is striking. These studies allowed precise determination of the ^{13}C hyperfine coupling tensors for the three C atoms of PA.[84]

The ^{1,2}H was also a dramatic demonstration of the possibility of quantitative ENDOR, since qualitative results were ambiguous. Only in the ‘‘perdeuterated’’ sample (DC≡C–CH$_2$OD in D_2O buffer) was a strongly coupled ($A_{iso} = 13.8$ MHz) ^{1}H signal absent in CW ^{1}H ENDOR. Thus the signal could not be clearly assigned either to the solvent nonexchangeable (near neutral pH) alkynyl H or to a hydrogen atom derived from the solvent. The answer was found by use of ^{1}H FMDST-ENDOR (*see* Section 3.3.3), wherein the signal intensity can be quantitated and is without sweep and other artifacts. The result is shown in Figure 14. As expected, the ‘‘perdeuterated’’ sample exhibits essentially baseline. The ‘‘perprotiated’’ sample (HC≡C–CH$_2$OH in H_2O buffer) exhibits the strongest signal, almost exactly twice the intensity of the two isotopologs of PA (DC≡C–CH$_2$OH and HC≡C–CH$_2$OD). The explanation for this behavior is that the PA-derived species bound to the FeMo-cofactor contains two magnetically equivalent H atoms, one derived from solvent (H_a^S) and one derived from H–C3 of PA (H_a^C). Extensive consideration of organometallic complexes, in combination with the hyperfine couplings known for organic radicals, led to the proposal that the species observed by ENDOR was a bound allyl alcohol (CH$_2$=CHCH$_2$OH), effectively with a symmetry plane through the C–C bond. The resulting structure is shown in Scheme 2, which includes the observed A_{iso} values for ^{13}C and ^{1}H atoms. Note that this scheme represents a σ-bound ferracyclopropane, ‘‘ferracycle’’, rather than a π-bound alkene.[84]

This result for PA led to a reevaluation of the binding of ethyne, which included extensive additional 35 GHz

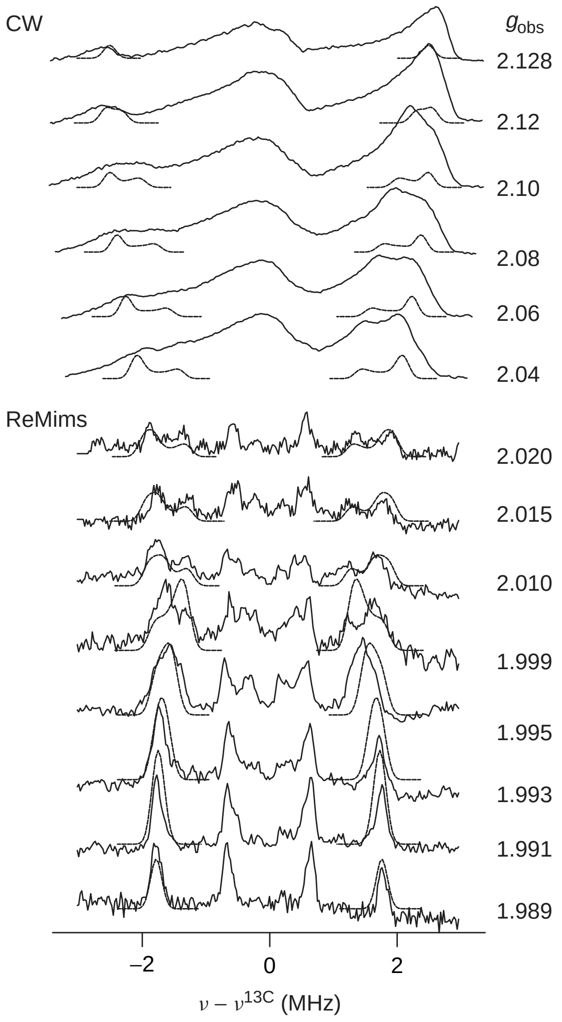


Figure 13 35 GHz ^{13}C CW ENDOR (upper set of spectra) and ReMims (Doan) ENDOR (lower set of spectra) of α-V70A-FeMo-cofactor under turnover conditions with propargyl alcohol (PA) labeled at C3: $H^{13}C{\equiv}C–CH_2OH$. The ENDOR spectra were recorded at field positions (g_{obs} values as indicated) across the EPR envelope of the PA intermediate, which has $\mathbf{g} = [2.123, 1.998, 1.986]$. Spectra are centered at the ^{13}C Larmor frequency ($\nu^{13C} = 13.4$ MHz at $g = 2.0$). Simulations are also shown as dashed lines for features of interest. (Adapted from Figure 4 in Lee, Igarashi, Laryukhin, Doan, Dos Santos, Dean, Seefeldt and Hoffman.[84] Reprinted with permission, © 2004 American Chemical Society)

^{57}Fe and ^{1}H CW ENDOR spectroscopy on α-H195Q-FeMo-cofactor.[113] As a result of this work, the binding of ethyne to the FeMo-cofactor is now proposed to be to a single Fe ion of the cluster, whether as a π-bound species or as a σ-bound ferracycle. Moreover, by analogy with the results for PA binding,[84] the trapped turnover state that is actually observed by ENDOR contains ethene, not ethyne, bound to the cluster. This is depicted in Scheme 3, where no substituents are given, since the specific geometry is not known. This scheme is a much simplified version of Figure 8 from Lee *et al.*[113]

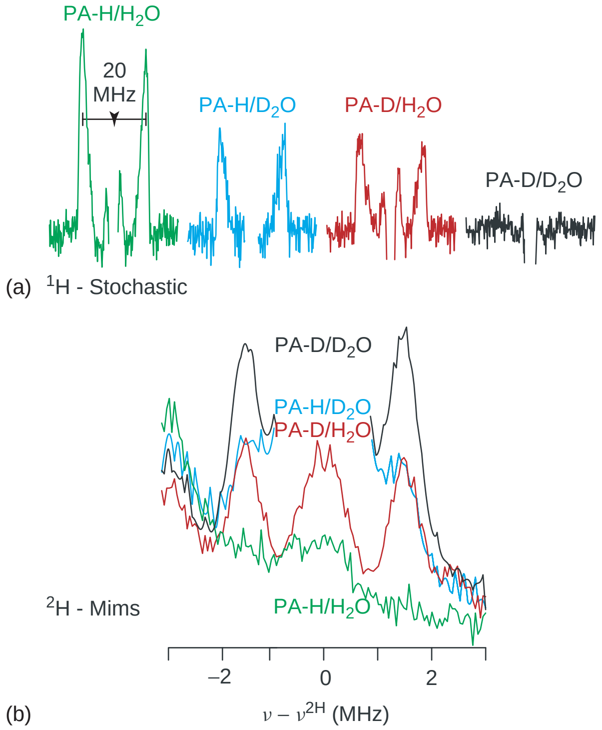

Figure 14 35 GHz ^{1}H FMDST-ENDOR (a) and ^{2}H Mims ENDOR (b) of α-V70A-FeMo-cofactor under turnover conditions with propargyl alcohol (PA) with various forms of hydrogen isotope labeling. The spectra were recorded at $g_{obs} = 1.989$ ($\sim g_{min}$). The abbreviations used in the figure are as follows: $DC{\equiv}C–CH_2OD$ in D_2O buffer: PA-D/D_2O; $DC{\equiv}C–CH_2OH$ in H_2O buffer: PA-D/H_2O; $HC{\equiv}C–CH_2OD$ in D_2O buffer: PA-H/D_2O; $HC{\equiv}C–CH_2OH$ in H_2O buffer: PA-H/H_2O. ^{1}H FMDST-ENDOR spectra are centered at the ^{1}H Larmor frequency, $\nu^{1H} \approx 53.7$ MHz; rf scale shown for strongest ^{1}H coupling, $A^{1H} \approx 20$ MHz). The ^{2}H Mims ENDOR spectra are centered at the ^{2}H Larmor frequency ($\nu^{2H} \approx 8.2$ MHz). In all cases, strong signals from distant $^{1,2}H$ nuclei, which are of no biochemical interest, are removed. (Adapted from Figure 6 in Lee, Igarashi, Laryukhin, Doan, Dos Santos, Dean, Seefeldt and Hoffman.[84] Reprinted with permission, © 2004 American Chemical Society)

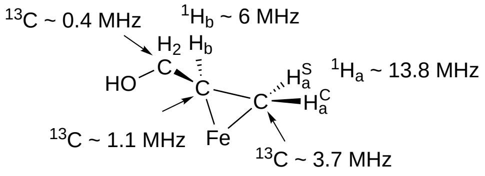
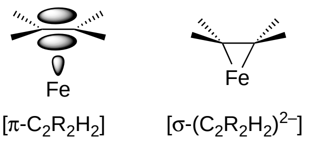


Scheme 2 Hyperfine couplings of propargyl alcohol bound to Fe of FeMo-cofactor

4.1.6 *Other Nitrogenase ENDOR Studies and Summary Comments*

There are additional ENDOR studies on nitrogenase FeMo-cofactor that have not even been mentioned here. These include studies on the alternative substrate carbon disulfide,



Scheme 3 Bonding of alkene to FeMo-cofactor as later refined.[113] Geometrical isomerism (E, Z) of $C_2R_2H_2$ is not specified

which yields an $S = 1/2$ intermediate that was investigated by ^{13}C ENDOR of samples trapped with bound $^{13}CS_2$.[114] The mutant α-V70I-FeMo-cofactor fails to react with any substrate, presumably due to blockage of the active site by the large isoleucine sidechain, but the enzyme can still perform the hydrogenase reaction under turnover conditions and exhibits a novel $S = 1/2$ EPR signal.[115] CW 35 GHz ^1H ENDOR studies revealed two types of strongly coupled ($A_{iso} \approx 23$ MHz) hydrogen atoms. The large coupling means that these are covalently bound to the FeMo-cofactor cluster, but their assignment as H^+ (hydron) or H^- (hydride) could not be made. Nevertheless, the comparison of the **A** matrices for these two ^1H atoms allowed speculation as to the geometry of their binding to the cluster.[115]

Of perhaps greater interest are the very recent EPR/ENDOR studies of turnover states derived from nitrogen-containing molecules, as opposed to carbon-containing molecules, namely methyl-diazene ($CH_3N{=}NH$) and hydrazine ($NH_2\,NH_2$) molecules,[116,117] with studies on diazene itself very recently reported.[118] Space limitations prevent discussion of these very recent results, but the method of analysis is as described here for the carbon-containing molecules. These doubly and singly nitrogen–nitrogen bonded molecules, which can be studied as both ^{14}N and ^{15}N isotopologs, are likely intermediates in the transformation of triply bonded N_2 into separate NH_3 molecules.

From a biochemical point of view, the summation of the ENDOR studies on nitrogenase FeMo-cofactor interacting with carbon-containing small molecules is an electron inventory of the resting state, lo-CO form, and ethyne-bound form (S_{EPR1}), resulting in the proposal that the resting state is two electrons more oxidized than the substrate/inhibitor-bound forms and further, that these forms could be placed into the context of the Lowe-Thorneley scheme of nitrogen fixation.[113]

From the point of view of inorganic chemistry, these ENDOR studies on nitrogenase FeMo-cofactor give definitive evidence of a remarkable series of bioorganometallic complexes, which should provide both a challenge and inspiration to synthetic chemists.

5 ACKNOWLEDGMENTS

I wish to thank Prof. Brian M. Hoffman, Northwestern University, for creating the outstanding laboratory where I have been exposed to ENDOR spectroscopy, beginning in the mid 1980s. I also wish to thank Dr. Peter E. Doan, Northwestern University, for many helpful instructions over the years, and other members of the Hoffman group, particularly Dr. Nicholas S. Lees and Dr. Rebecca L. McNaughton for their helpful comments on this paper. I also wish to thank Prof. Hong In Lee, Kyungpook National University, Korea, for his generous assistance with the sections on nitrogenase. I thank Prof. Judith N. Burstyn, University of Wisconsin-Madison, for providing samples of CooA.

6 ABBREVIATIONS AND ACRONYMS

CW = continuous wave; ENDOR = electron-nuclear double resonance; EPR = electron paramagnetic resonance; ESR = electron spin resonance; EMR = electron magnetic resonance; ESEEM = electron spin echo modulation; ESE = electron spin echo; FMDST = field modulation detected stochastic; hwhm = half-width half-maximum; HPLC = high performance liquid chromatography; NMR = nuclear magnetic resonance; PA = propargyl alcohol; pnZ = pseudonuclear Zeeman; rf = radiofrequency; RNR = ribonucleotide reductase; RSE = refocused stimulated echo; SOMO = semi-occupied molecular orbital; $2-Me-THF = 2-$ methyltetrahydrofuran; zfs = Zero-field splitting (for $S > 1/2$); D = Uniaxial zfs; E = Rhombic zfs; $\mathbf{g} = \mathbf{g}$ Matrix (for $S > 0$) with principal components g_x, g_y, g_z, or g_1, g_2, g_3; $\mathbf{A} = \mathbf{A}$ Matrix (for $I > 0$) with principal components A_x, A_y, A_z, or A_1, A_2, A_3; g_e = Free electron g value; g_N = Nuclear g value (isotropic) for a given nucleus N (nuclear spin $I > 0$); A^N = Hyperfine coupling constant for a given nucleus N (nuclear spin $I > 0$); P^N = Quadrupole coupling constant for a given nucleus N (nuclear spin $I > 1/2$); ν_+ = Higher frequency partner of an ENDOR signal (for $I = 1/2$) or partners (for $I \geq 1$); ν_- = Lower frequency partner of an ENDOR signal (for $I = 1/2$) or partners (for $I \geq 1$); $\nu_\pm$ = The two partners of ENDOR signal (for $I = 1/2$) or set of partners (for $I \geq 1$); ν^N = Larmor (NMR) frequency of nucleus N at a given external magnetic field B; rf = Radiofrequency (in MHz); τ = Delay time in a pulsed EPR or ENDOR sequence; t = Microwave or rf pulse time in a pulsed EPR or ENDOR sequence.

METHOD SUMMARY

Acronyms, Synonyms

- rapid freeze-quench (RFQ), (usually referring to freeze quench techniques with dead-times >5 ms).
- microsecond freeze-hyperquenching (MHQ), (refers to recently developed rapid freeze-quench techniques with dead-times below 200 µs).

Measured physical quantities

- None directly; the MHQ technique yields a frozen powder, which can be analyzed by various types of low-temperature spectroscopy like X-, Q-band EPR, UV-Visible spectroscopy, resonance Raman and potentially or in the near future by MCD, Mössbauer, ESEEM, ENDOR, EXAFS, W-, D-band EPR, MAS-NMR and FTIR spectroscopy.
- These spectroscopic techniques are already available for samples prepared with the RFQ method enabling determination of the electronic structure of metallo-sites or radicals in intermediates formed during the reaction.
- Calculation of the rate constants for the interconversion of one intermediate to another delineating a reaction pathway in, for example, enzymes, or more generally in (bio)chemical reactions.

Information available or not available

- Rates of chemical reactions
- Existence and temporal behavior of intermediates
- The analysis is determined by the kind of spectroscopy used. The current time limitation of the MHQ technique is approximately 60 µs.

Examples of questions that can be answered

- The high time resolution for MHQ allows one to study enzyme or chemical catalytic mechanisms in greater depth than hitherto, simply because more intermediates can potentially be trapped.

- In particular the higher time resolution compared to the stopped-flow (~1 ms) is important in this respect. In enzymes, many intermediates are formed on the microsecond time scale but have so far escaped detection.

Major advantages

- The technique is very general and applicable to all chemical and biochemical systems that are stable at room temperature. One can, for example, work aerobically or anaerobically, and at elevated pressures, tested so far up to 10 bar.
- Compared to the classical RFQ, MHQ samples are devoid of cryo-solvents like isopentane as the rapid freezing occurs on a rapidly rotating cold plate or cold surface.

Major disadvantages

- Sample requirements for MHQ are similar to or approximately twofold higher than in classical RFQ methods, a single time point requiring 2–5 mg of protein (~10–100 nmol) and thus quite high. However, this figure is very dependent on the type of analyzes one would like to perform. A kinetic analysis under one experimental regime will require 10–15 samples including controls. After reacting e.g., enzyme and substrate by 1:1 mixing a fine frozen powder is obtained, which is quite dilute (approximately eightfold with respect to the starting concentration, compared to 3–4 times in the classical RFQ).
- The powder obtained with the MHQ technique, which has to be maintained below 140 K to prevent further reaction, is more difficult to handle than that produced by the RFQ technique because of its finer structure. To apply the spectrocopies listed above to such a powder, one often has to construct specific adaptations to sample holders and/or sample compartments, in particular, to get the powder where required, without warming during handling and operation.

1 INTRODUCTION

Kinetic analyses serve to determine reaction rates, reaction rate constants and the rate law of a chemical reaction. The rate law contains information on the order (zero, first, second etc.), stoichiometry, or concentration dependence of the various reactants or (metastable) intermediates. The rate equation helps one to define the overall reaction. In favorable cases when (metastable) intermediates accumulate, (some of the) individual reaction steps might be revealed, thus solving the ''mechanism''. Traditionally, reactant and/or product concentrations are being measured as a function of time (seconds to hours) in a series of experiments in which the concentrations of the reactants, or their isotope analogues are being varied, in addition to pH, temperature, pressure, solvent etc., providing a full kinetic and thermodynamic profile.[1–3] While the rate equation is generally quite simple to derive, its integrated analytical form, describing the reactant/intermediate/product concentrations as a function of time (thus directly relating the experimental data to the theory), becomes a mathematical nightmare even for a simple consecutive three species ($A \Leftrightarrow B \Leftrightarrow C$) reversible scheme. The mathematical expression is greatly simplified when at least one of the reactions is (quasi-) irreversible, or when a relatively stable intermediate is formed. However, an insight into the complete mechanism is lost in this case, as the main information obtained is in relation to the major rate determining step. The above scenario—a steady-state kinetic approach with its roots in the late nineteenth and early to mid-twentieth century—might seem out of date, but is to this day the initial step of any (bio)chemical kinetic analysis concerning a new chemical or enzyme system. However, with the advancement of science and technology in the twentieth century, the timescale for kinetic analyses has decreased from seconds to femtoseconds enabling pre-steady state or transient-state kinetic studies. Within a century, the spectroscopic toolbox has vastly increased, from ''color vision'' to covering the electromagnetic spectrum from 10^{-10} m to m. Electron and nuclear spin states, or more generally, ''electronic states'' are related to molecular structure with the help of quantum mechanics. In the past five decades, the analytical resolution and sensitivity has increased from micromole amounts to the single molecule level. Ultrafast computers and sophisticated computer algorithms have obviated the need to search for analytically exact or approximate solutions, having replaced them by robust numerical calculations.

Much of the progress in transient kinetic analyses comes from the development and applications of Laser Flash Photolysis and has recently been comprehensively reviewed by Zewail.[4] With the present state of the art of technology, the field of kinetics has changed to ''structural kinetics and structural dynamics'' altering the concept of ''Transition State'' to that of a short-lived transient state (~500 fs), the very structure and dynamics of which can be determined experimentally.

2 THE PRE-STEADY STATE KINETIC EXPERIMENT

Kinetic experiments are performed in two different ways. In one an initial disequilibrium exists between two or more reactants, which after being rapidly *mixed*, combine to react toward equilibrium (*see* ***Rapid Scan, Stopped-Flow Kinetics***). Ideally, the mixing time is short with respect to the timescale of the reaction or actually with respect to the formation of intermediates. In contrast, in the *relaxation* experiment, the reactants are together and in equilibrium, and the whole system is ''instantaneously'' displaced from equilibrium. Subsequently, the system relaxes to the same or a new equilibrium state. Table 1 summarizes the approximate time resolution of various commonly applied mixing and relaxation techniques. The table indicates the superiority of the relaxation methods with respect to time resolution, mainly due to the development of ultrafast lasers. Mixing liquids on the (sub)microsecond time scale appears to present an important experimental barrier.

2.1 Relaxation Techniques Applied to Enzyme Catalysis

The pathway and kinetics of electron transfer in photochemically activated reaction centers of chloroplasts and photosynthetic microorganisms have been largely solved thanks to ultrafast lasers.[21] The initial steps of light-activated electron transfer do not involve the breaking and making of chemical bonds unlike the great majority of chemical and biochemical reactions. To study the latter type of reactions, the major practical limitation of the flash photolysis type of experiment — that the system under — study must be activated by a (short intense) flash of electromagnetic radiation — might be overcome by synthesizing a ''caged compound''. For example, an enzymatically inactive photolabile substrate analog might serve as a caged compound.[22–24] A wide variety of caged compounds are commercially available, such as ATP or neurotransmitter analogs, and Ca^{2+}-, H^{+}-, or NO-releasing compounds. The caged compound can be safely mixed with the enzyme, only liberating the active substrate upon a flash of light, thus obviating the need for rapid mixing to study fast reaction kinetics. Depending on the type of caged compound, the time resolution is determined by the photochemical bond breaking process (which is dependent on the particular chemical but may be as short as ∼1 ns) or by diffusion of the substrate to the enzyme.

Table 1 Time scales of kinetic techniques

Relaxation techniques	Approximate time scale
Laser Flash Photolysis[4]	5 fs
Photo(bio)chemistry[4]	5 fs
Pulse-probe[4]	100 fs
Temperature jump[5]	5 ps
Time resolved X-ray diffraction[6]	200 ps
Caged compounds/Flow-Flash[7,8]	1 ns
Temperature-jump[9,10]	1 μs
Pressure-jump[11]	50 μs
Mixing techniques (turbulent)	
Continuous-flow[12]	15 μs
Capillary micromixers[12,13]	60 μs
MHQ[(a)] [14,15]	60 μs
Chemical Quench[16]	60 μs – 1 ms
RFQ[(b)] [17]	5 ms
Stopped-flow[18]	0.5 ms
Mixing techniques (diffusion)	
Continuous-flow hydrodynamic focusing[19,20]	20 – 500 μs

[(a)] MHQ, Microsecond Freeze-HyperQuench.
[(b)] RFQ, Rapid Freeze-Quench.

The flow-flash method when applied, for example, in studies on cytochrome *c* oxidase, can be considered as a variant of the caged compound strategy.[7,8,25] The reaction of reduced cytochrome *c* oxidase with oxygen, and the formation of intermediates following the initial binding of oxygen is too fast to be resolved by the stopped-flow method (*see* ***Rapid Scan, Stopped-Flow Kinetics***). Instead, the CO-inhibited reduced enzyme is used to initiate the reaction and in fact, serves the role of the ''caged compound''. Since the CO-inhibited enzyme reacts slowly (seconds) with the substrate oxygen, the two compounds must remain separate, but mixing (called *flow*) prior to flash activation may be ''slow'' (∼seconds). Upon a flash of light, CO is liberated (<1 ns) and the active enzyme is ready to bind oxygen, the rate of binding (5 – 10 μs) being determined by the oxygen concentration (usually ∼0.5 – 1 mM O_2). Flash photolysis of small ligands bound, for example, to heme groups is not limited to CO; other photolabile small molecules like NO or azide might serve the same purpose. An important condition for the success of this type of experiment is that the rebinding of the photolabile ligand is slow with respect to the binding of say, for example, oxygen. Of course, flash photolysis of Fe(II) – CO complexes may be performed in the absence of the natural substrate. Studies with crystals of Fe(II) – CO myoglobin in conjunction with time-resolved X ray diffraction have yielded the CO-dissociation path in the molecule with (sub)nanosecond and sub-angström resolution.[26] The CO-rebinding path that was established in this study might be that of the natural substrate oxygen.

The time scale of the classical temperature-jump experiment (∼1 μs) as originally pioneered by Eigen has been shortened to nanoseconds and very recently to approximately 5 ps using lasers.[5,9] The classical temperature-jump experiment has found only limited application to biological systems, in spite of its great success in determining, for example, proton transfer rates or keto-enol isomerizations. An important reason for its limited application to enzyme research, apart from experimental difficulties such as ''optical artifacts'' as a result of the temperature-jump, is the relatively small deviation from equilibrium ($\Delta G = \Delta H -$

$T\Delta S \cong 0$) obtained with the 5–10 °C temperature shift and the proportionally small optical changes in UV-Visible spectroscopy associated with the transient disequilibrium state.[10] However, these limitations do not seem to apply to protein folding studies in which changes of tryptophan fluorescence or that of the fluorescently labeled proteins were monitored.[27,28] In addition to a temperature jump, protein unfolding can also be rapidly initiated by a pressure jump. The dead time of the recently developed pressure-jump instrument is 50 µs for a pressure jump of 100 bar.[11]

2.2 Rapid Mixing Techniques

Rapid mixing techniques find wide application in chemistry and biochemistry because they are general and versatile, in spite of their much lower time resolution (Table 1) compared to relaxation techniques. Diffusion and collision of the reactants constitute the ultimate steps in mixing. The perfect mixing device should—before the reaction can proceed—break up the two solvents into volume elements with approximately the size of the reactants resulting in very short diffusion distances. Turbulent flow conditions (Reynolds numbers $> \sim 2000-2500$ for pipe-flow geometries) greatly enhance dispersion of two solvents into small volume elements. Mixers are generally constructed to facilitate turbulent mixing. However, micromixers, with small flow channels can provide (sub)millisecond mixing through diffusion over µm distances under conditions of laminar flow.

2.2.1 Turbulent Mixing Instruments

The first subsecond turbulent mixing instrument (dead time ∼10 ms) has been described by Hartridge and Roughton in 1923; in 1930 the dead time had decreased to ∼2 ms.[29,30] The two reactants are efficiently mixed by a four-jet tangential mixer, actually a modified Rolls-Royce carburetor. The mixed reactants enter a flow tube and the reaction progress is monitored perpendicular to the flow tube at various distances. By knowing the flow rate the distance can be translated into reaction time. This mixing device is essentially a continuous-flow system in which the detection is, however, ‘‘discontinuous’’. Continuous-flow systems generally consume a lot of material, an important limitation to biochemical experimentation. Although the flow rate may be reduced to save material and obtain data points over a wide range of time, a low flow rate will eventually lead to incomplete (or even lack of) mixing, thus limiting the dynamic time range over which experiments can be performed.

A major breakthrough in time resolution (∼1 ms), dynamic range (‘‘unlimited’’) and reduction of sample amount came with the development by Britton Chance[31] of the stopped-flow technique (*see* ***Rapid Scan, Stopped-Flow Kinetics***), which is still widely used today. The stopped-flow techniques finds a major application in the study of enzyme pre-steady state kinetics. The stopped-flow apparatus is also frequently used to investigate reaction mechanisms in (bio)organic and (bio)inorganic chemistry. Modern instruments are designed with ‘‘solvent inert sample compartments’’ enabling experiments in a great variety of solvents. Anaerobic accessories are available. Cryostat pumps are easily integrated in the apparatus extending kinetic investigations down to temperatures of −80 °C, for example, to slow down reactions in nonaqueous solvents that are too fast to be monitored at room temperature, and/or to determine enthalpic and entropic contributions to the reaction rates over a wide range of temperatures.[32]

In the stopped-flow apparatus a powerful and fast drive ram system forces the two reactants into a small mixing/observation chamber where they are mixed. Contrast to the continuous-flow setup, the flow stops when the stop syringe is filled completely and the piston of the stop syringe hits the stop block. The void volume of the stop syringe is set prior to the experiment enabling a total flow volume of twice to three times (∼50–100 µl) that of the mixing/observation chamber, to ensure complete cleaning of the contents of the mixing chamber. Observations are made ‘‘continuously’’ for any length of time, starting when the two reactants enter the observation chamber (using a pre-trigger) or when triggered by the stop of the stop syringe. Commercial stopped-flow devices enable monitoring of the reaction by UV-Visible (*see* ***Electronic Spectroscopy***), fluorescence or circular dichroism (*see* ***Circular Dichroism (CD) Spectroscopy***) spectroscopies and have dead times of ∼1–2 ms, although dead times of ∼0.5 ms may be obtained with specially designed small mixing/observation chambers. Stopped-flow instruments have been designed to enable fourier transform infrared (FTIR) (*see* ***Vibrational Spectroscopy***) (dead time 5–15 ms)[33–37] or nuclear magnetic resonance (NMR) (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Inorganic/Organometallic Molecules***, ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Metallobiomolecules***) analyzes. Also high-pressure stopped-flow instruments have been developed (2 ms dead time, operating at 2000 bar) to study protein denaturation/unfolding kinetics.[38–43] A temperature jump stopped-flow apparatus has recently been designed to study enzyme kinetics at temperatures above the denaturation temperature extending the temperature range commonly covered to determine Arrhenius activation energies.[44]

2.2.2 Rapid Freeze Quench

Rapid-mixing rapid-freezing techniques were developed in the 1960s and 1970s. The development was initiated by workers in the field of ‘‘redox-enzyme’’ biochemistry—at that time in its infancy—to study the role of transition-metal sites in enzyme catalysis by electron paramagnetic resonance (EPR) spectroscopy (*see* ***Electron Paramagnetic Resonance (EPR) Spectroscopy***). Since EPR spectroscopy of transition metals has to be performed, in general, at low temperatures to slow

down relaxation, the continuous-flow and stopped-flow techniques, which are suitable for liquid samples were inadequate. EPR spectroscopy requires relatively high concentrations of protein, yielding solutions of high viscosity necessitating, for example, the construction of mixers capable of mixing viscous solutions and a more powerful sample-delivery device than used in the stopped- or continuous-flow apparatus.

A schematic diagram of the rapid-mixing/rapid-freezing setup is depicted in Figure 1. The instrument, which is commercially available, is essentially the continuous-flow system originally designed by Roughton and Millikan except for the quenching bath.[18] The construction and specifications of the rapid freeze-quench (RFQ) have been extensively reviewed by the original designers.[17,45–50] Briefly, the pistons held in the syringes containing the reactants, are pushed by a powerful (∼0.5 hp) hydraulically, pneumatically, or stepper-motor driven ram. The reactants are led to the mixing chamber and subsequently enter a tubing ending in a nozzle (∼0.25 mm), which sprays the mixture into a cryo-medium where the reaction is quenched. The distance between the mixer body and the cryo-medium is approximately 1–2 cm. The reaction time is varied by varying the length of the tubing rather than changing the ram speed; too low a ram speed might result in inadequate mixing of the viscous solutions. The shortest reaction times are obtained by omitting the tubing and mounting the nozzle directly on the mixer body. The overall dead time of the RFQ is 5–7 ms.[17,51] The most commonly used cryo-media for quenching are liquid isopentane (at ∼135 K) and liquid ethane (at ∼90–120 K). The advantage of liquid ethane is that it can be pumped off under vacuum providing a solvent-free powder amenable to, for example, resonance Raman spectroscopy at low temperatures.[52]

The cold powder thus obtained after spraying into, liquid isopentane is difficult to handle; it has to remain cold (T < ∼130–140 K) to prevent further reaction and its consistency depends, on the nozzle size and flow rates during the experiment. The powder is usually very static, which leads to clogging and sticking to quartz or glass during sample preparation. With some experience the cold powder can be transferred to, for example, X-band EPR tubes, which are also adequate for low-temperature UV-Visible diffuse reflectance spectroscopy, resonance Raman spectroscopy or D-band EPR. Specific devices and sample holders have been constructed enabling UV-Vis spectroscopy, Q-, W-band EPR, electron nuclear double resonance (ENDOR) (*see* ***Electron-Nuclear Double Resonance (ENDOR) Spectroscopy***), electorn spin scho envelop modulation (ESEEM) (*see* ***Electron Spin Echo Envelope Modulation (ESEEM) Spectroscopy***), magnetic circular dichroism (MCD) (*see* ***Magnetic Circular Dichroism (MCD) Spectroscopy***), Mössbauer spectroscopy, resonance Raman spectroscopy or X ray Absorption Spectroscopy (XAS, EXAFS; *see* ***X-Ray Absorption Spectroscopy***).[53–60]

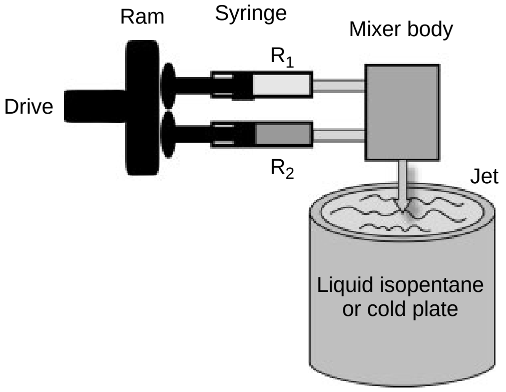

Figure 1 Basic sketch of the rapid-mixing rapid-freezing setup as used in the RFQ and microsecond freeze-hyper quenching (MHQ) devices. R_1 and R_2 denote reactant 1 and reactant 2, respectively. See text and original papers for further details[17,18,45–50]

The RFQ setup can be easily extended to a double mixing system by using three syringes, plus a second mixer. The sequential mixing strategy (''push–push'') enables one to study reactions in which one of the reactants is an unstable or metastable compound. Sequential mixing is also applied to chemical-quench rather than freeze-quench experiments.[61] The third syringe contains the quenching medium and is mixed with the contents of the first mixer in the second mixer. The tube connecting the two mixers or the delay line determines progress of the reaction. As quenching media, highly acidic or basic solutions may be used, or a solvent in which the reaction no longer proceeds and/or the reactant/products become phase separated may suffice. The overall dead time of ∼2 ms is somewhat shorter than for RFQ, but dead-times of 60 µs for chemical quenching have been obtained with capillary micromixers.[16]

EPR spectroscopy of radicals (in contrast to transition-metal ions) can usually be performed at room temperature. A continuous-flow aqueous sample cell for X-band EPR spectroscopy with a dead time of ∼5 ms—suitable for kinetic studies on radical systems—has been commercially available for a long time. It is, however, very uneconomical in terms of material.

Recently a sophisticated aqueous sample cell has been constructed, which enables the kinetic resolution of the rapid refolding of spin-labeled iso-1-cytochrome *c*.[62] The aqueous sample cell consists of a miniaturized quartz capillary mixer with a dead time of ∼150 µs. This design is based on the continuous-flow capillary mixer (dead time ∼60 µs) used for fluorescence spectroscopy.[13] The major disadvantage of the continuous-flow systems is the uneconomical use of protein (∼1 mL at ∼0.5 mM for an experiment), despite the spectacularly small detection volume of ∼0,5 µL and the very short dead time of the micromixer. Due to the relative insensitivity of aqueous sample EPR spectroscopy, fairly high concentrations of sample are required. Consequently, in practice the detection of (''native'') transient radicals accumulating to amounts <10% of the enzyme concentration is generally not possible, limiting the main biochemical

application to spin label-modified proteins. To study native transient radicals, the Microsecond Freeze-HyperQuench (MHQ) device has been developed.[14]

2.2.3 Laminar Flow Micromixers

High (linear) flow rates are required to induce turbulent mixing and to minimize the time between mixing and observation or quenching, known as ''the dead time''. Due to the high flow rates, the pressure in the system increases. The working pressure of the mixing devices described above is maximally 10 bar (stopped-flow) and may be up to ∼20 bar in RFQ when viscous solutions are used.

Current lithographic techniques make it possible to construct microfluidic systems with flow channels of ∼1 µm or even smaller.[63] In these µm channels the diffusion of small molecules (D ∼ 10^{-9} $m^2\,s^{-1}$) takes ∼1 ms, according to equation (1)

$$t_{(\mathrm{diff})} = \frac{d^2}{D} \qquad (1)$$

in which d represents the channel diameter or the diffusion path length and D the diffusion constant ($m^2\,s^{-1}$). Laminar flow micromixers work on the principle of diffusion only. The continuous-flow rates are very small, down to several $nL\,s^{-1}$ thus saving material. The pressure in the system is very close to ambient. Under favorable conditions so-called hydrodynamic focusing may occur, reducing the diffusion distance to below 50 nm and yielding a mixing dead time of ∼20 µs.[19,20,64–66] Unfortunately, the slow beginning of mixing usually results in true dead-times of ∼0.5–1 ms (Table 1). The small dimensions (pathlength) enable detection mainly of fluorescent compounds. However, an important new development is the fabrication of a micromixer enabling small angle X ray scattering on hydrodynamically focused protein solutions using synchroton radiation.[19] Protein folding was studied with a time resolution of 200 µs.

The quadratic dependence between channel dimensions and diffusional mixing times in equation (1) might serve as a stimulus to manufacture channels with small diameters (<50 nm) enabling complete mixing in microseconds.

3 FROM MILLISECONDS TO MICROSECONDS

The ultimate step to achieve complete mixing of two liquids is constituted by diffusion of solvent and solute molecules. The shorter the diffusion pathlength, which solvent and solute molecules have to travel, the shorter the mixing time. For example, the shortest mixing time for continuous-flow mixers is approximately 15 µs corresponding to diffusion of an ordinary solute ($D = 10^{-9}\,m^2\,s^{-1}$) over ∼100 nm using equation (1); the dimension of ∼100 nm represents the average size of the diameter of the volume elements obtained after mixing. Taking a value of ∼1 nm as the size of a single solvent/solute particle, rapid-mixing of two liquids—that is, dispersion to this ''molecular level''—yields a shortest dead time of ∼1–10 ns for the mixing technique. In enzymes the fastest protein back bone movements associated with catalysis might occur within ∼1 µs, though electron transfer reactions, internal proton transfer and side-chain rotations are in general much faster, necessitating the use of relaxation techniques for their study.[26,67–71] However, in the light of the simple calculation above, the ultimate mixing device would suffice to unravel enzyme reaction pathways and detection of (all) transient catalytic intermediates.

Rapid and complete mixing in cylindrical channels ($d > 100\,\mu m$) is obtained in the turbulent regime. Turbulence is expressed by the dimensionless Reynolds number, *Re*, according to

$$Re = \rho \bullet \langle v \rangle \bullet \frac{d}{\eta} \qquad (2)$$

Table 2 Technical specifications of various rapid-mixing devices under conditions of most rapid mixing[(a)]

	Stopped flow	Continuous flow[72]	RFQ[(b) 17]	MHQ[(c) 14,15]
Mixing volume	30 µL	63 nL	68 nL	10 pL
Channel or Orifice diameter, µm	2000	250	200	20
Re in mixing chamber or in orifice	40 000	30 000	7000	4000
Max. backpressure (bar)	2–8	<5	9–15	200–400
Max. flow rate ($ml\,min^{-1}$)	3000	90	83	4
linear speed ($m\,s^{-1}$) in channel or jet	20	6	44	200
Mixing Dead time	100–500 µs	15 µs	50 µs	<1 µs
Experimental Quenching time	NA	NA	4–6 ms	30–40 µs
Total instrumental Dead time	∼0.5–1 ms	60–100 µs	5–7 ms	60–80 µs

NA: Not applicable.
(a) Calculations based on $\rho = 1000\,kg\,m^{-3}$ and $\eta = 10^{-3}\,kg\,m^{-1}\,s^{-1}$.
(b) RFQ rapid freeze-quench.
(c) MHQ microsecond freeze-hyperquenching.

in which $\langle v \rangle$ is the (average) linear flow velocity ($m\,s^{-1}$) in a channel, ρ the solvent density (e.g., $1000\,kg\,m^{-3}$ for water), d is the channel diameter (m) and η is the dynamic viscosity (e.g. $10^{-3}\,kg\,m^{-1}\,s^{-1}$ for water at 20 °C). Sufficient turbulence in pipe channels resulting in complete mixing requires $Re > 2000-2500$. High flow velocities also cause a pressure (ΔP) buildup in the system according to Bernoulli's velocity/dynamic pressure equation:

$$\Delta P = 0.5 \bullet \rho \bullet (\langle v \rangle)^2 \qquad (3)$$

Equation (3) implies that at linear flow rates $>10-15\,m\,s^{-1}$, pressures of >1 bar above ambient pressure will buildup. Technical specifications for the most common rapid-mixing devices are shown in Table 2. The stopped-flow apparatus achieves very high Reynolds numbers owing to its large flow rates in relatively large (2 mm) channels; however, when performing studies at low temperatures (∼0 °C) in fairly concentrated enzyme solutions, the viscosity might easily increase by a factor of 5–10, proportionally lowering the Reynolds number and decreasing the extent of mixing.

Given the Reynolds equation in which ρ and η are relatively constant, the two main parameters permitting manipulation of the instrumental *mixing time* are the flow rate and the dimensions of the mixer, in particular the channel diameter and length. The instrumental *dead time* includes the mixing time and the time taken to travel the distance between the mixing and observation point (for continuous flow), or for filling the observation chamber (for stopped-flow) (Table 2, Figure 2). The relatively large observation/mixing compartment of the stopped-flow, and abruptly stopping the flow are the major causes for its poorer time resolution than the continuous-flow devices. However, given the small observation volume, the current continuous-flow mixing setups are used mainly in connection with fluorescence spectroscopy, whereas the stopped-flow instrument allows a broader range of spectroscopies, including the relatively insensitive UV-Vis absorbance spectroscopy.

The stopped-flow dead time might be improved to that of the continuous-flow methods (∼50 µs), by using higher flow rates, but this might lead to cavitation effects and certainly will lead to higher pressures in the system (∼100–200 bar) necessitating a much more robust design. The simplest way to improve the stopped-flow performance in the author's opinion is to use a smaller observation chamber. This will require a 10–20 fold more sensitive UV-Vis absorbance spectroscopy setup, something that has apparently not been developed during the last 40 years for reasons that are unclear.

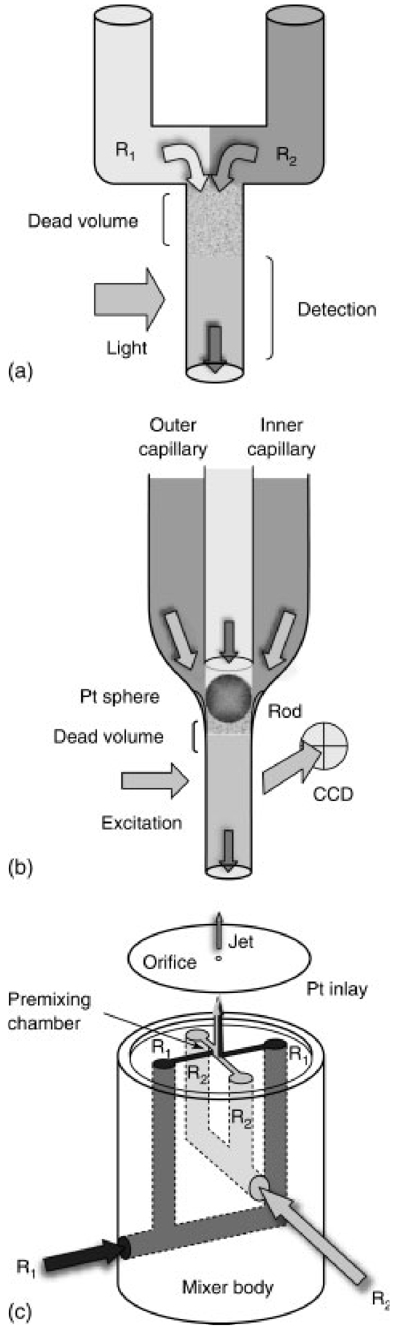

Figure 2 Drawings of commonly used mixers in continuous-flow and stopped-flow devices. Mixing in the four-jet tangential mixers occurs in the orifice of the Pt inlay (MHQ) or in a Teflon gasket (RFQ). R_1 and R_2 denote reactant 1 and reactant 2, respectively

3.1 Commonly Used Mixers

Over the years various types of mixers have been designed. The most frequently used today are the T-mixers (stopped-flow), four (or more)-jet tangential mixers (freeze-quench), the Berger-ball mixer (stopped-flow) and the coaxial type mixers like the ball-mixer used in the capillary micromixers (continuous-flow) (Figure 2).[12–14,16,17,30,31,51,72–76]

T-mixers are the most classical mixer types (Figure 2a). Mixing starts, but is generally not complete, at the point where the two fluids collide. Complete mixing should occur over a short distance just downstream (dead volume), in the region between the initial collision point of

the two fluids and the observation chamber. The total dead time of the T-mixer corresponds approximately to that of the time needed to fill the dead volume region and the observation chamber.

In coaxial mixers, the two reactant fluids are initially in an outer and an inner capillary. The two fluids run parallel over a short distance toward a Pt sphere. At this stage they do not mix because of the low Reynolds number of the flow, which is essentially laminar (Figure 2b). The two fluids meet at a small (50–250 µm) platinum sphere, which is positioned at the tapered end of the outer capillary. The two fluids are forced between the small space (5–10 µm) between the Pt sphere and the outer capillary where they are accelerated creating a small zone of high turbulence ($Re \sim 30\,000$). Without the sphere, the channel dimensions and flow rates would yield a calculated *Re* of ∼1500, which is insufficient for mixing.

Regenfuss *et al*. designed the original coaxial ball mixer or capillary micromixer. The mixer was impractical because it was very delicate to manufacture and the optical (fluorescence) measurements had to made on an unstable free flowing thin jet at various distances.[12] Shastry *et al*. among others have successfully improved the original design by using quartz instead of glass, enabling the construction of an observation chamber, which no longer necessitated measurements on a free jet.[13] Detection of fluorescence changes occurs by a sensitive charged coupled device (CCD) camera covering the whole length of the observation cell, enabling facile transformation of distance into time. The short mixing (15 µs) and small total dead time (60 µs) made it possible to study the folding of cytochrome *c* by monitoring Trp fluorescence and fluorescent resonance energy transfer (FRET) in specifically labeled proteins.[72]

The capillary micromixer has proven to be a fast and versatile mixing device. The great advantage of the capillary micromixers are the short dead time while operating at low pressures. The small observation volume so far precludes application of, for example, UV-Vis absorbance spectroscopy, for which the sample requirements are relatively high.

Four-jet tangential mixers (Figure 2c) are mostly used in RFQ and MHQ instruments (in a miniaturized form in the latter).[14,17] The (micro-)mixer consists of four channels (arranged in a cross), which lead the reactants to a premixing chamber, in the middle of the cross. The opposite channels are offset in respect to each other by a half- or full-width of the channel, so that the liquid streams are premixed with a resulting angular momentum at relatively low Reynolds numbers; the amount of pre-mixing is less than 1%. After premixing, the 4-stream solution is forced through a constriction in the channel—perpendicular to the plane of the channel. Here the solution is accelerated to a high linear velocity yielding $Re \sim 7000$ and a calculated mixing time of 50 µs for the RFQ design (Table 2). The mixture subsequently enters the sample-delivery tube and is sprayed through a nozzle into cold isopentane. In practice the four-jet tangential mixers are capable of efficiently mixing concentrated protein solutions, apparently more so than T-mixers. It is possible that the presence of the angular momentum of the flow helps to accomplish this.

In spite of the short mixing time, the total dead time of the RFQ is 5–7 ms. In general, the freeze-quench mixing-and-sampling procedure (both RFQ and MHQ) can be divided into three steps, which determine the total instrumental dead time. First, the chemical reaction is initiated by rapid mixing of the reaction components. In the second step, the sample is transported from the mixer in a tubing (of variable length) and subsequently as a free jet to the cryo-medium. In this stage the reaction proceeds and the reaction progress can be manipulated by varying the length of the tubing. Finally, the sample is quickly frozen in the cryo-medium (e.g., liquid isopentane) or on a rotating cold plate (MHQ), quenching the chemical reaction.

The total sample-ageing time, τ_a, can be expressed as a sum of three terms,

$$\tau_a = \tau_m + \tau_t + \tau_c \tag{4}$$

where τ_m is the mixing time, τ_t is the sample-transport time, and τ_c is the cryofixation or quenching time.[14] So for RFQ the first term is ∼50 µs; the shortest transport distance—in the case the spraying nozzle being attached to the mixer body—to the cold liquid isopentane bath is ∼1–2 cm taking 0.5–1 ms at the (maximal) linear jet speed of ∼44 m s^{-1}. The actual freezing time has been determined to be ∼5 ms in isopentane at 135 K with a nozzle of 200 µm.[17] Thus the total dead time for RFQ is 5–7 ms (Table 2). The rate of freezing is dependent on the temperature of the quenching medium and was found to be 8–9 ms for isopentane at 100 K.[17]

3.2 Microsecond Freeze-Hyperquenching (MHQ)

Given the specifications above for the RFQ methodology, there are several possibilities to improve the dead time from milliseconds to microseconds. This can be achieved by minimizing the mixing time and shortening both the sample-transport time and the quenching time. In practice this was accomplished by scaling down the mixer dimensions, increasing the linear flow rate and omitting the sample-delivery tubing. A detailed description of the stainless steel micromixer and the operation and properties of the MHQ setup have been reported recently.[14,15,77,78]

Regarding the sample-transport time, by increasing the (linear) flow rate, the working pressure will also increase in the system. Given the Reynolds and Bernoulli equations, linear flow rates of 200 m s^{-1} will allow sufficient turbulence for mixing in channels of ∼10–20 µm at pressures of ∼400 bar (Table 2). Most enzymes can stand this pressure without denaturation given the biochemist's experience that French pressure devices used to break open cells might yield similar pressures and that HPLC systems commonly applied in the purification of enzymatically active proteins operate

at these pressures. Although the specific pressure needed to induce protein unfolding and denaturation is a protein-specific property, pressure sterilization of nonbarophilic microorganisms like *E. coli* or *B. subtilis* requires pressures above 1500 bar, implying that the great majority of proteins are stable and active at these high pressures.[79] This is in agreement with studies on isolated proteins displaying unfolding at pressures $>\sim 2$ kbar, though some remain active at 5 kbar.[43,80] To prevent uncontrolled protein denaturation under the MHQ experimental conditions, HPLC pumps are used in the MHQ setup rather than a powerful drive ram system as the sample delivery means. With HPLC pumps full control overpressure and consequently the flow velocity is obtained during the experiment allowing accurate calculation of the reaction time. At pressures >400 bar, the pumps automatically shut down in case of. clogging of the nozzle, ensuring that the samples are not denatured due to transient high pressure buildup.

A major factor contributing to the dead time in RFQ is the freeze-quenching process itself. In general the rate of freeze-quenching is determined by the rate of heat transfer between the sample and the cryo-medium (cold plate or cold liquid). The heat-transfer rate is determined by the heat capacities of the sample and the cryo-medium, and their temperature difference. In the freeze-quenching process heat transfer occurs predominantly through surface contact between the cryo-medium and the jet. The rate of heat transfer is proportional to the surface area of the jet, or importantly to the square of the jet diameter. In the classical RFQ setup, jet diameters of ∼250 μm were used yielding a ∼5 ms quenching time; in the MHQ setup the jet diameter is only 20 μm resulting in the experimentally determined freeze-quenching time of 30−40 μs in agreement with the square of the ratio of the jet diameters $(20/250)^2$ used in the two different experimental setups.

In the original publication on the MHQ apparatus, liquid isopentane was used as quenching medium[14] and later a rotating cold plate.[15,78] The minimal transport distance between mixer and cold liquid isopentane was ∼2 cm, yielding minimal sample-transport time of 100 μs at a jet speed of $200\,\mathrm{m\,s^{-1}}$; for the cold plate the minimal sample-transport distance is only 5−7 mm, yielding a minimal sample-transport time of 25−35 μs. All of the mixing occurs in the smallest constricted region of the platinum inlay (Figure 2c) constituting both mixer and orifice, where *Re* is maximally 4000 (Table 2). The total mixing time is <1 μs, and the total dead time of the MHQ device with the rotating cold plate amounts to 60−80 μs. With this improved time resolution we were able to detect hitherto unknown transient tryptophan radicals (by EPR) formed during the catalytic cycle of cytochrome *c* oxidase[14,15,78] and a new short-lived (∼100 μs) high-spin ferric-azide intermediate (by resonance Raman spectroscopy) in the reaction between metmyoglobin and azide.[77]

3.2.1 Jet Break-up

During the development of the MHQ setup, serious problems of break up of the 20-μm jet were detected at ambient pressures, for example, by studying the behavior of the jet under a microscope. Jet break up and the consequent decrease of the jet speed (several fold) and broad distribution of jet velocities were experimentally verified by Laser Doppler Anemometry.[81] By decreasing the pressure to 30 mbar, the 20 μm jet was found to be sufficiently homogeneous to define a single rate (>85% of the jet with a speed within 10% of the maximum speed). The maximum jet velocity turned out to be ∼10% higher than that calculated on the basis of the volumetric flow rate and orifice diameter, which is what one would expect for fluid flow in μm channels due to the absence of flow at the liquid/wall interface reducing the effective diameter.[81]

The MHQ apparatus is built entirely in a low-pressure chamber to prevent jet break up of tiny free jets. The low ambient pressure, the high jet velocities, and the relatively short distance to the cryo-medium result in (adiabatic) cooling of the jet. It was determined that even though the reactants are initially at ambient (20−22 °C) temperature the effective reaction temperature was 10 ± 2 °C for the cold plate setup and 8 ± 0.5 °C for quenching in liquid isopentane.[14]

3.2.2 Determination of the MHQ Dead Time

To characterize the instrumental dead time of the MHQ the binding of azide to metmyoglobin was used as a molecular timer as originally used for the RFQ apparatus. The rate constants for the reaction were determined in the stopped-flow apparatus at various temperatures between 5 and 25 °C, at $[N_3^-]$ up to 1 M. This high concentration of azide was necessary to obtain sufficient formation of the myoglobin-azide complex on the microsecond time scale to calculate a reliable value for the sample aging time. Various ''anomalies'' of the reaction progress were detected on the shortest timescale,[14] which were, however, not observed by others[82,83] using newly designed freeze-quench setups with dead-times of 50 μs and 200 μs or with the slower RFQ setup.[17,47] One was the formation of a novel transient intermediate living for ∼100 μs,[14,77] (*see* later in Section 4.2) the other the apparent decrease of the second order rate constant for the reaction at $[N_3^-] > 10$ mM. A careful analysis of the reaction enabled the experimental determination of all the instrumental parameters listed in Table 2. The true mixing time (<1 μs), the maximal jet velocity, and the true freeze-quench time (see also below) determined experimentally, all closely match theoretical and practical considerations. In this light it was argued previously that two novel sophisticated freeze-quench instruments, for which the author claimed dead-times of 50 μs and 200 μs, could not, in fact, achieve such short reaction times. The arguments given previously[14] are in the opinion of the author still correct, and will not be

repeated here. Additional simple arguments that can now be made after the original papers were published and on the basis of more recent publications are the following. While working with the same systems as the author, that is, the reaction between metmyoglobin and azide for testing and cytochrome bo_3 oxidase to study its catalytic cycle, neither the transient high-spin heme azide intermediate living for ~100 µs[77] nor the Trp-radical of cytochrome bo_3 oxidase[15,84] disappearing after 500 µs were detected.[83] With respect to the system described by Tanaka *et al*.,[82] the freeze-quenching of the jet (60 µm diameter) itself would take ~300–400 µs (given the 30–40 µs for a 20 µm jet and the dependence of freeze quenching on the square of the jet diameter). Regarding the system by Lin *et al*.,[83] jet break up of the 10 µm × 100 µm jet is very severe at ambient pressures (less so for the 60 µm jet, but not absent), leading to much longer sample aging times than based on calculations of the jet speed using the volumetric flow rate and orifice diameter. In addition, the freezing is not ''instantaneous'' as suggested.[82] Neither Tanaka *et al*. nor Lin *et al*. took the potential cooling of the jet into account, which must be significant with the rotating copper or silver wheels at 77 K, used to quench the reaction, leading to turbulent cold air in contact with the jet. The author estimates an instrumental dead time of 0.5 ms for both devices, which is, nevertheless, more than a 10-fold improvement in time resolution with respect to the classical RFQ. Both systems employ state of the art micromixer technology and yield high quality and concentrated (more so than obtained via MHQ) powder samples, suitable for EPR and resonance Raman spectroscopy.[82–85]

3.2.3 Hyperquenching

The design parameters used for the MHQ setup were inspired by the High-pressure jet-freezing and droplet cryoplate freezing equipment developed by Mayer to study the properties of vitrified water.[86]

Mayer showed that the spraying of fast jets (~200 m s^{-1}) of small diameters (10–20 µm) into a liquid cryo-medium (e.g., isopentane at 120 K) results in the formation of vitrified water. Cooling under these circumstances is so rapid—calculated as 3×10^6—10^7 K s^{-1}—that water does not have time to form a crystal lattice. Water vitrifies to an amorphous solid bypassing the liquid-ice phase transition.[86–88] The metastable amorphous solid water is structurally similar to liquid water.[89–93] It undergoes a reversible liquid–liquid transition at ~130 K,[94] forming a highly viscous, deeply metastable supercooled extension of normal liquid water,[95–97] which begins to crystallize on warming to ~160 K.[98–100] Vitrification of samples is widely used in cryobiology for tissue storage and for preparation of samples for electron microscopy, to avoid structural damage of biological specimens due to the expansion of the aqueous phase during the liquid-ice phase transition.[101–103]

The experimentally determined freeze-quenching time of 30–40 µs amounts to a cooling rate of $3–5 \times 10^6$ K s^{-1}, in good agreement with calculations.[88] Indeed the formation of vitrified water can be observed by eye. Spraying of aqueous solutions by the MHQ setup on a cold plate initially yields a transparent frozen material. This simple observation and the quenching time of 30–40 µs strongly suggest the formation of hyperquenched samples by the technique, hence it's name, MHQ. X-ray analysis or infrared spectroscopy should provide more direct proof of the vitrified state of the samples obtained by the method.

4 EXAMPLES

4.1 RFQ of Cytochrome P450

Cytochrome P450 (P450) enzymes are heme-containing monooxygenases found in Bacteria, Archaea and Eukarya that catalyze hydroxylations of aliphatic and aromatic compounds (''RH'') according to the overall reaction:[104–106]

$$RH + O_2 + 2e + 2H^+ = ROH + H_2O \qquad (5)$$

The P450 enzyme from *Pseudomonas putida* (P450cam or CYP101), which hydroxylates camphor to 5-exo-hydroxycamphor has been studied in detail and is regarded as a model protein for other P450s. The electron donor to P450cam is putidaredoxin, which can deliver one electron at a time. In the course of the reaction, an activated oxygen atom from the heme iron is transferred to the unactivated C–H bond of the substrate. A Fe(IV)=O porphyrin-π-cation radical has been proposed as the key iron-oxo intermediate, compound I (Cpd I),[104] but it has remained elusive so far in studies of the enzyme with substrate (''RH'').

The resting enzyme can be loaded with RH, reduced by one electron and reacted with oxygen, yielding a stable Fe(II)–O_2–RH complex. To this complex, the second electron must be added to initiate the reaction, but injection of this second electron as reduced putidaredoxin was too slow (~5 ms) to detect any transient formation of Cpd I.[107] Experiments in which the Fe(II)–O_2–RH complex was prepared at room temperature, frozen and subsequently reduced radiolytically in the cryogenic state did not reveal any buildup of Cpd I, though superoxo and peroxo intermediates were found and the enzyme went through a full catalytic cycle.[108]

Alternatively, the Cpd I of P450 enzymes might be formed via the so-called ''shunt'' reaction[109,110] using H_2O_2 or peroxy acids (in the absence of substrate), that is analogous to formation of the stable Cpd I by chloroperoxidase (CPO) from *Caldariomyces fumago* according to:

$$\text{Por–Fe(III)} + H_2O_2 = \text{Por}^{\bullet+}\text{–Fe(IV)=O} + H_2O \qquad (6)$$

Since both CPO and P450 have cysteine as the proximal iron ligand, rather than histidine, Cpd I of P450 might yield a similar UV-visible spectrum: (partial) bleaching and blue shifting of the Soret band and appearance of Q-bands between 650 and 700 nm.[111,112] Indeed, stopped-flow studies in which P450 was rapidly mixed with peroxy acids indicated the formation within ~10 ms of a transient species that has been ascribed to Cpd I.[113,114] This species accumulated to ~10% of the starting [P450] and had the expected optical characteristics.

To determine Fe(IV)=O and radical character of the transient intermediate unambiguously, RFQ experiments have been performed in conjunction with Mössbauer spectroscopy and multifrequency EPR (*see* ***Electron Paramagnetic Resonance (EPR) Spectroscopy***; Figure 3).[55,109,110,115–117]

Mössbauer spectroscopy of the ^{57}Fe-containing P450 indicated the formation after 8 ms of ~10% Fe(IV) $S = 1$ species, the other 90% representing the initial Fe(III) state (Figure 3a). The P450 Fe(IV) is characterized by a doublet with an isomer shift of $\delta = 0.13$ mm s^{-1}, similar to the value of $\delta = 0.14$ mm s^{-1}for the CPO Cpd I. The P450 quadrupole splitting ($\Delta E_Q = 1.94$ mm s^{-1}) is, however, much larger than in CPO ($\Delta E_Q = 1.02$ mm s^{-1}), suggesting that the cysteine in P450 might be protonated.[110]

In contrast to the Mössbauer spectroscopy, EPR did not reveal the characteristic signal of a Fe(IV) species antiferromagnetically coupled to a porphyrin radical.[118] Instead, the anisotropic signal detected at D-band frequency (285 GHz) indicates formation of a tyrosine radical, ascribed to Y96 based on site-directed mutagenesis (Figure 3b).[115,116]

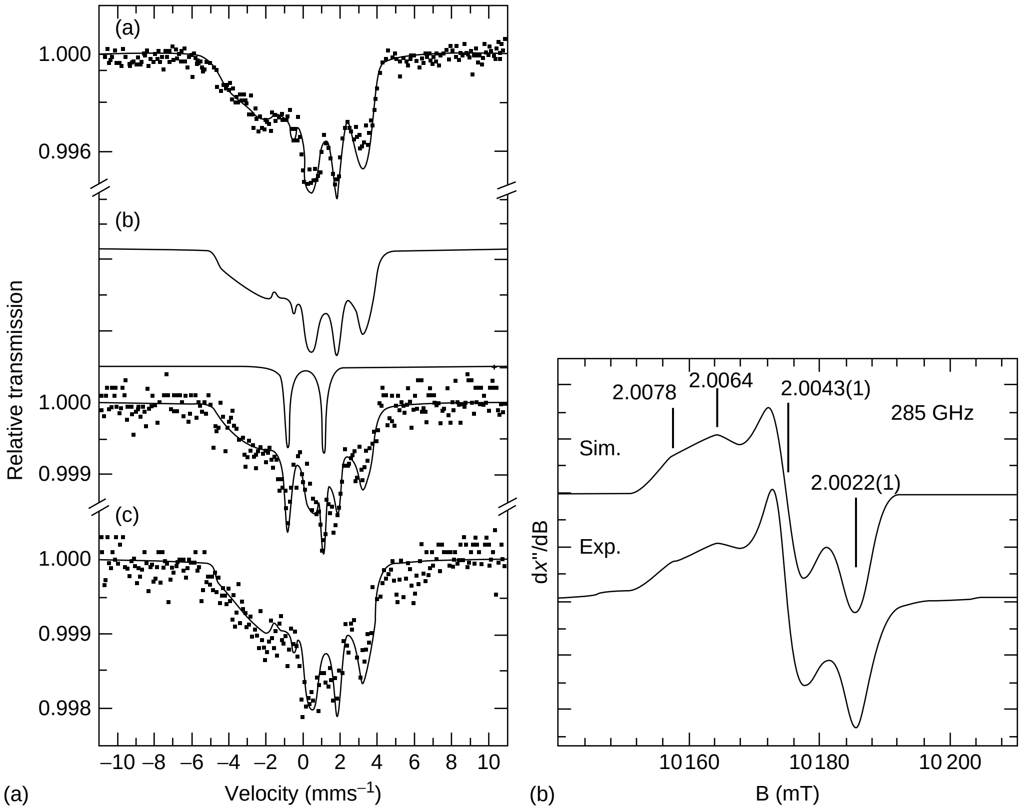

Figure 3 Mössbauer (a) and D-band EPR spectra (b) of P450 reacted for 8 or 40 ms, respectively with peroxy acetic acid. A, trace (a): Mössbauer spectra of substrate-free cytochrome P450cam recorded at 4.2 K in a field of 20 mT perpendicular to the γ-beam. The solid line is a spin-Hamiltonian simulation with parameters $\delta = 0.38$ mm s^{-1}, $\Delta E_Q = +2.85$ mm s^{-1}, $\eta = -1.8$, $\Gamma = 0.30$ mm s^{-1}, $g = (1.91, 2.26, 2.45)$, $A/g_N\mu_N = (345, 10, 19)$ T. Trace (b): Mössbauer spectrum of P450cam after mixing with peroxyacetic acid for 8 ms recorded at 4.2 K in a field of 20 mT perpendicular to the γ-beam. The solid line is a spin-Hamiltonian simulation assuming two components: a doublet with $\delta = 0.13 \pm 0.01$ mm s^{-1} and $\Delta E_Q = 1.94 \pm 0.01$ mm s^{-1} characteristic of Fe(IV) ($S = 1$) (13 ± 2% relative contribution) and the ferric starting material (calculated with the parameters given in trace (a); 87 ± 2% relative contribution). Trace (c): Mössbauer spectrum of P450cam after addition of peroxyacetic acid and 5 min reaction time taken at 4.2 K in a field of 20 mT perpendicular to the γ-beam. The solid line is a spin-Hamiltonian simulation with the parameters used for the ferric starting material, see trace (a). (Reproduced from Schunemann, Lendzian, Jung, Contzen, Barra, Sligar and Trautwein[115] by permission of American Society for Biochemistry and Molecular Biology.) B, the Y*96 in ^{56}Fe-P450cam reacted for 40 ms. EPR conditions: T = 5 K; modulation amplitude 2.4 mT, modulation frequency 0.8 kHz, microwave frequency 285 GHz, field sweep 0.5 mT s^{-1}. *Exp*, experimental spectrum; *Sim*, simulated spectrum after field calibration using $g_z = 2.0022$ (from 94 GHz EPR simulations) yielding the g_y value and a distribution of g_x values around two maxima at $g_x = 2.0064$ and $g_x = 2.0078$. Single component linewidth used in the simulation: 4 mT. (Data from ref. 115)

The relaxation of the radical is fast, consistent with a distance for Y96 of 9.4 Å from the Fe(IV).

The apparent discrepancy between the RFQ and stopped-flow experiments was recently ascribed to differences in pH between the two studies.[117] The pH influences the pre-equilibrium concentrations between Cpd I (Soret maximum at 367 nm) and the Y*96 radical intermediate (Soret maximum at 406 nm):

$$\text{Tyr-Por}^{\bullet+}\text{–Fe(IV)=O} \longleftrightarrow \text{Tyr}^{*}\text{-Por-Fe(IV)=O} \quad (7)$$

In a recent study, Cpd I was prepared by irradiation with 355 nm laser light of Cpd II (Fe(IV)=O, obtained by reaction of the resting enzyme with peroxynitrite).[119] Surprisingly, Cpd I was relatively stable (~200 ms) and unreactive toward its substrate laurate. While it is possible that laurate cannot bind to the P450 prepared in the Cpd I state, the key hydroxylating intermediate might not be Cpd I, but rather a peroxy intermediate $Fe(III)O_2^{2-}$ or $Fe(III)O_2H^-$. Whatever the nature of the hydroxylating intermediate, its lifetime is definitely short requiring RFQ and MQH methods to trap it.

4.2 MHQ of Metmyoglobin in Reaction with Azide

The reaction between metmyoglobin and azide has traditionally been used to calibrate the time scale and calculate the dead time of the RFQ and MHQ instruments.[14]

$$Fe^{3+} - H_2O + N_3^-\text{(high spin)} \rightarrow Fe^{3+} - N_3^- + H_2O \quad \text{(low-spin)} \quad (8)$$

The reaction shows second order kinetics up to $[N_3^-]$ of ~1 mM. While calibrating the dead time and performance of the MHQ instrument, the author observed clear deviations from second order behavior at higher $[N_3^-]$ including the formation of a short-lived transient intermediate (Figure 4a).[14,77]

Upon binding of azide to metmyoglobin, the high-spin Fe^{3+} changes to low spin (equation 8), which can easily be detected by EPR or (low-temperature) UV-visible spectroscopy. The reaction in equation (8) is a simple two-component system. The reaction progress can easily be determined by simulation of the resulting spectra obtained in a time series from the weighted sum of the initial high-spin spectrum and the final low-spin spectrum that serve as reference spectra.[14] When no intermediates are formed, the residuals of the weighted sum should be zero. However, the spectrum obtained after 95 µs reaction time (Figure 4a) could not be simulated as a simple sum of the initial and final spectrum. Analysis of the UV-Vis spectrum of the residual (~20% of the total metmyoglobin) indicated that it had already bound azide, but not exactly as in the final state. In the sample obtained after 245 µs, the amount of the residual was already much lower (~2%).

Resonance Raman spectroscopy of the 95 µs and 245 µs samples, followed by weighted subtraction of the resonances in the spectra of the initial and final state, yielded the spectra of the residuals shown in Figure 4(b).[77] Consistent with the UV-visible spectroscopy, the residual was much smaller in the 245 µs sample indicating a lifetime <100 µs.

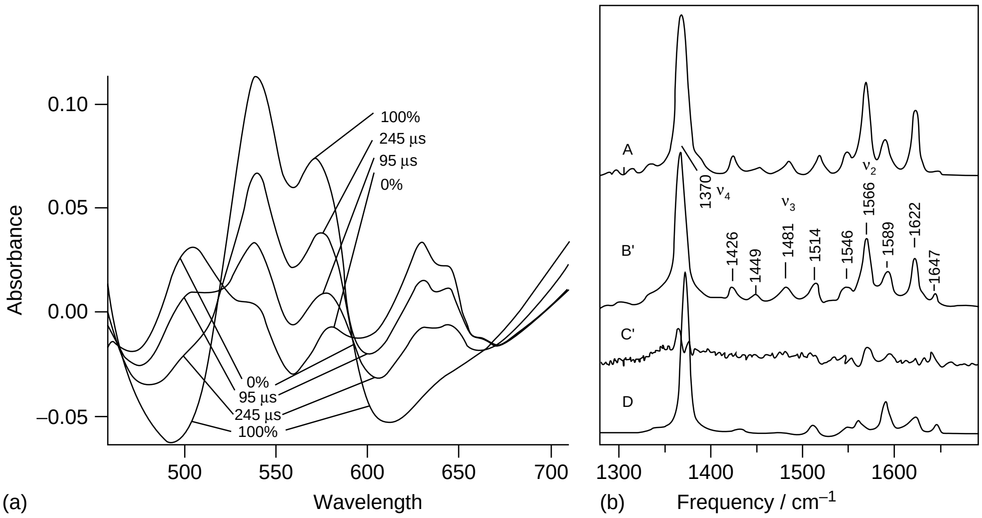

Figure 4 Low-temperature UV-visible spectra (a) and resonance Raman spectra of the same samples (b) recorded at 77 K. The 95-µs and 245-µs MHQ samples were obtained after mixing of 1 M azide and 0.35 mM metmyoglobin at a calibrated distance from the nozzle and the precooled cylinder. The azide-free metmyoglobin sample and a pre-incubated metmyoglobin azido complex were used as reference samples.[14] (b) Trace B′ and C′ represent the residual spectra of the 95-µs MHQ (B′) and 245-µs MHQ samples (C′) after maximal subtraction of the contribution from the starting material (trace A) and the end-product (trace D). Traces B′ and C′ were multiplied by four to allow easy comparison with those of metMb (A) and metMb pre-incubated with azide (D). (Reproduced from Lu, Wiertz, de Vries and Moënne-Loccoz.[77] © 2005 John Wiley & Sons, Ltd)

The resonance Raman spectrum suggests that the intermediate is a six-coordinate high-spin species.

$$Fe^{3+} - H_2O + N_3^- \quad \text{(high spin)} \rightarrow Fe^{3+} - N_3^- \quad \text{(high spin)}$$
$$\rightarrow Fe^{3+} - N_3^- + H_2O \quad \text{(low-spin)} \qquad (9)$$

However, it remains to be determined whether the azido group is already coordinating the iron(III), since the ligand field splitting is smaller compared to that of the resting azido complex. The other possibility is that the azide is not coordinating the iron but perturbs interactions between the iron-aqua ligand and its distal-pocket environment.

These results illustrate the complexity of ligand binding in a ''simple two-component'' system. The results further indicate the time resolution of the MHQ technique. The reaction between metmyoglobin and azide is a useful molecular timer, but the kinetics are not proportional to $[N_3^-]$; observation of the intermediate described here can be used to argue that the particular rapid-freezing instrument operates below the 100 µs time scale.

4.3 Ultrarapid Freeze-Quench of NO Reductase

Nitric oxide reductase (Nor) forms part of the denitrification pathway found in Bacteria and Archaea.[120,121] Denitrification is the five-step conversion of nitrate to dinitrogen according to: $NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$. Nor catalyzes the reaction,

$$2NO + 2e + 2H^+ \rightarrow N_2O + H_2O \qquad (10)$$

Nor is a member of the superfamily of heme-copper oxidases that also include the cytochrome oxidases (found e.g. in mitochondria[122]). Although no crystal structure of Nor is known at present, the number of transmembrane α-helices and the location and structure of their cofactors (heme c, heme b, heme b_3 and Fe_B) are highly similar to those of the cytochrome oxidases.[122,123]

Biochemical and biophysical studies have indicated that Nors contain a binuclear heme-Fe/nonheme Fe active site (b_3-Fe_B) where reduction of NO to N_2O occurs (Figure 5a).[124–126]

In the resting (oxidized) state (**1**) the iron atoms of the binuclear b_3-Fe_B site are antiferromagnetically coupled via a single strong Fe–O–Fe bond. The heme b_3 iron is five-coordinate in the oxidized state (**1**); upon reduction (**2**) the heme Fe is still five-coordinate, but bound to the proximal histidine. Intermediate (**2**) is ready to bind the two molecules of NO. Kumita *et al.*[85] attempt to answer the question whether both NO molecules bind to Fe_B (the ''cis'' mechanism[127,128]) or one to b_3, the other to Fe_B as depicted in (3) of Figure 5(a) (the ''trans'' mechanism[124–126,129]).

In the experiments the Nor was fully reduced containing four electrons allowing two consecutive turnovers (**2**–**5** followed by **6**–**8**, Figure 5a), each of two NO. The reduced Nor was rapidly mixed with NO and the reaction was quenched after 0.5–10 ms.[85] In a second series of experiments (shown here), the sample quenched after 0.5 ms was subsequently annealed and monitored optically and by EPR (Figure 5b). The Nor went through two full catalytic cycles in the frozen state.

EPR spectroscopy indicates the formation of a low-spin ferrous heme-NO complex ($g = 2.012$, Figure 5b) and of a high-spin ferrous-NO complex ($S = 3/2$; $\{FeNO\}^7$) at $g \sim 4$. In addition, the oxidation of the low-spin hemes b and c ($g = 2.97$, 2.27 and $g = 3.56$, respectively) could be followed. The fully oxidized enzyme (**8**) showed a $g = 6$ signal due to heme b_3 and a $g = 4.3$ signal due to the Fe_B; in other words, the Fe–O–Fe bond was absent and the two centers are no longer antiferromagnetically coupled as in (**1**).

The finding of EPR signals due to both a low-spin ferrous heme-NO complex and a high-spin ferrous heme-NO complex strongly argues in favor of the ''trans'' mechanism as depicted. The close proximity of the two NO molecules (**3**) allows electrophilic attack of one NO to the other leading to formation of the diiron bridged ''N_2O_2'' (hyponitrite (**4**)) intermediate containing the N–N bond. Subsequent protonation would yield N_2O and H_2O (**5**) that would leave the active site and the enzyme is ready to bind and convert the next two NO (**7**, **8** Figure 5a).

5 OUTLOOK

In spite of the superior time resolution of continuous-flow mixing and relaxation techniques, rapid-mixing rapid-sampling techniques have contributed significantly to our understanding of catalysis of a wide range of enzymes. Rapid-mixing rapid-sampling techniques are general, versatile and easily combined with a large array of spectroscopic techniques, greatly contributing to their success. In the nearly fifty years since the development of the Rapid-Freeze Quench methodology, the pre-steady state kinetics of numerous metalloenzymes have been analyzed. The possibility to analyze the powder samples by a wide range of spectroscopies have provided detailed information on the oxidoreduction kinetics, ligand- and protonation-state changes during catalysis of heme centers, iron–sulphur centers, di-iron centers, single and multiple Mn-, Fe-, Co-, Ni-, Cu-, Mo-, W-sites, amino-acid main-chain and side-chain radicals, quinone, flavin, pterin radicals and so on. Given the dead time of 5–7 ms for the RFQ device and the fact that catalysis,—that is, substrate binding followed by breaking of the chemical bond- occurs at time scales from approximately a microsecond onwards, we may expect that the faster novel freeze-quench technologies will provide in the near future additional new insights in the first steps of (metallo) redox-enzyme catalysis. At present

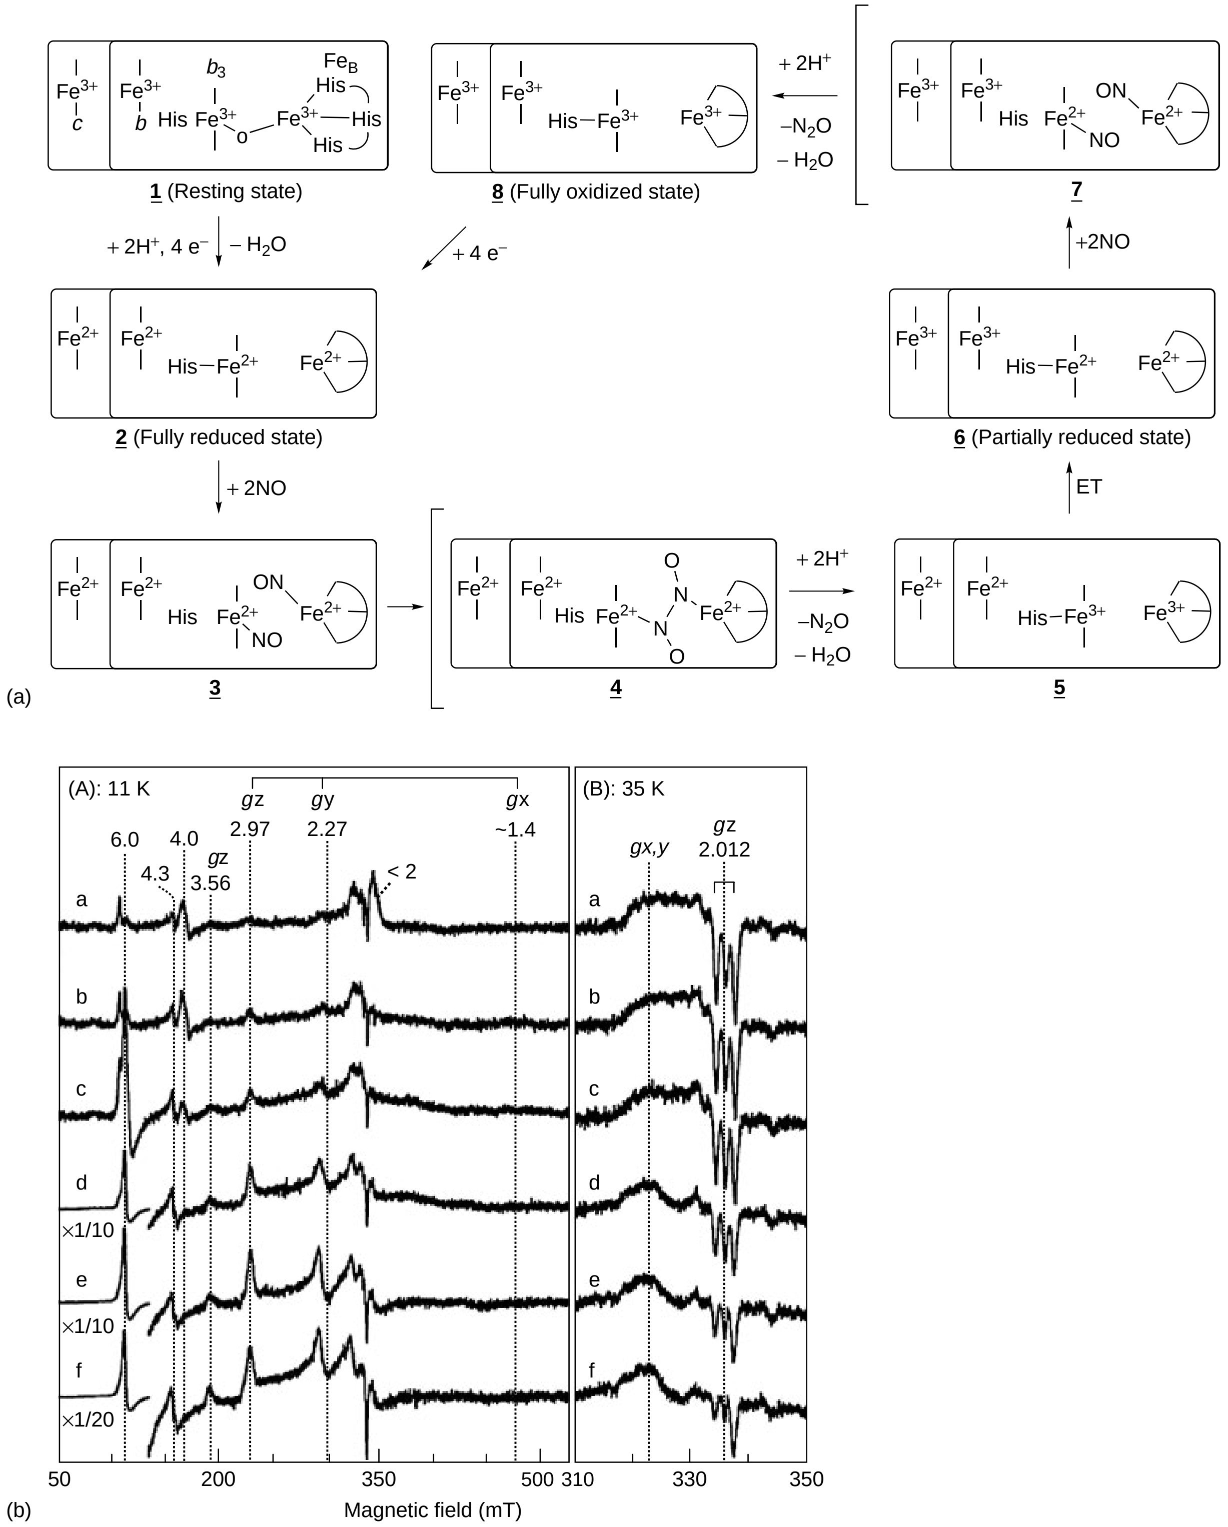

Figure 5 Proposed catalytic cycle for NO reductase from *Pseudomonas aeruginosa* (a) and EPR spectra of freeze-quenched samples (b). A: The catalytic nonheme iron Fe_B, the high-spin heme b_3, the low-spin heme *b*, and heme *c* are indicated from *right* to *left* in each state. B: Panels A and B show the spectra recorded at 11 and 35 K after annealing, respectively. Traces *a–f* show the X-band EPR spectra for the samples quenched at 0.5 ms after mixing the fully reduced NOR with NO buffer and annealing at 193 K for 120 min (trace a), 223 K for 5 min (trace b), 243 K for 5 min (trace c), 263 K for 10 min (trace d), 263 K for 30 min (trace e), and 263 K for 90 min (trace f). The *g*-values are indicated for the various species. (Reproduced from Kumita, Matsuura, Hino, Takahashi, Hori, Fukumori, Morishima and Shiro[85] by permission of American Society for Biochemistry and Molecular Biology)

the fast technologies enable EPR, resonance Raman and low-temperature UV-Vis analyses, but this can be quite easily extended to the range of techniques currently available to the RFQ powder samples.

The current dead time of 60–80 μs for the MHQ setup is not determined by the mixing time, but by the sample-transport time and the freeze-quenching time. The latter can potentially be reduced to ∼8–10 μs by using a jet of 10 μm diameter instead of 20 μm, but in doing so the Reynolds number will decrease to ∼2000, at the limit of complete mixing. Although the Reynolds number might be increased to ∼4000 by doubling the flow rate, thus halving the sample-transport time, the pressure will increase with $\langle v \rangle^2$, necessitating additional investigation of the enzyme's stability at ∼1600 bar. All in all, a minimal dead time of 20–30 μs is estimated for the MHQ and similar setups.

The production of hyperquenched samples means that the trapped intermediates are in a (near) native state, as if in aqueous solution. Analysis of their structure by Magic-Angle Spinning Nuclear Magnetic Resonance (MAS-NMR) (*see* ***Nuclear Magnetic Resonance (NMR) Spectroscopy of Inorganic/Organometallic Molecules***) at 77 K would yield a 3D-structure of a true catalytic intermediate in the native state, something that has not been achieved so far in biochemistry. Analysis of a series of samples quenched after various times would yield a 3D-movie delineating structure-function relationships of enzyme catalysis in great detail, aiding in exploiting the principles of catalysis for future applications.

6 ACKNOWLEDGMENTS

The author greatly acknowledges the contributions made to the development of the MHQ setup by Drs. A. V. Cherepanov, L. A. M. Pouvreau, Ir. F. G. M. Wiertz, Ing. M. J. F. Strampraad, S. Mitic, N. de Jong and A. Paulus. The development of the MHQ instrument has been supported by the TU Delft, The Netherlands Research Organization (NWO grants 98014 and 700-50-025) and NanoNed (project TAC. 6380).

7 ABBREVIATIONS AND ACRONYMS

CCD = charged coupled device; CD = circular dichroïsm; CPO = chloroperoxidase; ENDOR = electron nuclear double resonance; EPR = electron paramagnetic resonance; ESEEM = electron spin echo envelope modulation; EXAFS = extended X-ray absorption fine structure; FRET = fluorescent resonance energy transfer; FTIR = fourier transform infrared; MAS-NMR = magic-angle spinning nuclear magnetic resonance; MCD = magnetic circular dichroïsm; MHQ = microsecond freeze-hyperquenching; RFQ = rapid freeze quench; XAS = X-ray absorption spectroscopy.

1 INTRODUCTION

Homogeneous catalysis by gold salts and complexes has evolved in the last few years from being an almost neglected field to becoming one of the most active areas of research in organometallic and organic chemistry.[1–11] Gold complexes usually surpass the reactivity shown by other electrophilic metal salts and complexes for the activation of alkynes. These complexes are remarkably reactive Lewis acids, with a high affinity for π-bonds. This unique π-acidity is a result of relativistic effects, which reach a maximum in the periodic table with gold.[11–15]

In addition to AuCl, $AuCl_3$, or $HAuCl_4$ and its salts, most common gold catalysts are cationic complexes generated by in situ abstraction of chloride from $[AuCl(PPh_3)]$, or similar phosphine complexes, using an equivalent of silver salt with a noncoordinating anion to form in situ cationic complexes $[Au(S)(PPh_3)]X$ (S = solvent or substrate molecule).[16–18] The same complexes can be obtained by cleavage of the Au–Me bond in $[AuMe(PPh_3)]$ with a protic acid.[16,19–21] Gold-oxo complex $[(Ph_3PAu)_3O]BF_4$[22,23] has also been used as a catalyst.[24] Gold(I) complexes (**1a**–**d**) bearing bulky, biphenyl-based phosphines lead to very active catalysts upon being mixed with Ag(I) salts.[25] Cationic complexes (**2a**–**b**) and (**3**)[17] are very reactive as catalysts in many transformations.[26–29] The structures of (**1a**–**d**), (**2a**–**b**), and (**3**) have been confirmed by X-ray crystallography.[30,31] Related complexes (**2c**–**d**) with weakly coordinated bis(trifluoromethanesulfonyl)amide NTf_2 (Tf = CF_3SO_2) have also been prepared.[32] Gold(I) complex (**4**) bearing the bulky ligand tris(2,6-di-*tert*-butylphenyl)phosphite leads to a highly electrophilic cationic Au(I) catalyst in situ by chloride abstraction with $AgSbF_6$.[33,34] Gold complexes with donating N-heterocyclic ligands (NHC) such as (**5a**–**d**) are also good precatalysts.[35,36] Cationic complexes bearing NHC ligands such as (**6**), which shows moderate stability at room temperature,[37] and those with NTf_2 ligand (**7a**–**b**) have also been reported.[38,39] Au(III) complex (**8**) has also been used as an alternative to $AuCl_3$.[40,41]

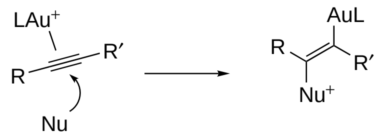
2 REACTIONS OF ALKYNES WITH HETERONUCLEOPHILES

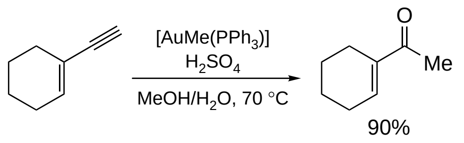
In a simplified form, the nucleophilic attack to the $[AuL]^+$–alkyne complex gives trans-alkenyl-gold complexes as intermediates (equation 1). Although simple alkyne–Au(I) complexes are usually stable only at low temperatures,[42,43] a few compounds of this type have been characterized.[44–47]



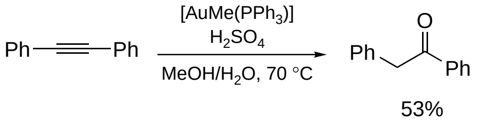
(1)

2.1 Oxygen Nucleophiles

The first examples of hydration of alkynes catalyzed by gold salts were reported in 1976 by Thomas.[48] Later, Utimoto found that the reaction could be carried out with lower amounts of catalyst.[49,50] Tanaka and coworkers reported a general hydration of alkynes using cationic Au(I) complexes generated in situ by protonolysis of $[AuMe(PPh_3)]$ as depicted in equations (2) and (3).[20,21] Markovnikov-type addition is observed in all cases. Other complexes of Au(I) and Au(III) have proved to be effective in this reaction.[51–53] The somewhat related gold-catalyzed addition of HCl to alkynes is an industrial process for the generation of vinyl chloride.[54]

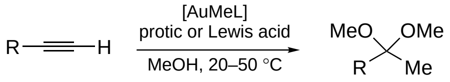


(2)

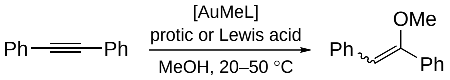


(3)

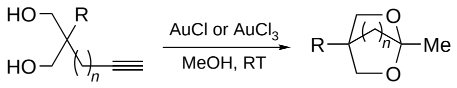
The nucleophilic addition of alcohols to alkynes was reported by Utimoto[49] with $NaAuCl_4$ and later by Teles with cationic gold complexes.[19,55] The enol ethers formed can be hydrolyzed to form carbonyl compounds or trapped as ketals (equations 4 and 5). An intramolecular version of this reaction was reported by the group of Genêt to give bicyclic ketals (equation 6).[56–58] On the basis of this concept, a glycosidation reaction was developed using propargyl glycosides as glycosyl donors with $AuCl_3$ as catalyst in acetonitrile.[59]



(4)

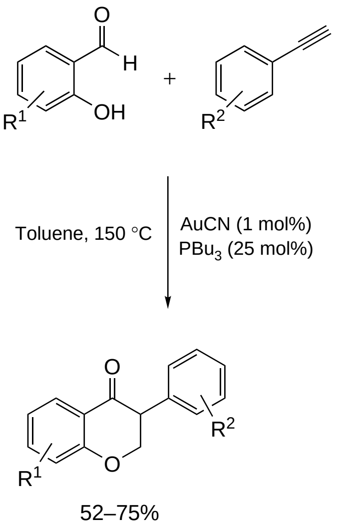


(5)

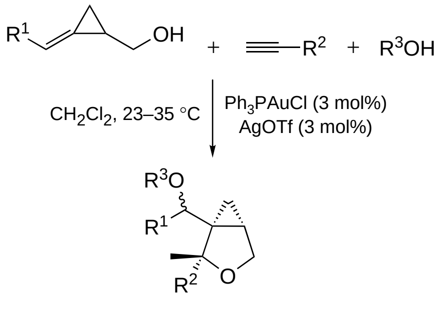


(6)

Intermolecular additions of alcohols to alkynes can be coupled with other tandem reactions of the alkenyl-gold intermediate. Thus, reaction between salicylaldehyde and phenylacetylenes can give access to the isoflavanone skeleton[60,61] (equation 7), whereas a three-component addition of methylenecyclopropylcarbinols, arylalkynes, and alcohols leads to bicyclic compounds (equation 8).[62]

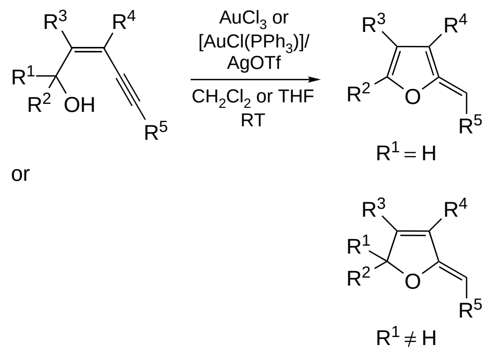


(7)



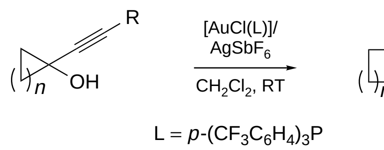
(8)

Hashmi reported the gold-catalyzed formation of furans by intramolecular addition of alcohols to alkynes[63] (equation 9) and, more recently, Liu *et al.* applied this reaction for the synthesis of dihydrofurans.[64] Propargylic alcohols undergo a Meyer–Schuster rearrangement leading to the formation of α,β-unsaturated ketones[65,66] or α,β-unsaturated esters in the case of ethoxyalkynyl carbinols.[67,68] In a recent report, Zhang showed a Meyer–Schuster rearrangement coupled with the intramolecular oxidation of the resulting gold carbene by a sulfoxide to yield 1,3-dicarbonyl compounds.[38]



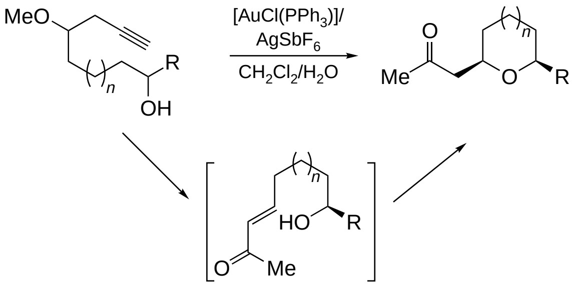
(9)

In contrast, propargylic cyclopropanols and cyclobutanols undergo ring expansion to form cyclobutanones and cyclopentanones with Au(I) catalysts[69] (equation 10).



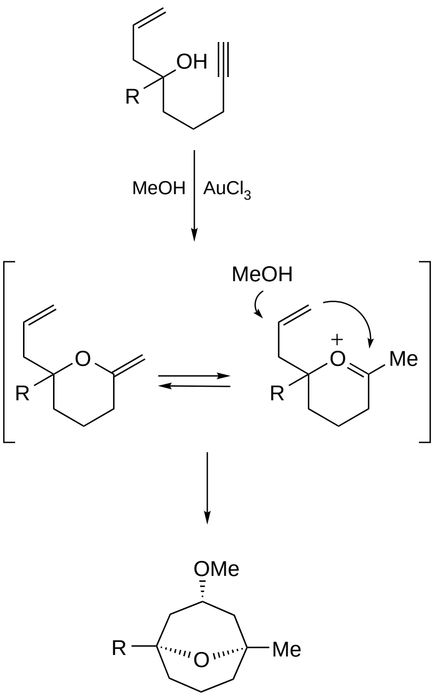
(10)

A related transformation was reported by the group of Floreancig for the synthesis of substituted tetrahydropyrans (equation 11).[70] This transformation initially involves a hydration of the alkyne and then an elimination of a leaving group at the β position, followed by a conjugate addition.



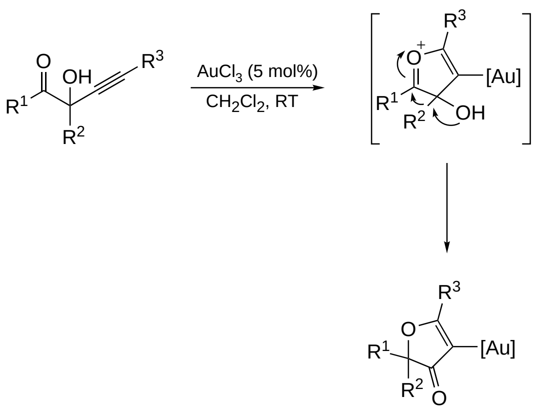
(11)

The group of Barluenga reported the formation of enol ethers, which are protonated in situ to form oxonium intermediates that undergo Prins reaction yielding eight-membered ring carbocycles (equation 12).[71]

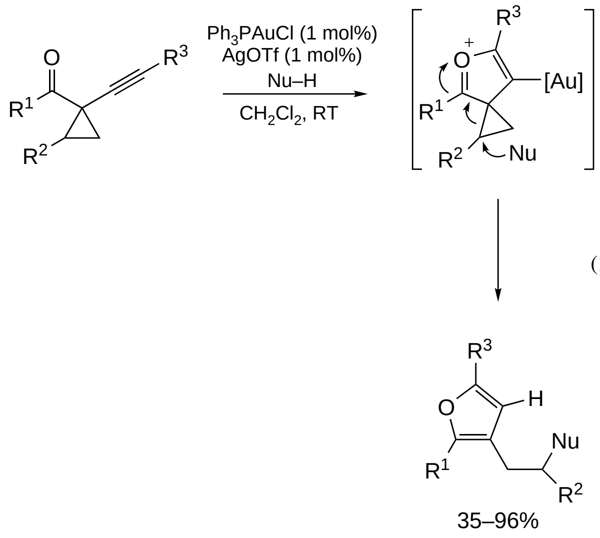


(12)

Carbonyl compounds and epoxides also act as nucleophiles in the addition to alkynes to give furans.[63,72–76] Cyclic acetals are obtained with some epoxyalcohols,[77] whereas cyclic enones are the products of the cyclization of alkynyl ketones.[78] An interesting transformation occurs upon treatment of hydroxyketones to give 3(2H)-furanones with $AuCl_3$ at 23 – 38 °C in CH_2Cl_2 (equation 13).[79] The reaction proceeds by carbonyl attack to the enyne and pinacol-type rearrangement, where a 1,2-migration of the propargylic substituent takes place. When R^1 and R^2 are part of a ring, this rearrangement leads to a ring contraction.[80] A related conversion occurs in the gold(I)-catalyzed reaction of alkynylcyclopropanes, which gives furans (equation 14).[81] In this case, when the nucleophile is an indole, the furanyl–gold intermediate can be trapped by the indolinium cation formed in the first step.[82]

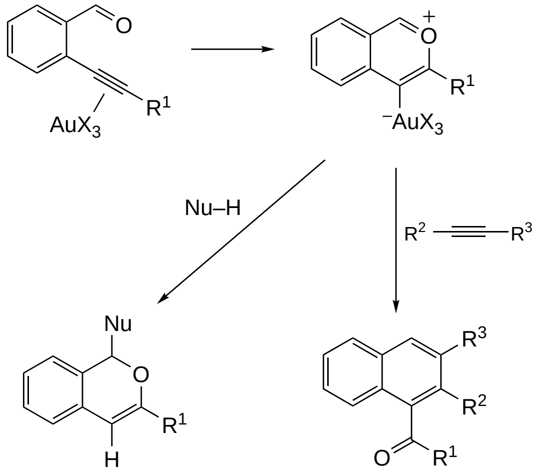


(13)



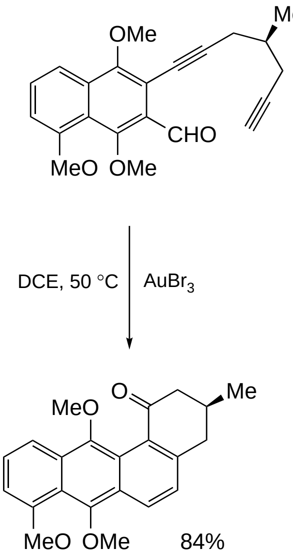
(14)

An interesting class of reactions are initiated by the intramolecular attack of a carbonyl group to the alkyne to form pyrylium ions, which can react further with alkynes to form naphthalenes by a [4 + 2] cyloaddition followed by a cycloreversion or suffer addition of external nucleophiles (equation 15).[83]

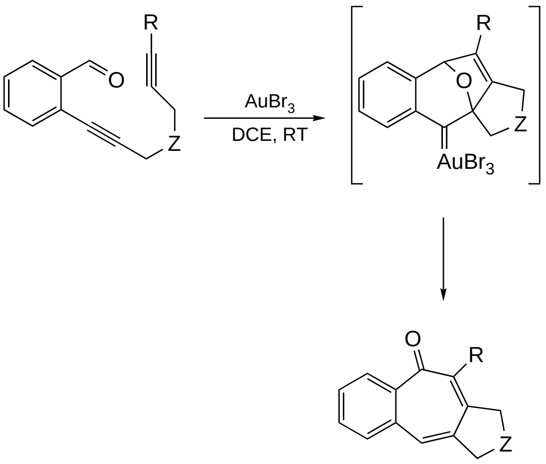


(15)

This chemistry has been studied extensively by the groups of Asao,[84–90] Dyker *et al.*[91,92] Oh,[93] and others[94–96] and has been recently reviewed.[97] A notable application of this chemistry is the synthesis of the tetracyclic compound in equation (16), which was transformed in one or two steps into the angucyclinone antibiotics (+)-rubiginone B_2 and (+)-ochromycinone.[98] The intermediate pyrylium gold species can also undergo [3 + 2] cycloaddition to form tricyclic compounds as shown in equation (17).[93] Formation of intermediate azomethine ylides by reaction of imines with alkynes catalyzed by gold has been reported by the group of Iwasawa.[99]

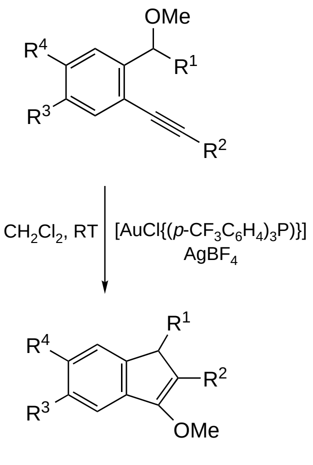


(16)



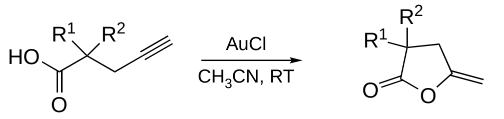
(17)

Arylalkynes bearing benzylic ethers at the ortho position also cyclize with cationic Au(I) catalysts to give indenyl ethers (equation 18).[100] As per a recent report, the cation formed from the intramolecular attack of carboxylates onto related substrates was used as an effective alkylating agent, producing isocoumarins as side products.[101]

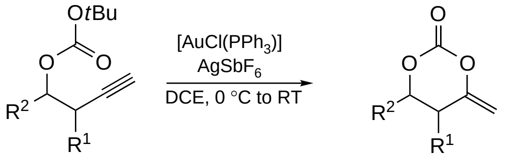


(18)

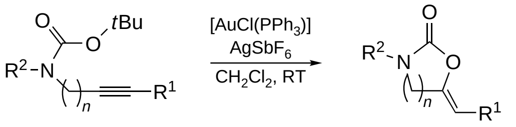
Carboxylic acids,[102–104] carbonates,[105–107] carbamates,[108–110] sulfoxides,[111] and related nucleophiles[112] also add to alkynes (equations 19–22). Similarly, the intramolecular addition of amides to alkynes leads to oxazoles by isomerization of the initially formed 5-methylene-4,5-dihydrooxazoles (equation 22).[113] An interesting reaction was reported by Yamamoto and Asao in which nitro groups add to alkynes intramolecularly with $AuBr_3$ as catalyst.[114]



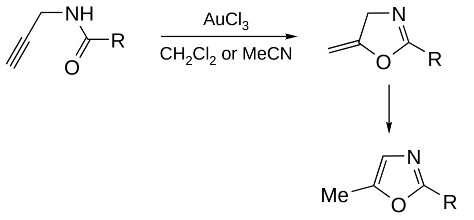
(19)



(20)

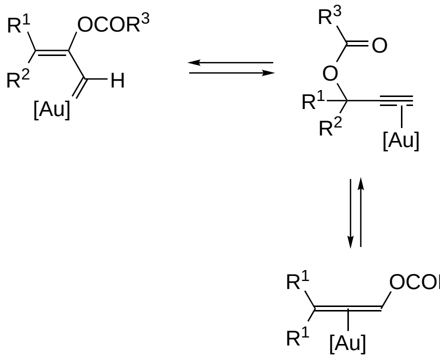


(21)

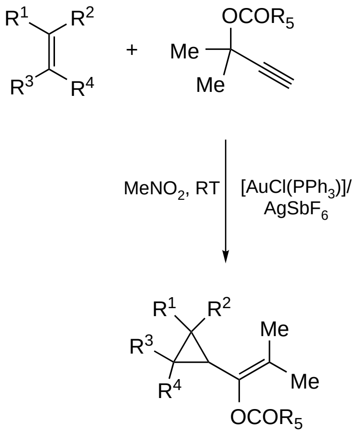


(22)

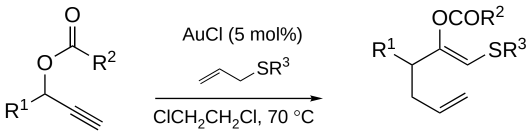
Propargylic esters coordinate with gold to form complexes that can undergo 1,2- or 1,3-acyl migrations to form α-acyloxy-α,β-unsaturated carbenes or allene–gold complexes (equation 23).[115–117] According to DFT (density functional theory) calculations, formation of these two species is not concerted, but proceeds in two steps through five- and six-membered ring intermediates, respectively.[116,117] Evidence for the involvement of gold carbenes has been obtained in intermolecular cyclopropanation reactions with alkenes (equation 24),[118–122] trapping with carbon nucleophiles[123] and sulfides (equation 25),[124] and oxidation with Ph_2SO to form α,β-unsaturated carbonyl compounds.[125]



(23)

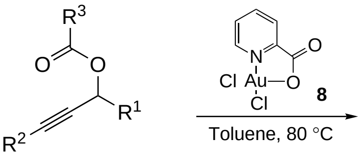


(24)



(25)

Simple propargylic esters also undergo a 1,3-acyl migration catalyzed by Au(III), leading finally to 1,3-dicarbonyl compounds as mixtures of E and Z isomers (equation 26).[126–128]



(26)

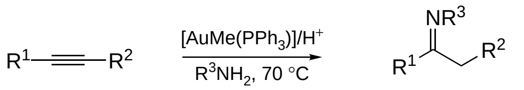
Other 1,3-acyl migrations of propargylic carboxylates catalyzed by gold give intermediate allenes, which can afford heterocyclic compounds by intramolecular attack of the appropriate nucleophiles.[129] The intermediate allenes formed by 1,3-acyl migrations can also react intramolecularly with alkynes to form naphthalenes, although this reaction proceeds more efficiently with Ag(I) catalysts,[130] and is discussed in the alkyne–carbon nucleophile section.

Related transformations take place from propargylic carboxylates by using Au(I) catalysts for the synthesis of enones through 1,3-migration.[131–133] Tandem sequences exploit the potential of this rearrangement to obtain, by means of allenyl or carbene intermediates, structurally different substrates.[134]

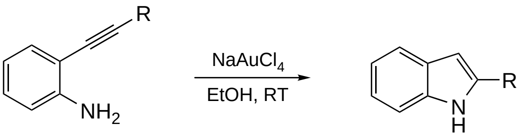
2.2 Nitrogen Nucleophiles

The hydroamination of terminal alkynes with $NaAuCl_4$ was developed in 1987.[135] In 1991, Utimoto described the preparation of tetrahydropyridines from 5-alkynylamines with Au(III) catalysts.[136] This idea was further extended by Müller to give the corresponding iminium compounds.[137,138]

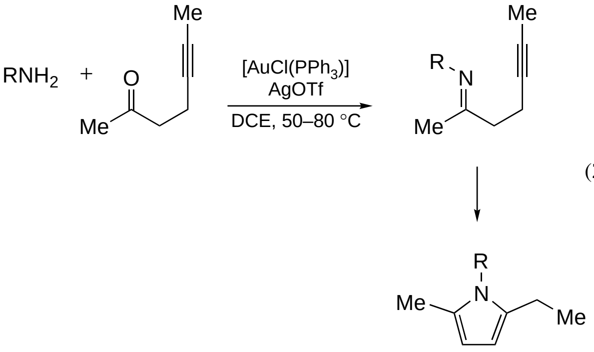
Later, Arcadi showed that β-keto-imines react with alkynes intramolecularly to give pyrroles.[139] The intermolecular amination with anilines was later developed by Hayashi and Tanaka[21] using a cationic Au(I) catalyst to form imines (equation 27). More recently, Arcadi *et al.* developed an intramolecular version for the cyclization of *o*-alkynylanilines to form indoles (equation 28)[140–142] and Li reported a double intra- and intermolecular hydroamination to obtain *N*-vinylindoles.[143] *O*-Substituted hydroxylamines can also undergo this type of transformation to dihydroisoxazole derivatives.[144] Tandem sequences that involve a first alkyne-hydroamination step with anilines have been recently developed[145,146] and are similar to the previously discussed additions with phenols that access isoflavone skeletons.



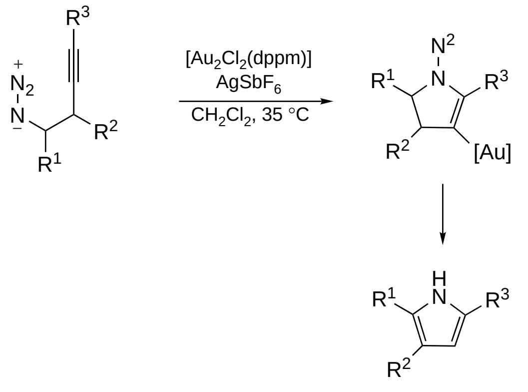
(27)



(28)



(29)



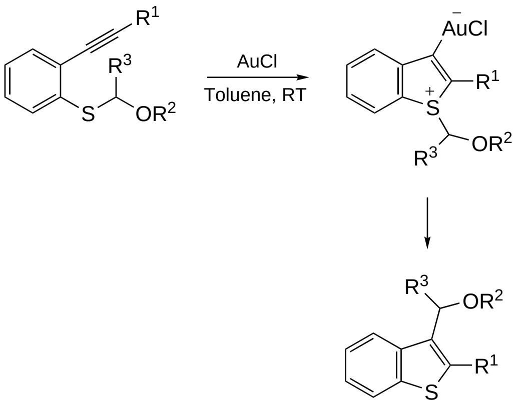
(30)

Gagosz recently showed that tertiary tosylamides can react with alkynes and the cationic enammonium intermediate evolves by a [3,3]-sigmatropic rearrangement to yield pyrrols.[147]

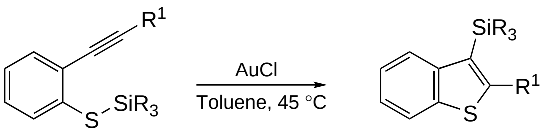
Imines react with alkynes to give pyrroles (equation 29).[148] A related transformation of azides has been reported by the group of Toste to afford pyrroles by an acetylenic Schmidt reaction (equation 30).[149] In an intermolecular-related addition, gold triazolates are obtained.[150] The intramolecular hydroamination of trichloroacetimidates derived from propargyl and homopropargyl alcohols also proceeds with cationic Au(I) as catalysts.[151]

2.3 Sulfur Nucleophiles

The addition of sulfur nucleophiles to alkynes is a less developed transformation. However, Yamamoto described the attack of the sulfur atom of aryl thioethers to afford benzothiophenes (equation 31).[152] More recently, it has been showed that propargylic thioethers or thioacetals undergo migration to give carbenes that cyclize in hydroarylation processes[153] and thiocarbamates that evolve by propargylic rearrangement.[154] Thiosilanes can perform as both sulfur nucleophiles and silicon electrophiles in intramolecular reactions to afford benzothiophenes (equation 32).[155]



(31)

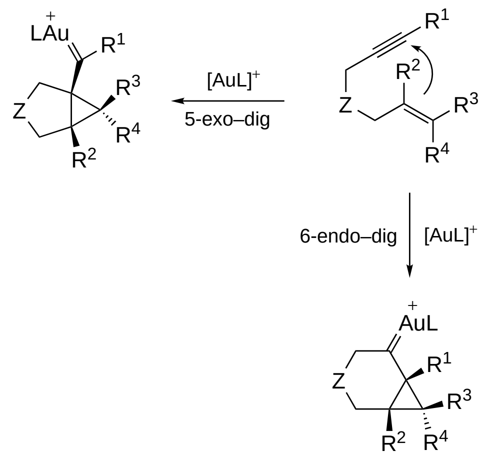


(32)

2.4 Carbon Nucleophiles

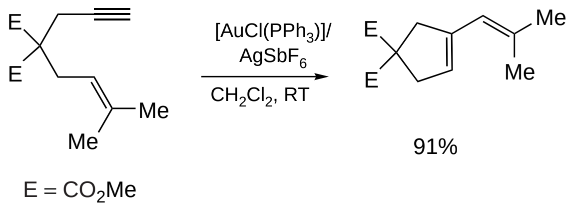
Alkenes act as nucleophiles with alkynes in the presence of gold catalysts.[9,156] In the most simple version of the reaction, enynes are converted with gold complexes or salts, and in the absence of nucleophiles, into rearranged dienes, cyclopropanated carbocycles, and/or bicyclic cyclobutenes. Depending on the length of the tether and the nature of the substituents, the olefin attack to the alkyne occurs in an endo or an exo fashion (equation 33). Besides, substitution at the alkene plays an important role on the regioselectivity of the nucleophilic attack.[9]

It is important to note in an overview of this chemistry that the formation of most of the products can be mechanistically explained as proceeding via cyclopropyl gold carbene intermediates. The involvement of these species has been previously proposed in enyne cyclizations with other metals and their structures have been later determined by calculations.[8,156]

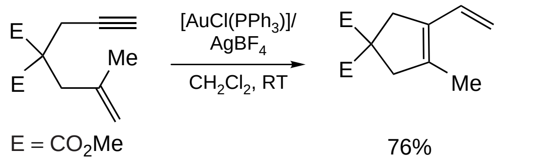


(33)

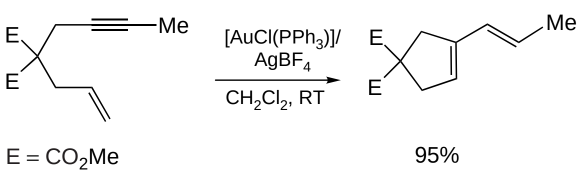
The skeletal rearrangement of enynes proceeds through that kind of intermediates. Two basic types of products are obtained when an exo pathway is followed: *single cleavage* and *double cleavage*, named owing to the fact that only the olefin or both the alkene and the alkyne are cleaved in the transformation. Some examples are depicted in equation (34–36).[157]



(34)

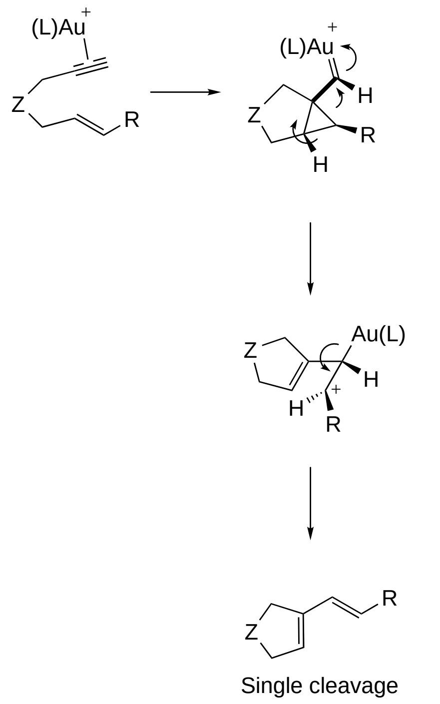


(35)

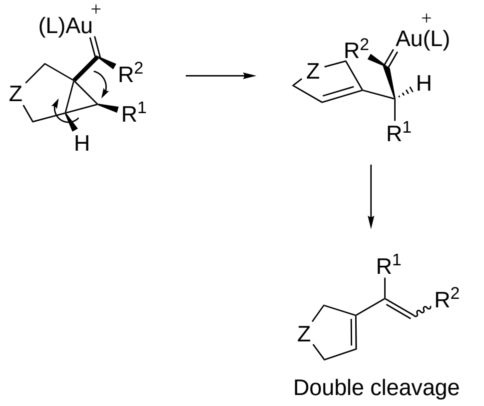


(36)

For 1,6-enynes, the initial cyclopropyl gold carbene formed in the 5-exo–dig cyclization (equation 37) evolves to form a carbocation, which then undergoes metal elimination to give the single-cleavage diene.[158] For the double-cleavage rearrangement (equation 38), the intermediate can suffer a dyotropic rearrangement[159–161] to give a rearranged carbene, which then eliminates an α-hydrogen to give the double-cleavage diene.[158]

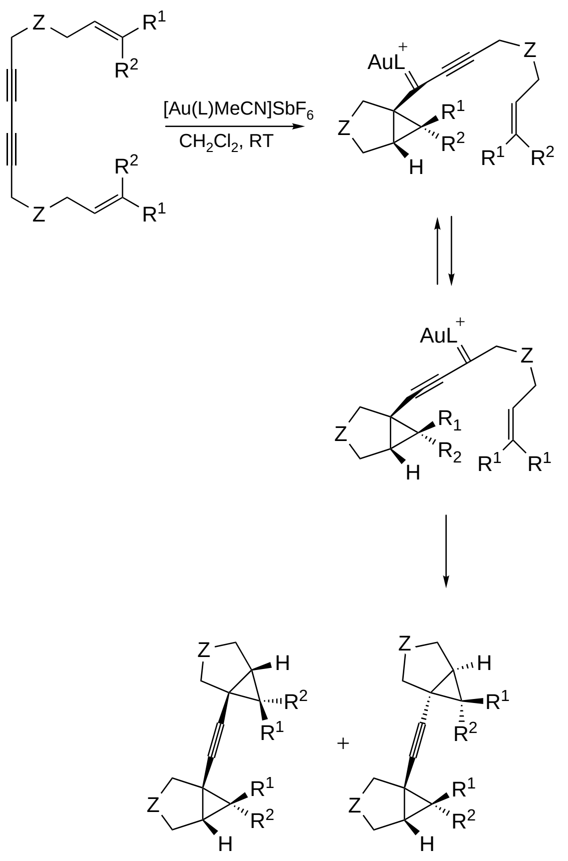


(37)



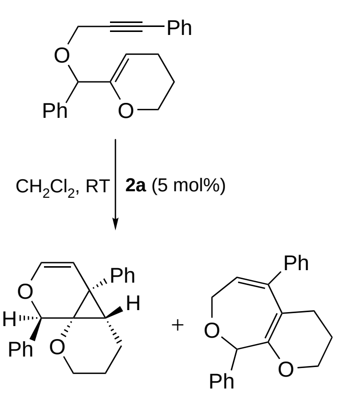
(38)

Additional evidence for the involvement of metal carbenes in these processes was obtained in the reaction of dimeric substrates with a cationic Au(I) catalyst to give disubstituted alkynes (equation 39).[33] These reactions can be explained by isomerization of the initially formed cyclopropyl gold carbene by a [1,3] metallotropic shift, followed by intramolecular trapping of the gold carbene by the alkene. Other examples of [1,3] metallotropic shifts in gold chemistry have been observed recently.[162,163]



(39)

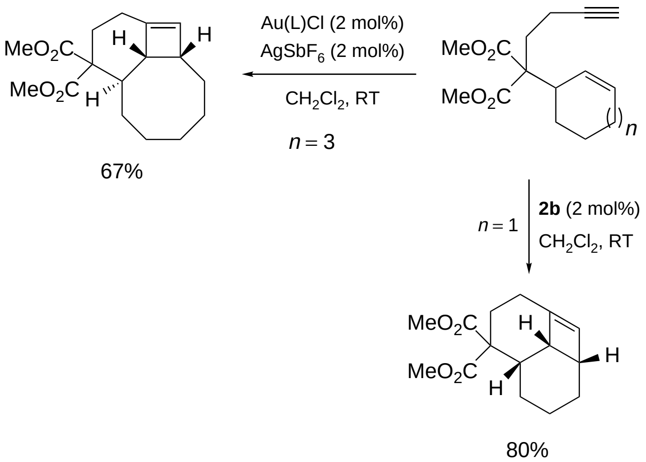
Endo-skeletal rearrangements also take place with 1,6-enynes, but the proposed mechanism is just a variation of the exo-single-cleavage rearrangement. Formed by endo cyclization, bicyclo[4.1.0]hept-4-ene derivatives arise in some cyclizations of 1,6-enynes by proton loss and protodemetalation of the endo cyclopropylcarbene.[164–168] That is the case from 1,6-enynes tethered as sulfonamides and in the intramolecular cyclization of 1,6-enol ethers with alkynes (equation 40).[166]



45% 14%

(40)

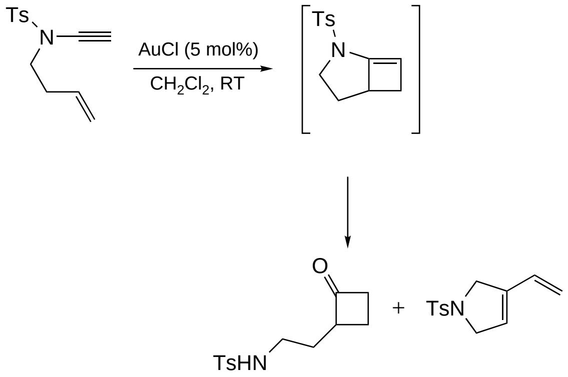
A few examples of single-cleavage skeletal rearrangement of 1,7-enynes have been reported by using gold.[169,170] Cyclobutenes are obtained in the cyclizations of some 1,7-enynes with Au(I) catalysts, presumably as a result of a syn-attack of the alkene on the alkyne-Au(I) complex (equation 41).[158]



80%

(41)

Albeit no examples of a stable bicyclo[3.2.0]hept-5-ene obtained by a metal-catalyzed reaction from a 1,6-enyne have been observed, interestingly, following earlier work done with $PtCl_2$ as catalyst,[171] it was found that the gold-catalyzed reaction of 1,6-ene-ynamides gives cyclobutanones (equation 42),[172] in a process that probably proceeds through unstable bicyclic enamines.

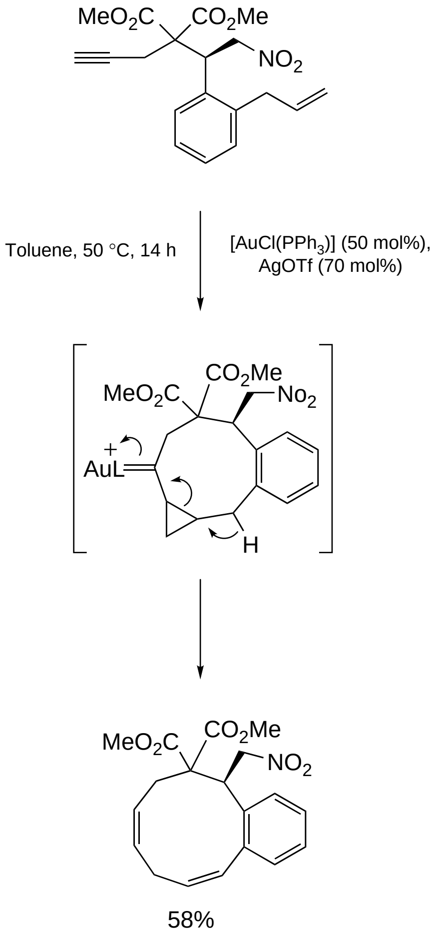


(42)

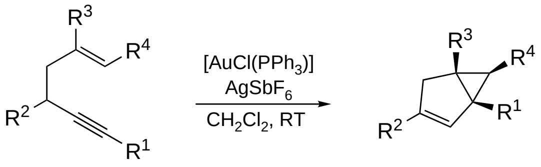
40–61% <10%

A remarkable cyclization of a 1,9-enyne (equation 43) to form a 10-membered ring has been disclosed.[173] The aromatic ring may play a role in the cyclization, but still this result shows that formation of large rings from 1,n-enynes ($n \geq 7$) by using gold chemistry is possible. Cyclizations of 1,8-enynes that probably proceed by a different mechanism have also been reported.[174]

The cyclization of 1,5-enynes to give bicyclo[3.1.0]hexanes under mild conditions was reported by Toste (equation 44).[175] Interestingly, in a similar reaction, Gagosz found that 1,5-enynes gave the expected bicyclo[3.1.0]hexane

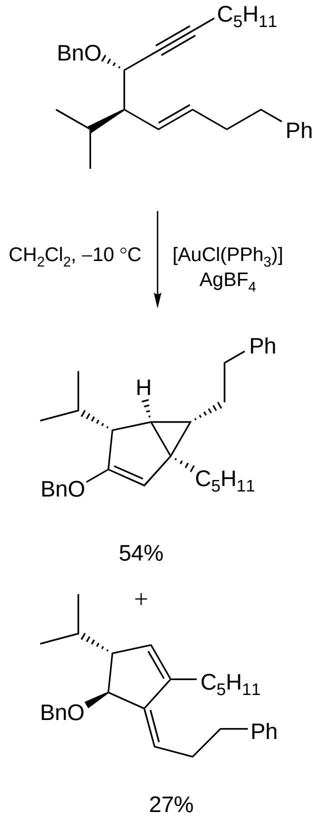


(43)



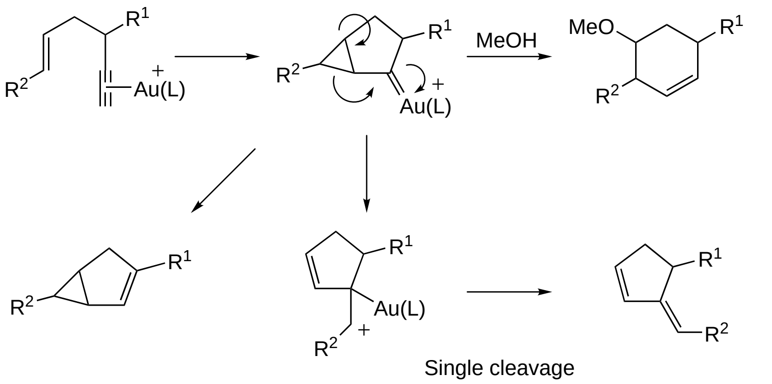
(44)

accompanied by a product of skeletal rearrangement (equation 45).[176]



(45)

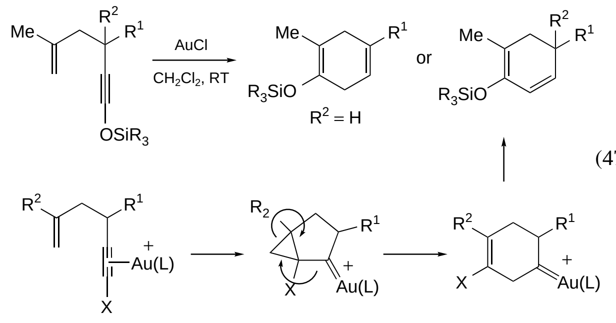
The formation of these products can be rationalized as shown in equation (46). Thus, upon complexation of Au(I) to the alkyne in the reacting enyne, an endo cyclization occurs to form a cyclopropyl gold carbene,[177] which can be trapped by a nucleophile.[175] However, the lack of stereospecificity observed in some of these reactions,[32,176] suggests the formation of open six-membered ring cations as intermediates, which can be intercepted by an *O*-Boc group.[178] 3-Hydroxy-1,5-allenynes react similarly with Pt(II) catalysts.[179]



(46)

Kozmin found that siloxy 1,5-enynes react with Au(I) catalysts to give cyclohexadienes (equation 47),[180,181] which is

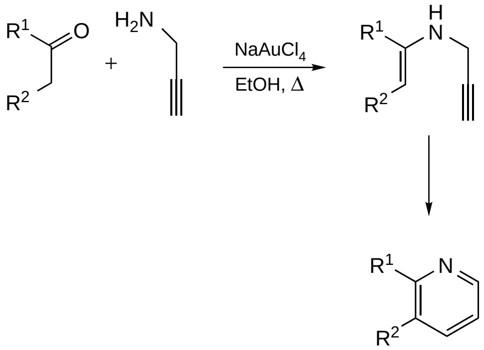
probably another example of a double skeletal rearrangement. A similar transformation has been found with other 1,5-enynes.[176,181]



(47)

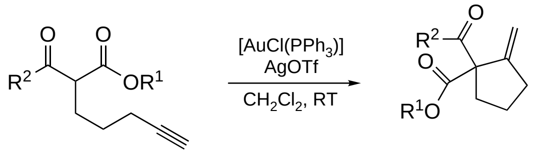
Other 1,5-endo cyclizations are observed for 1-alkynyl-2-alkenylbenzenes to form naphthalenes.[182,183] However, in this case, exo cyclization was also observed as a minor pathway from substrates bearing terminally substituted alkynes.

Yet the first examples of cyclization of 1,5-enynes with gold were disclosed by the group of Arcadi in the context of a new synthesis of pyridines (equation 48).[184] The cyclization of propargyl enamines catalyzed by sodium tetrachloroaurate gives substituted pyridines in a general way. The enamines were formed in situ from propargylamine and the corresponding ketone.

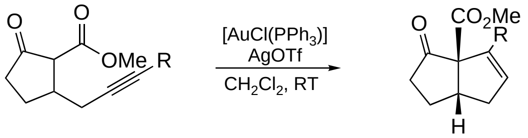


(48)

Related to this cyclization of enamines, Toste described the addition of enols of β-ketoesters to alkynes catalyzed by gold(I).[185,186] The regioselectivity of the process is, as in many other cases, dependent on the length of the tether (equations 49–50). The reaction can be also performed efficiently using a gold catalyst with a triethynylphosphine ligand bearing bulky silyl end caps[169] or with a catalyst generated in situ from a cyclic thiourea–AuCl complex and AgOTf.[187] An enantioselective version of this reaction was developed using chiral palladium complexes.[188] Silylketene amides or carbamates react similarly with alkynes to form cyclopentanes or dehydro-δ-lactams.[189] The analogous reaction of silyl enol ethers with alkynes catalyzed by gold[190,191] was applied for the synthesis of the alkaloids (+)-licopladine A[190] and (+)-fawcettimine.[192] Reactions of more simple substrates bearing a 1,5- or 1,6-relation between silyl enol ether and the alkyne take place in an exo fashion to form five- or six-membered rings.[191]

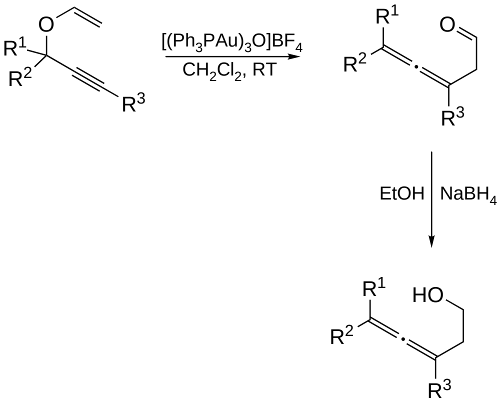


(49)

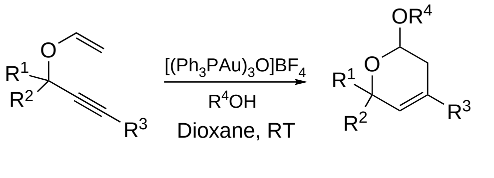


(50)

Propargyl vinyl ethers undergo Claisen rearrangement with Au(I) catalysts to give allenes, which were isolated as the corresponding alcohols (equation 51).[24] A similar gold-catalyzed transformation of propargyl allyl ethers, which proceeds by the initial isomerization to the propargyl vinyl ethers, has also been observed.[18] A related palladium-catalyzed process has also been described.[193] Indeed by performing the reaction in the presence of water or alcohols, dihydropyrans were obtained in good yields (equation 52).[194] A related transformation has been reported by Kirsch in which similar substrates are converted into allenes, which cyclize to afford furans (equation 53).[195] A variation of this procedure has been developed for the synthesis of pyrroles by performing the first rearrangement with an Ag(I) catalyst. The intermediate 1,3-dicarbonyl compound was then condensed with primary amines, which was followed by a final Au(I)-catalyzed cyclization.[196]



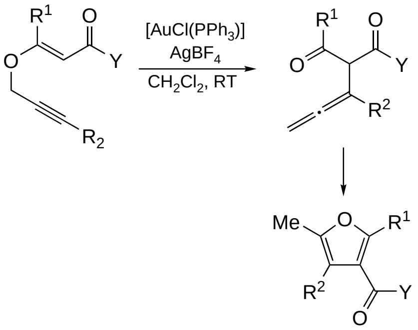
(51)



(52)

Recently, the groups of Lee and Toste reported that allyl silyl alkynes react with Au(I) catalysts in the presence of

alcohols to give alkenylsilanes[197,198] by a process that might involve the fragmentation of a cyclopropyl gold carbene.

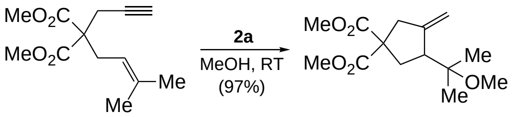


(53)

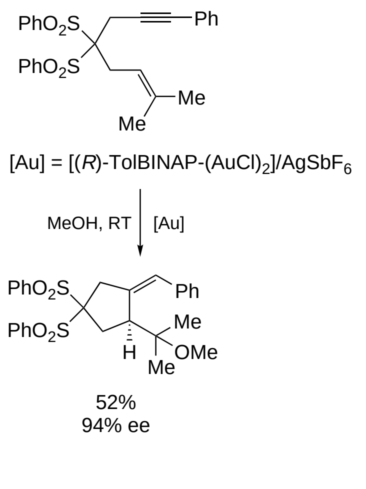
2.5 External Nucleophiles

In the presence of external nucleophiles, the situation changes and the behavior of cyclopropyl gold carbenes as delocalized electrophiles becomes manifest. Nucleophilic attack then takes place at either the cyclopropane ring or at the carbene carbon.

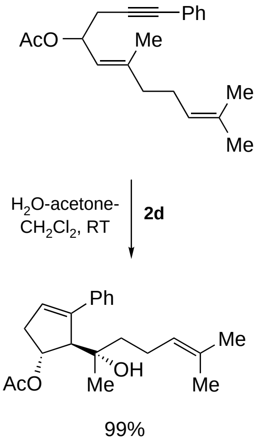
Thus, by using conditions developed by Tanaka and coworkers for the hydration of alkynes,[21,22] reaction of enynes with [AuMe(PPh_3)] and a protic acid in MeOH led to the formation of products of methoxycyclization.[9,17] Similar results were obtained from [AuCl(PPh_3)] and $AgSbF_6$ or from preformed cationic gold complexes (equation 54). Thus, for example, the enyne in equation (55) was readily converted into the corresponding product[17,32] by using a chiral Au(I) complex, with 94% ee, although lower enantiomeric excesses were obtained with other enynes.[199] Intramolecular attack of the hydroxyl function in equations (57) and (58) afforded tetrahydrofuranyl derivatives in good yields.[17] Related intramolecular hydroxycyclizations, as well as related sulfonamide cyclizations, have also been observed from 1,5-enynes (equations 56 and 58).[200,201]



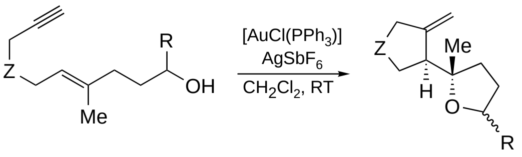
(54)



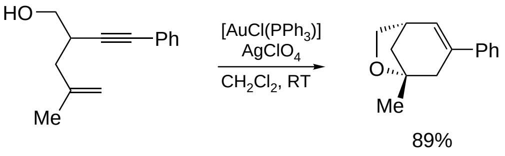
(55)



(56)

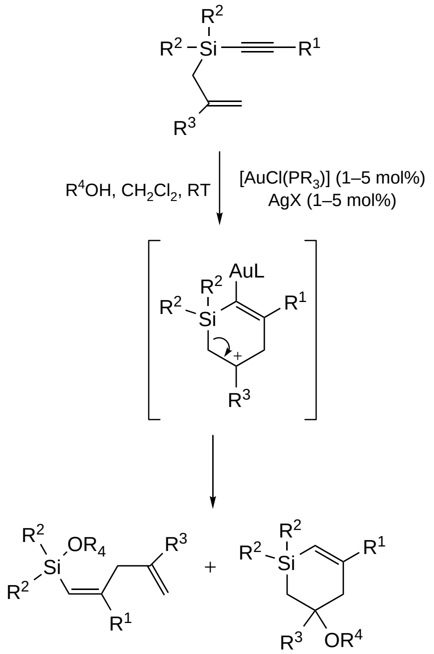


(57)



(58)

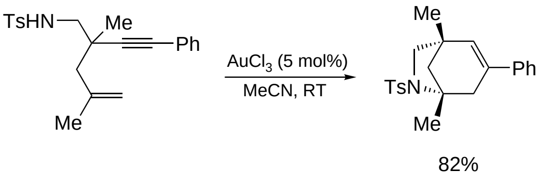
Allyl propargyl ethers (oxygen-tethered 1,6-enynes) also react intermolecularly with alcohols or water to give six-membered ring acetals or hemiacetals (equation 52).[166] Allyl silyl alkynes react somewhat similarly with Au(I) catalysts in the presence of alcohols to give cyclic or open alkenylsilanes (equation 59).[197,198] Both types of products are the result of



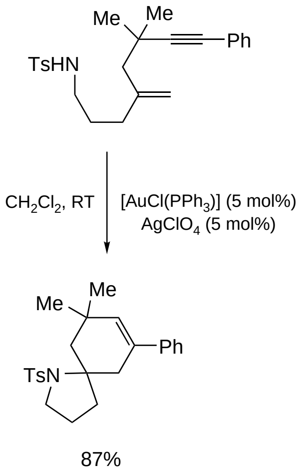
(59)

an endocyclic cleavage of the initial cyclopropyl gold carbene shown here as an open carbocation, by attack of the nucleophile at the silicon atom or at the cyclopropane carbon.

The intramolecular amination of 1,5-enynes proceeds similarly to the intramolecular hydroxycyclizations of related substrates to give the products shown in equations (60) and (61).[201] The intermolecular reaction of 1,6-enynes with a series of carbamates RO_2CNH_2 or anilines $ArNH_2$ has also been reported.[202]

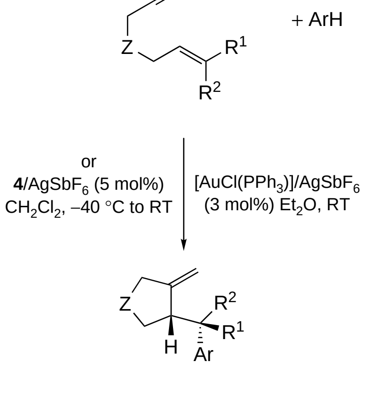


(60)

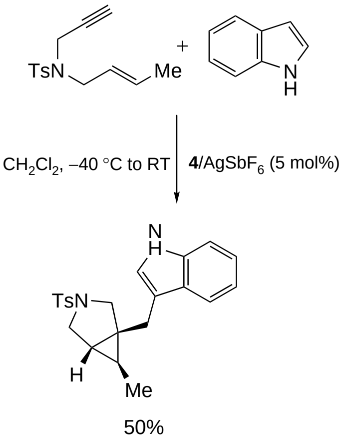


(61)

Electron-rich aromatic and heteroaromatic compounds add to 1,6-enynes in the presence of Au(I) catalysts (equations 62 and 63).[203,204] This reaction leads stereospecifically to adducts related to the products in the alkoxycyclization by nucleophilic addition on cyclopropyl gold carbene intermediates. Interestingly, in a few cases, addition of the nucleophile takes place at the carbene carbon to give adducts of the type in equation (63).[204]

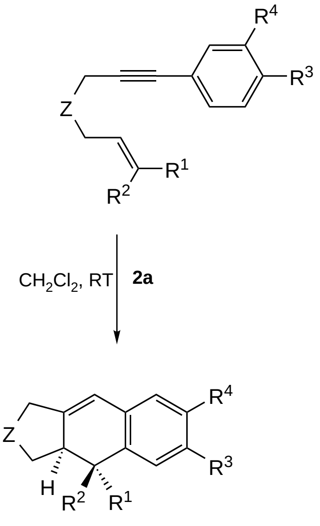


(62)

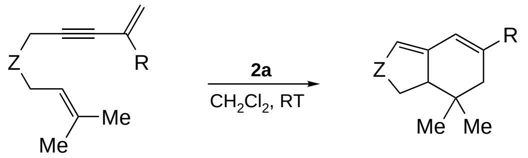


(63)

Similarly, enynes substituted at the alkyne with an aryl group led to products resulting from a formal intramolecular [4 + 2] cycloaddition occurring at an unusual low temperature (equation 64).[25,34] On the other hand, substrates with $R^1 = R^2 = H$ or $R^1 = Me$, $R^2 = H$ gave cyclobutenes with Au(I)[25,34] or Pt(II) catalysts.[205] Dienynes react with cationic Au(I) catalysts leading to products of formal [4 + 2] cycloaddition as well (equation 65).[25,34] Somewhat related cyclizations of allenes with alkynes[206,207] and diynes[208,209] have been described.



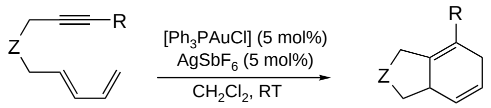
(64)



(65)

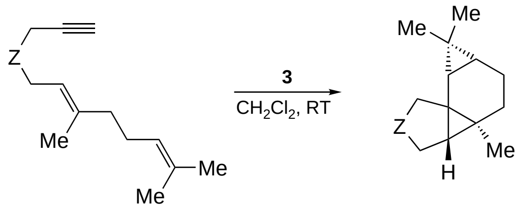
1,3-Dien-8-ynes undergo formal intramolecular Diels–Alder reactions catalyzed by Au(I) to give adducts like in equation (66).[210] This reaction was proposed to take place by evolution of the intermediate vinylcyclopropyl gold carbenes by a metalla-Cope rearrangement or by formation of a six-membered ring cation. Indeed, vinylcyclopropyl gold carbenes

could be trapped intramolecularly by a hydroxy group at the diene chain or by a phenyl at the alkyne in a [4 + 2] cycloaddition process as in equation (64).

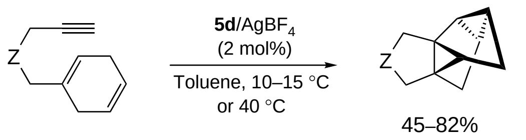


(66)

Other double bonds on the alkenyl chain can trap the initial gold carbenes leading to cyclopropanes. Thus by using Au(I) catalysts, dienynes in equations (67) and (68) undergo totally stereoselective cyclizations to yield tetracyclic compounds under milder conditions[9,26,211] than those required with other metal catalysts.[212–215]

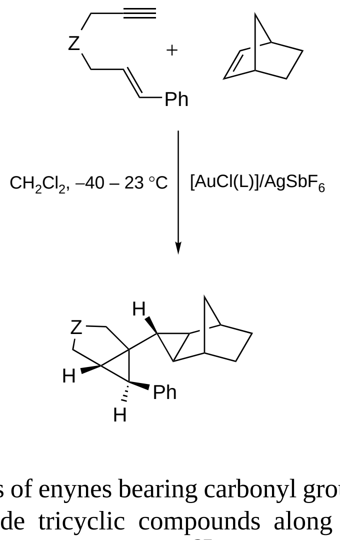


(67)



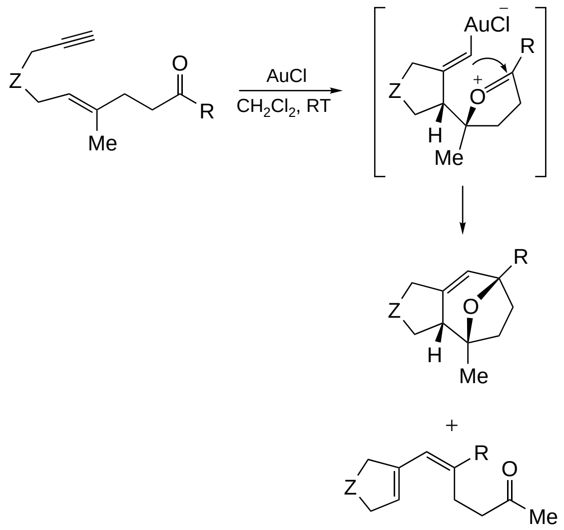
(68)

Similarly, the intermolecular reaction between enynes and alkenes proceeds with Au(I) catalysts (equation 69).[33]



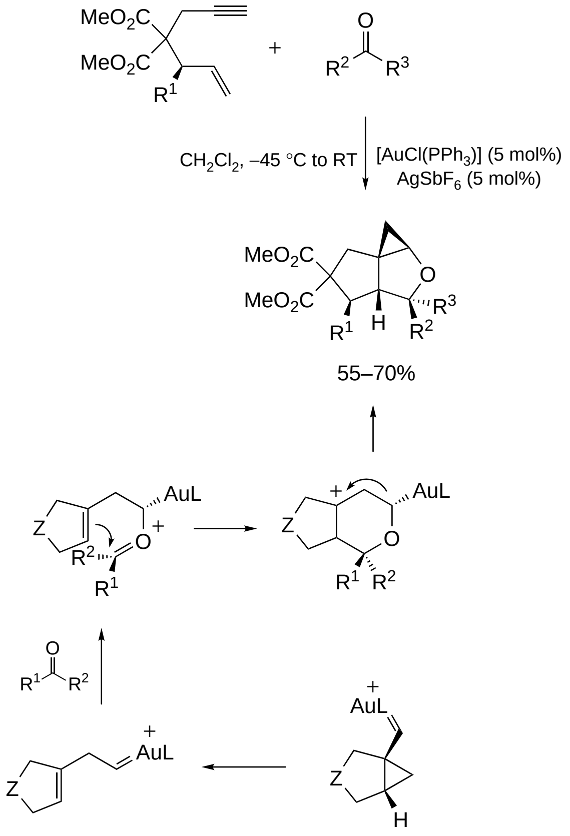
(69)

Cyclizations of enynes bearing carbonyl groups with Au(I) catalysts provide tricyclic compounds along with ketones, as minor products (equation 70).[27] In these cyclizations, the carbonyl group acts as an internal nucleophile to form an oxonium cation, which undergoes an intramolecular Prins reaction to give tricycles and carbonyl compounds as shown in equation (70).



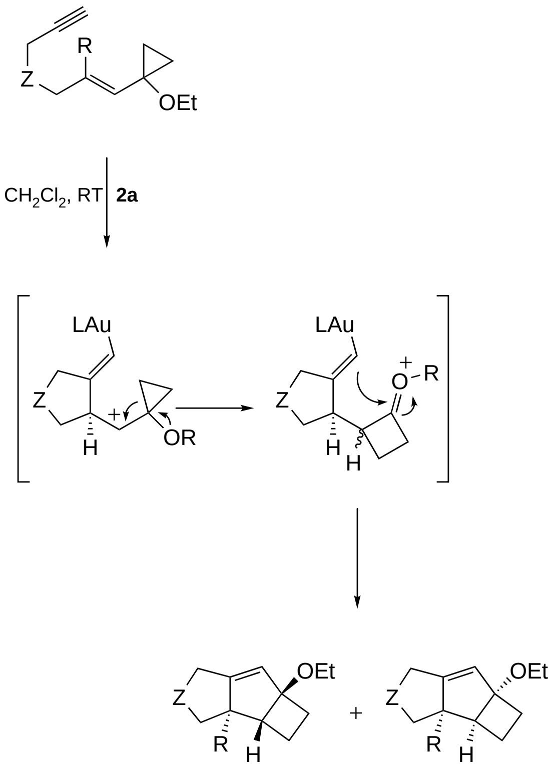
(70)

Carbonyl compounds can also act as the nucleophiles in intermolecular processes with 1,6-enynes.[216] Thus, the gold(I)-catalyzed reaction between enynes and aldehydes or acetone gives stereoselectively tricyclic compounds (equation 71). The transformation is mechanistically intriguing, as it proceeds by a rearrangement of the initially formed cyclopropyl gold carbene (the intermediate in the double-cleavage mechanism), which is then trapped by the carbonyl compound to form the products.



(71)

A Prins cyclization is also involved in the reaction of the cyclopropylenynes in equation (72) with AuCl or cationic Au(I) complexes to give tricyclic derivatives with an octahydrocyclobuta[*a*]pentalene skeleton.[33] The formation of stereoisomers was unexpected and suggests the involvement of cationic intermediates (equation 72).

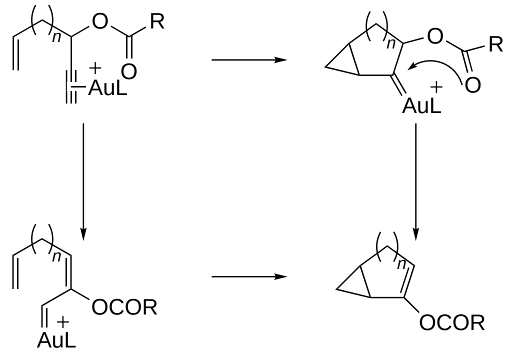


(72)

3 CYCLOISOMERIZATIONS OF ENYNES BEARING PROPARGYLIC CARBOXYLATES OR ETHERS

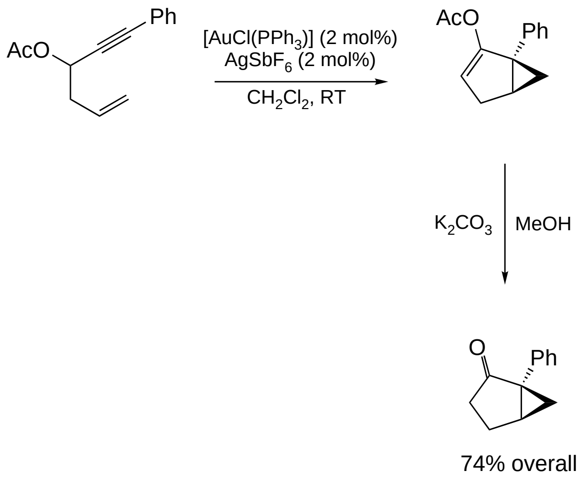
As pointed out earlier, propargylic esters coordinate to gold to form complexes that can undergo 1,2- or 1,3-acyl migrations to form α-acyloxy-α,β-unsaturated carbenes or allene-gold complexes (equation 23).[115–117]

For the gold-catalyzed cyclization of enynes bearing α-acyloxy substituents at the propargylic position, in principle, two mechanistically distinct possibilities exist depending on the order of attack of the acyloxy group and the alkene to the gold-alkyne complex (equation 73). If the alkene reacts first, the cyclopropyl metal carbene would be formed, which could then suffer an intramolecular attack of the acyl to the carbene, followed by an elimination (formal 1,2-migration of the acyl) to give the enol carboxylate after metal loss. Alternatively, the carboxylate group might first undergo the 1,2-migration to form an open carbene, which would then evolve by intramolecular cyclopropanation. The overall process is known as the *Ohloff–Rautenstrauch rearrangement*, or more simply as the *Rautenstrauch rearrangement*, following the original discovery in the context of zinc- or palladium-catalyzed cyclizations of similar systems.[217,218]



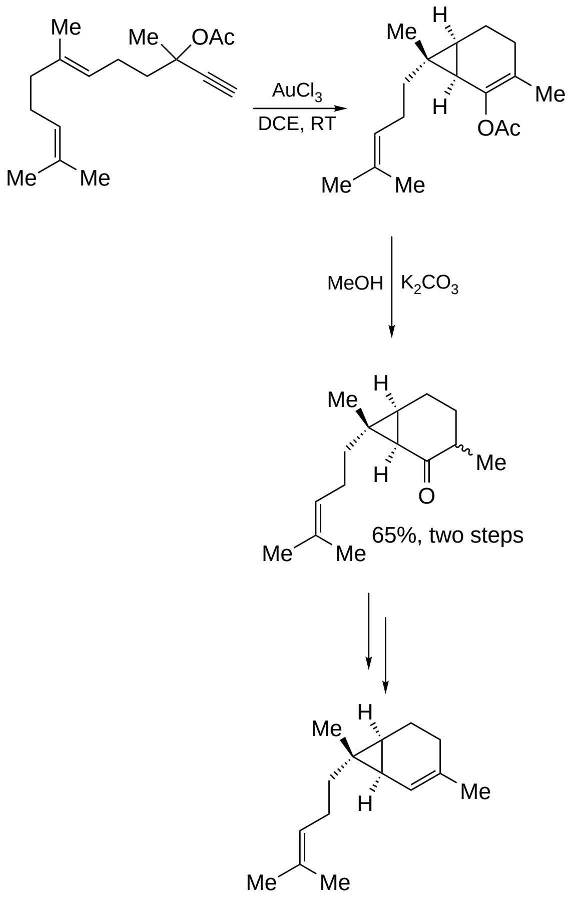
(73)

The gold-[219,220] and platinum-catalyzed Rautenstrauch rearrangements were discovered independently by two groups.[214] Thus, for example, the gold-catalyzed cyclization of the propargylic acetate in equation (74) gives the product of cyclization and 1,2-acetate migration, which was methanolyzed to yield the corresponding ketone.[219]



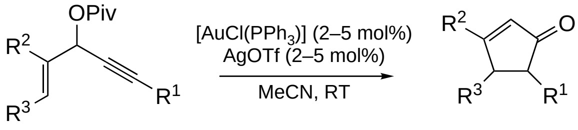
(74)

The first mechanistic pathway in equation (73) is probably followed when $n = 2$, as shown in a key Pt(II)-catalyzed cyclization for the synthesis of (−)-α-cubene and (−)-cubebol.[221] This was established on the basis of observation that the configuration at the stereogenic center carrying the acetate translates into the configuration of the final products, which excluded planarization of the intermediate. (−)-Cubebol was also synthesized using a similar cyclization catalyzed by Pt(II), Au(I), or Cu(I).[222] A cyclization of this type with $AuCl_3$ was used for the synthesis of 2-sesquicarene and related compounds (equation 75).[221,223]

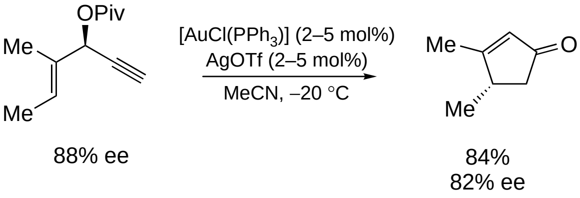


(75)

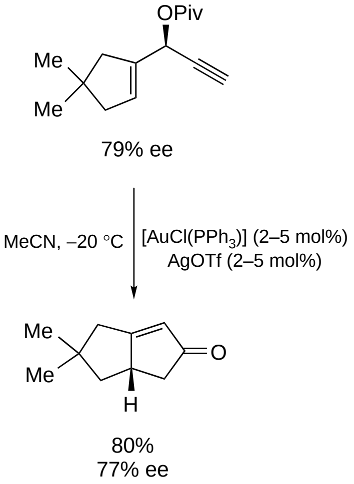
In some of these reactions, substantial loss of the enantiomeric excess was observed,[222] but for 1,4-enynes substituted at the propargylic position with a carboxylate[220] (equations 76–78), the reaction proceeds with remarkable transfer of chirality allowing the efficient enantioselective synthesis of cyclopentenones from the corresponding enantiomerically enriched propargylic pivalates. The enantioselectivity can be explained by a remarkable center to helix chirality transfer, which was supported by DFT calculations.[224] These results indicate that the cyclization is faster than rates of helix interconversion and carboxylate rotation.[224]



(76)

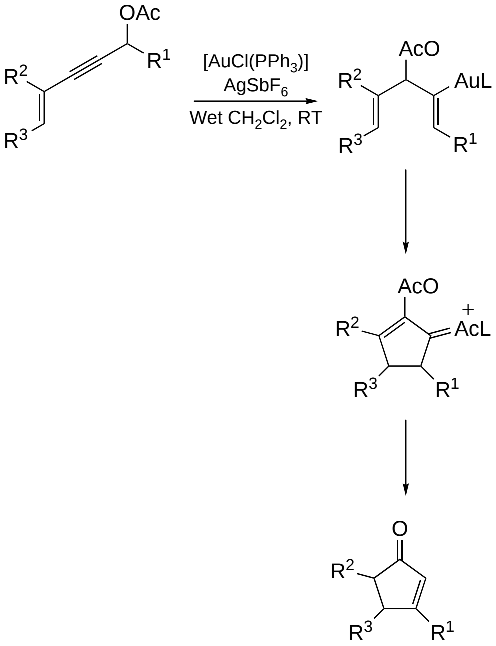


(77)



(78)

A synthesis of cyclopentenones somewhat related to those shown earlier was found from conjugated 1,3-enynes (equation 79).[225] Cyclopentenones are obtained by the hydrolysis of the enol acetates. This transformation involves a 1,3-migration of the acetate to form pentadienyl cation and the formation of the gold carbene after a Nazarov-type cyclization. DFT calculations support this mechanism and provide interesting insight into the mechanism of the final stages of the process.[116]



(79)

Propargylic acetates in equation (80) react differently in a process that also takes place via a 1,3-acyl migration.[226] Thus, the reaction of such substrates gives bicyclo[3.1.0]hexenes, which can be transformed into cyclohexenones on treatment with K_2CO_3 in MeOH. As shown in equation (81),

the reaction takes place with nearly complete transfer of the stereochemical information via the allene-gold complexes.

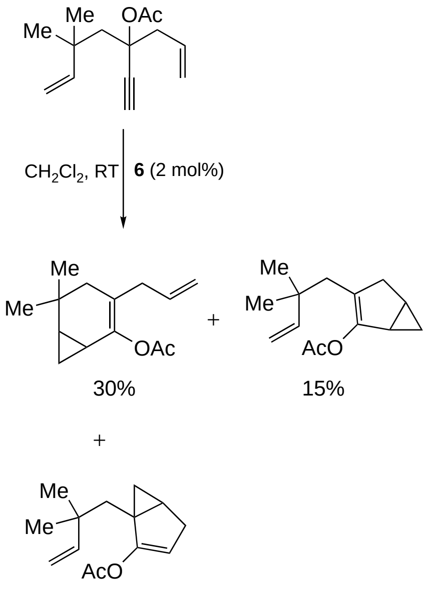
92%
90% ee

(81)

An interesting cyclization of the allyl-homoallyl-propargylic acetate in equation (82) has been shown to afford a mixture of three compounds by using an Au(I) complex with an NHC as ligand.[227] The first product is that expected from a 1,6-enyne cyclization, whereas the formation of the other two products by cyclization of the 1,5-enyne suggests that alternative mechanisms take place in this case.



(82)

The cyclization of other propargylic acetates as in equations (83) and (84) gives tricyclic derivatives with high stereoselectivity by an endocyclic pathway.[174] In the cyclization of this type of substrates, better yields were usually obtained with $PtCl_2$ or $AuCl_3$ as catalysts. Remarkably, the cyclization in equation (83) is an example of a cyclization of a 1,8-enyne, although mechanistically it could be interpreted as an intramolecular cyclopropanation of the terminal alkene by the gold carbene formed in a 1,2-acyl migration.

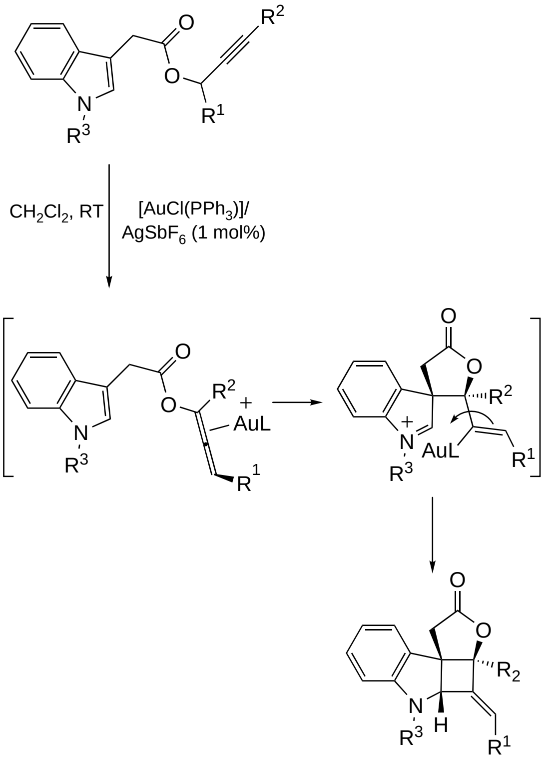
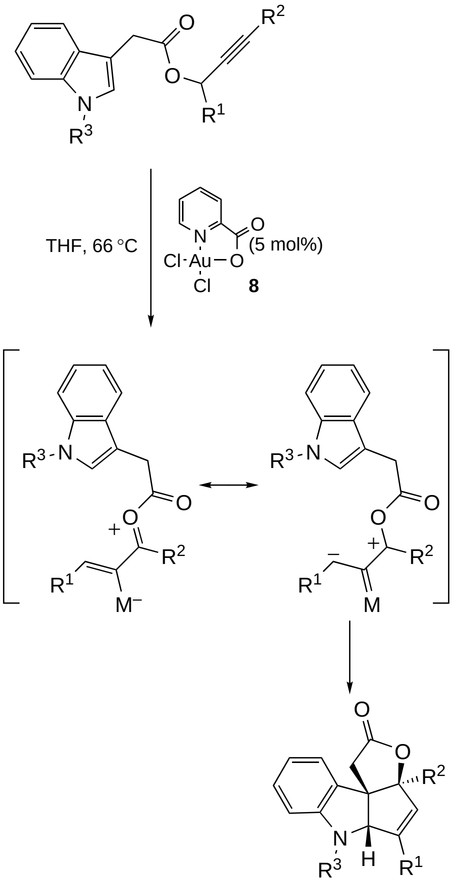
3.1 Cycloisomerizations of Related Substrates Proceeding via 1,2- or 1,3-Acyl Migration

An interesting transformation involving the indole nucleus was found from propargylic carboxylates to give tetracyclic compounds with Au(I) (equation 85).[228] This reaction proceeds by an allene-gold complex in equilibrium with the alkenyl-gold species, which reacts intramolecularly with the indole to form the product. When the reaction of these substrates is performed with dichloro(pyridine-2-carboxylato)gold(III) or Pt(II) as catalysts, products in equation (86) are obtained instead.[229] This new reactivity can be explained by a formal [3 + 2] cycloaddition of 1,3-dipole

intermediates with the indole nucleus (equation 86).

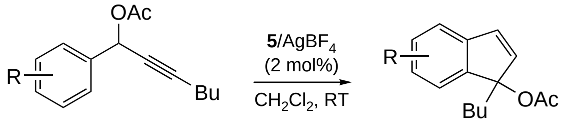


(85)



(86)

The acyl migration of benzylic acetates was also applied for the synthesis of indenes (equation 87).[230] Isomeric indenes were also obtained as minor products. The transformation was actually shown to proceed via allenes, which could be independently prepared by Ag(I)-catalyzed 1,3-acetate migration from the same starting materials. Propargylic sulfides and dithioacetals undergo similar transformations as propargylic carboxylates to give indene derivatives with Au(I) or Au(III) catalysts.[153]



(87)

A different type of 1,3-acyl migration occurs from homoallyl acetates (equation 88).[231] In this case, upon coordination of the alkyne with Au(III) and migration of the acetate, a zwitterionic species is probably formed and collapses to afford the final product.

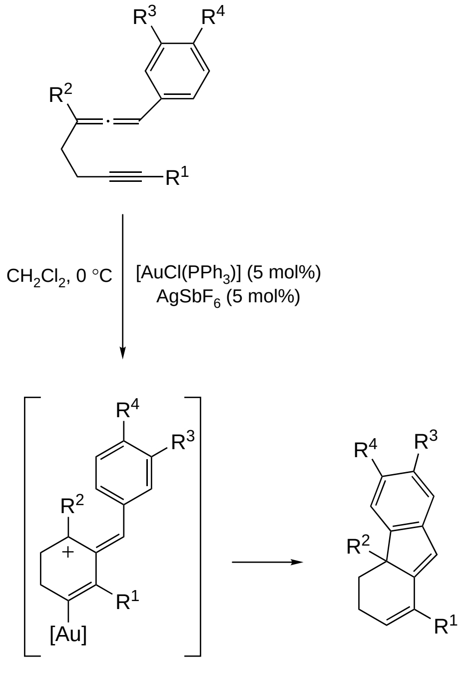
4 ALLENYNES

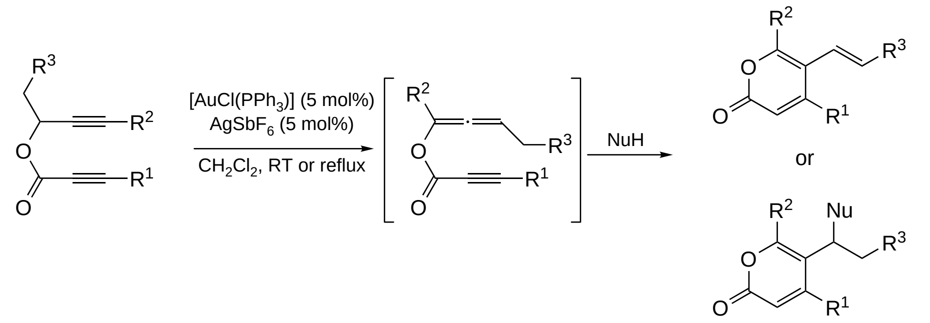
Very recently, the cyclizations of allenynes have been described.[179,206,207] It has already been pointed out that gold

species can coordinate allenes as well as alkynes. In the reactions of substrates where both functionalities are present, it may not be clear, in principle, which would be the first moiety coordinated. Probably, as in the case of olefins, an equilibrium exists and kinetic factors determine the reaction pathway to the observed products. Those kinetic aspects are related to the higher nucleophilicity of allenes compared to alkynes and, therefore, it is not surprising to find that in the gold-catalyzed reactions of allenynes most of the mechanistic explanations involve coordination to the alkyne followed by attack of the allene.[179] This results in allyl-cation and vinyl-gold intermediates that can undergo different steps in tandem, depending on the substituents and functionalities present in the molecule. Examples can be found in the cycloisomerization of allenynes described by Malacria with concomitant Friedel–Crafts cyclization by aryl groups or the addition of alcohols like in the alkoxycyclization of enynes.[179] Liu also found a similar behavior with a different substitution pattern (equation 89).[207]



(89)

Toste observed the aromatization of the new cycle in a different type of reaction, in which the allene had been formed in situ by acyl migration of a propargyl carboxylate.[130] In a similar vein, cyclizations of diynes bearing propargyl carboxylates have been described to synthesize dienes[232] and pyrones (equation 90).[233] In the last case, a new cascade allows the intermolecular addition of electron-rich arenes.[233]



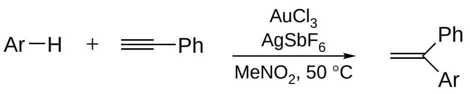
(90)

5 MECHANISTICALLY RELATED REACTIONS OF ARENES AND HETEROARENES WITH ALKYNES

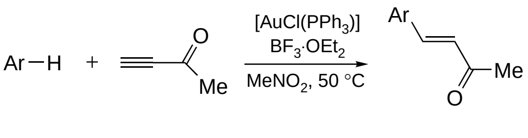
5.1 Cyclizations of Arylalkynes by Friedel–Crafts-type Processes

In general, two pathways are followed in the reactions of alkynes with arenes catalyzed by transition metals. Reaction of $[M(CO)_6]$ (M = Cr, Mo, W) and certain Ru(II) complexes with terminal alkynes or with alkynes substituted with migrating groups (SiR_3, SR, and I) may proceed via vinylidene metal complexes. On the other hand, electrophilic metal salts or complexes favor coordination to the alkyne, triggering electrophilic substitution reaction with the arene. Gold complexes generally promote reactions according to this second pathway.[234] The direct metalation (auration) of electron-rich arenes and heteroarenes is a well-known reaction,[235–239] but the resulting ArAuL complexes are apparently not involved in subsequent C–C bond-forming reactions with alkynes.

The gold-catalyzed intermolecular hydroarylation of alkynes (or alkenylation of arenes) leads to 1,1-disubstituted alkenes (equation 91).[240–243] 1,2-Disubstituted derivatives are obtained from alkynes with electron-withdrawing groups (equation 92).[244]

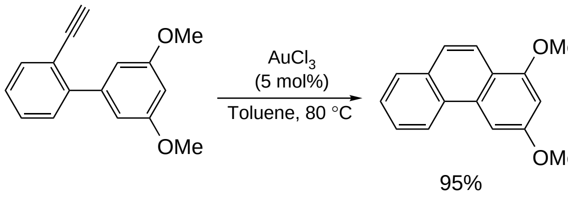


(91)

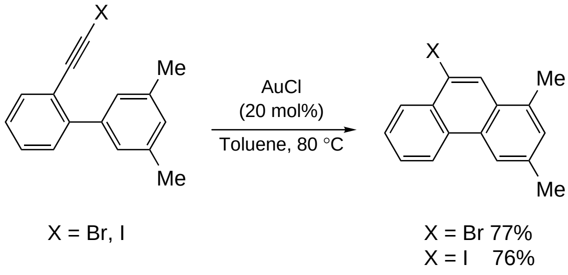


(92)

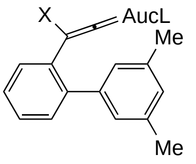
The cyclization of ortho-alkynylated biphenyl derivatives in equation (93) with Au(III) and other metal catalysts proceeds preferentially by the endo pathway leading to phenanthrenes.[245–247] Interestingly, the analogous haloalkynes in equation (94) react with AuCl to give phenanthrenes in which the halide has suffered a 1,2-shift. In contrast, the reaction of those substrates with the stoichiometric amount of $InCl_3$ gives the corresponding phenanthrenes with halide retention. These results suggest that in these cases the cyclization proceeds via gold vinylidene species, which is supported by DFT calculations for the cyclization catalyzed by AuCl.[248] Gold–vinylidene species were also suggested as intermediates in some gold(I)-catalyzed cyclizations of 1-alkynyl-2-alkenylbenzenes to form naphthalenes,[182] as well as in the reaction of 2-(prop-2-ynyl)pyridines form indolizines.[249]



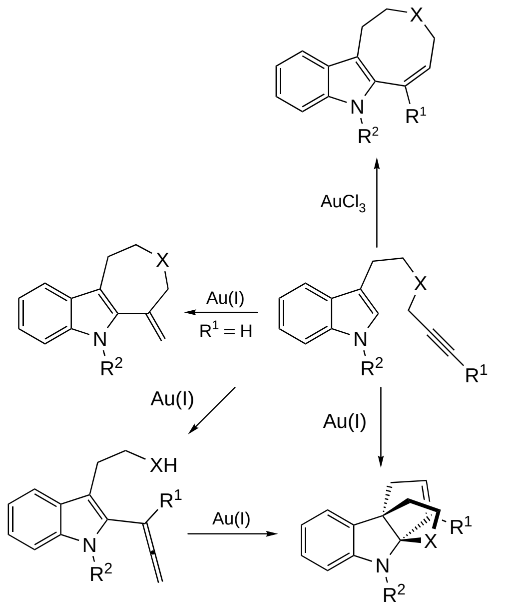
(93)



(94)



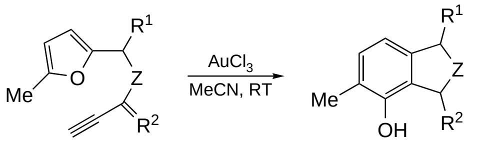
The reaction of substituted indoles with alkynes catalyzed by Au(I) or Au(III) leads to seven- and eight-membered rings, respectively (equation 95).[28,29] Eight-membered ring derivatives are formed in an 8-endo–dig process, a type of cyclization that has not been observed in other hydroarylations of alkynes or cyclizations of enynes. Allenes and tetracyclic compounds could also be obtained. The isolation of spiro derivatives in one of the cyclization reactions suggests that cyclizations of indoles catalyzed by gold(I) can take place by first forming a C–C bond at C–3 followed by a 1,2-migration to give the final indoles. The gold(I)-catalyzed intermolecular reaction of indoles with alkynes also takes place.[29]



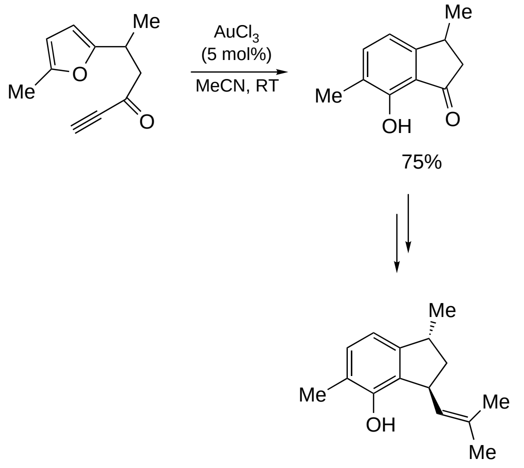
(95)

5.2 Reactions of Furans with Alkynes

In contrast to the usual Friedel–Crafts-like cyclizations of arenes with alkynes, alkynyl furans afford phenols in good to excellent yields by using $AuCl_3$ as catalyst (equation 96).[250–256] Au(I),[257] heterogeneous gold,[258] and Pt(II)[259,260] can also be used as catalysts. Phenols bearing bulky groups at the ortho position can also be prepared by this method.[261] In addition, the gold-catalyzed Michael addition of furans to ethynyl vinyl ketones gives substrates[262–264] that can undergo in situ cyclization leading to hydroxyindanones in a domino process (equation 97).[263] A synthesis of sesquiterpene jungianol, together with its cis isomer, illustrates the application of this phenol synthesis (equation 97).[253]



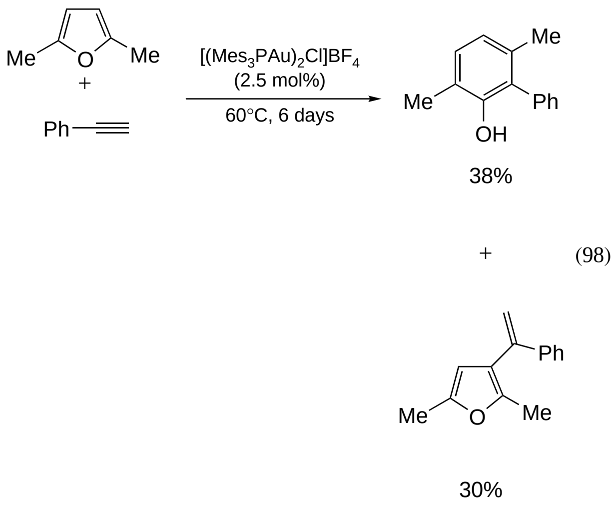
(96)



(97)

Experimental and theoretical studies on gold- and platinum-catalyzed reactions[41,251,254] explained the mechanism of this phenol synthesis. Oxepines and arene oxides have been observed in the reaction catalyzed by Au(III).[254,265]

Although proceeding in moderate yield and in the absence of solvent, the formation of phenols in the intermolecular reaction of 2,5-dimethylfuran with phenylacetylene is remarkable (equation 98).[244,266] This reaction required the use of the Schmidbaur–Bayler salt $[(Mes_3PAu)_2Cl]BF_4$ as Au(I) catalyst,[267] and also provided the product of a Friedel–Crafts-type process, the furan in equation (98).



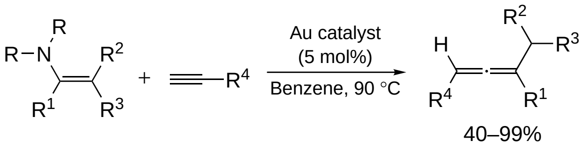
(98)

6 ALLENES

Like alkynes, allenes are electron-rich π-systems that can coordinate Au species. Their higher reactivity compared to olefins makes them better substrates and accounts for the fact that additions to allenes have been more widely studied.

The performance of allenes is similar to alkynes in the presence of gold complexes and, in fact, many of the reactions of propargyl esters presumably proceed through allenyl intermediates. It means that gold catalyzes the propargyl–allenyl isomerization and that the coordinated allene–gold complexes are electrophilic species, as previously described for the alkyne-gold ones. It is easy to predict then that the variety of nucleophiles that have been added to alkynes may attack allenes as well,[268] but the number of references is much lower so far. In any case, the axial chirality of allenes is a factor to consider both as a drawback when mixtures of products are obtained and as an advantage when that chirality can be transferred to the products.

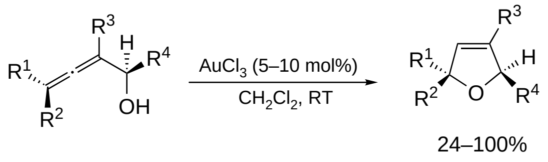
As for the alkynes, the reactions here are arranged by the nature of the nucleophile. Thus heteronucleophiles, mainly nitrogen- and oxygen-based, and carbon nucleophiles are discussed. However, first of all, a gold-catalyzed enantioselective synthesis of axially chiral allenes will be accounted, although it is not an allene activation. It was first discovered by Bertrand in 2007 that enamines and alkynes can be coupled with gold to obtain allenes in a process in which the terminal alkyne and the enamine react by an acid–base equilibrium to form an acetylide and an iminium cation that give propargylamines (equation 99). This species then evolves to an allene.[46] Wong and Che later reported the chirality transfer from the amine to the allene starting from chiral propargylamines.[269]



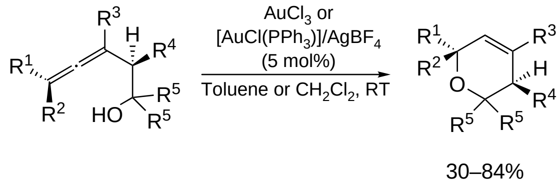
(99)

6.1 Heteronucleophiles

The gold-catalyzed addition of alcohols to allenes was first described in 2001 as an intramolecular reaction of α-hydroxyallenes to yield dihydrofurans with $AuCl_3$ as the catalyst (equation 100).[270] The analogous cyclization of hydroxy–allenamides has been reported later.[271] A study of the stability of $AuCl_3$ in these reactions showed evidence of the involvement of vinyl–gold species in the reaction mechanism.[272] The regioselectivity in the nucleophilic attack was modified by changing the length of the tether and thus β-hydroxyallenes afforded dihydropyrans (equation 101),[273] γ-hydroallenes gave vinyl–tetrahydrofurans,[274] and δ-hydroxyallenes gave vinyl–tetrahydropyrans.[275,276]

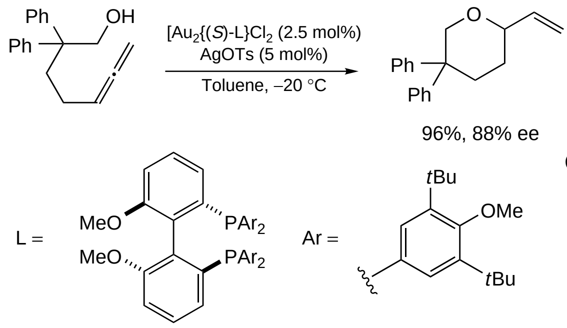


(100)

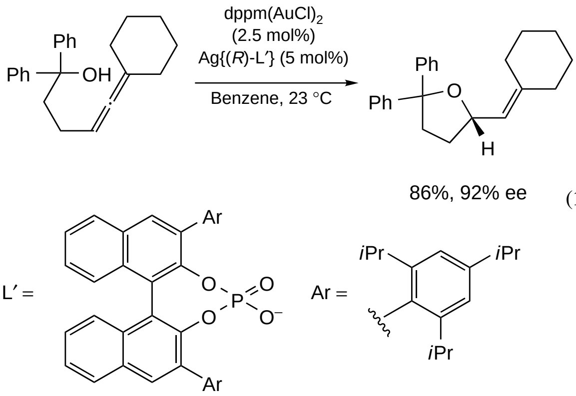


(101)

Enantioselective versions of this reaction have been recently developed with achiral substrates. Two different strategies have been applied to obtain an effective chiral catalyst for that purpose: the usual chiral phosphine ligand (equation 102)[276] and the novel employment of a chiral counterion of the metal catalyst as the source of chirality (equation 103).[277]

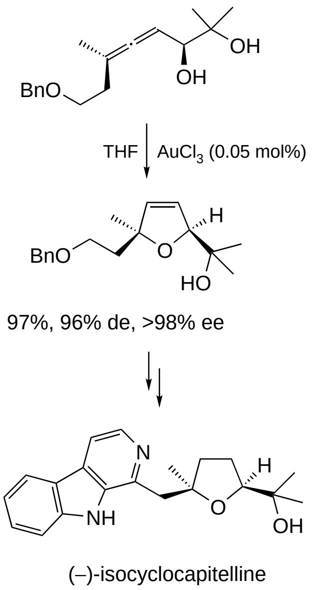


(102)



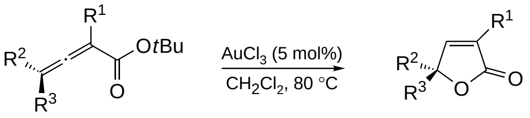
(103)

Examples of these alkoxycyclizations have been applied by Krause to the synthesis of the alkaloids (−)-isochrysotricine and (−)-isocyclocapitelline (equation 104)[278] and furanomycin derivatives.[279]

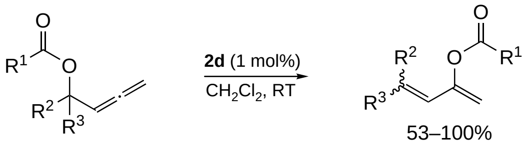


(104)

Carbonyl compounds also react with allenes and, in fact, the first example of a gold-catalyzed addition of a nucleophile to allenes was the formation of furans from allenones.[280] The reaction was applied by Gevorgyan to the synthesis of substituted furans[281] and in the case of bromide-substituted allenes halide migration was observed.[282] Similar additions of carbonyls from esters have been studied as well (equations 105 and 106), with protocols that have been improved from $AuCl_3$ at 80 °C[283] and $AuCl_3$/3AgOTf in AcOH at 70 °C[284] to the use at room temperature of biphenylphosphine-based cationic Au(I) catalysts.[285]

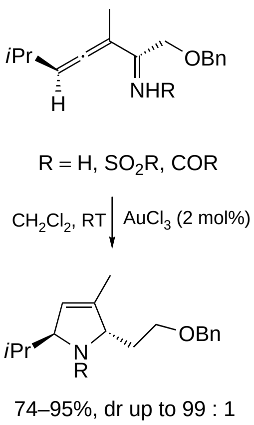


(105)

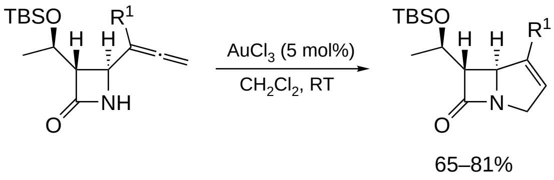


(106)

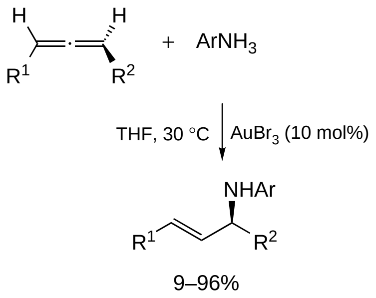
Gold-catalyzed hydroamination of allenes[286] has been the object of study of several research groups. The first report by Krause illustrated the formation of 3-pyrrolines from either protected or unprotected α-aminoallenes.[287] Allene-α-substituted acetamides, sulfonamides, carbamates, free amines,[287] and lactams[288,289] undergo the intramolecular hydroamination, giving in all these cases the corresponding five-membered rings (equations 107 and 108). The regioselectivity followed the same pattern as in the additions of alcohols, being dependent on the number of carbons between the nitrogen and the allene.[290] The intermolecular hydroamination was achieved with anilines (equation 109)[291] and even with an aliphatic amine.[292] The complete transfer of chirality to the products was observed to be effective when unprotected amines were used, but some loss occurred in protected substrates.[293]



(107)

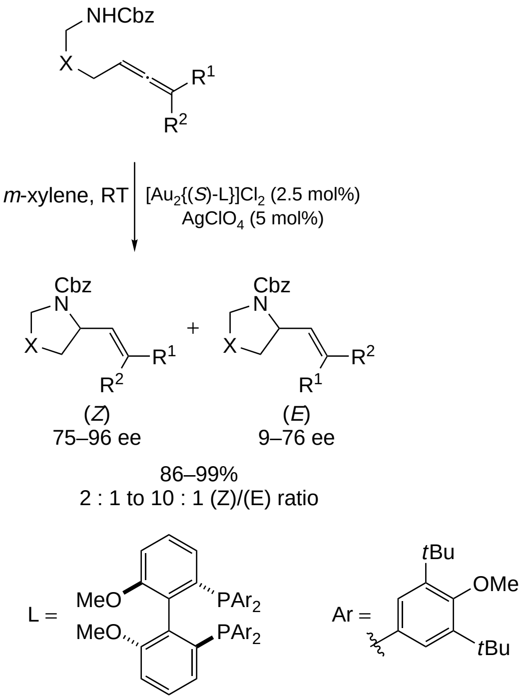


(108)



(109)

The enantioselective hydroaminations of allenes with chiral phosphine catalysts was accomplished with substrates that had a terminal symmetric substitution and with the amines protected as carbamates[294] or sulfonamides.[295] The same symmetric substituents were necessary for the enantioselective transformation using chiral counterions.[277] However, very recently, high enantiomeric excesses were reached with trisubstituted asymmetric allenes by a dynamic kinetic enantioselective hydroamination of allenyl carbamates (equation 110),[296] even though the E/Z ratio of the products was not optimal.



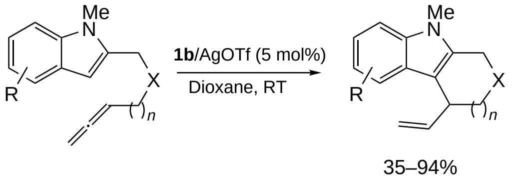
(110)

For sulfur nucleophiles, the intramolecular gold-catalyzed hydrothiolation of allenes was described in 2006. α-Thioallenes led to the formation of 2,5-dihydrothiophenes in moderate to good yields and with complete stereoselectivity.[297]

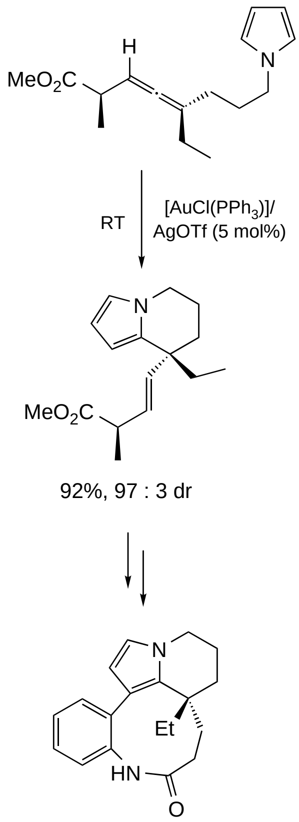
6.2 Carbon Nucleophiles

It is noteworthy that most of the examples in this section correspond to papers that appeared in 2007, which is an evidence of the great boost and potential of these transformations.

The first carbon addition to allenes catalyzed by gold was described by Hashmi and was the addition of furans to allenones,[280] a reaction that is discussed as a conjugate addition to carbonyls. Then the annulation of 2-allenyl indoles was described (equation 111),[275] and an enantioselective version was later developed for terminal allenes.[298] Then Nelson described the cyclization of an N-substituted pyrrol in the synthesis of (−)-Rhazinilam (equation 112).[299] In that case, gold notably improved the yields and selectivities obtained with Pd(II) or Ag(I), and gave complete retention of the chiral information of the allene. The most recent report is on the hydroarylations of allenes with gold-covered substituted benzenes as substrates.[300]



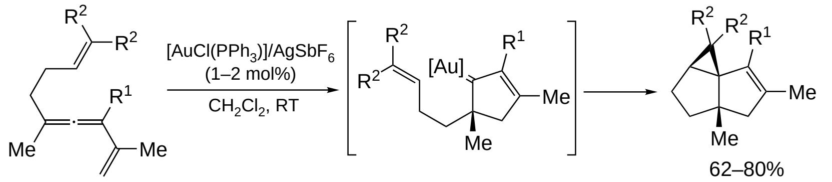
(111)



(–)-rhazinilam

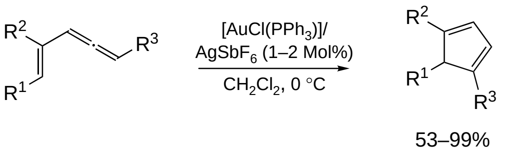
(112)

Double bonds of enynes act as nucleophiles and for ene-allenes perform similarly. Actually, some of the reactions of enynes with propargylic carboxylate substitution may

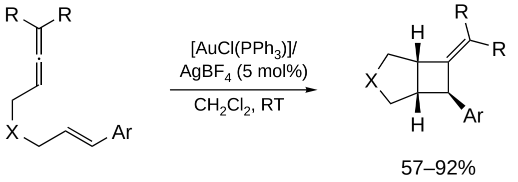


(117)

be considered reactions of allenes since, in most of them, the isomerization occurs prior to the alkene attack. The first report showed the endo cyclization of vinyl–allenes to cyclopentadienes (equation 113).[301] The introduction of more carbon atoms between the allene and the olefin gave different results depending on the allene substitution. In γ-vinyl-allenes, cyclohexenes were obtained by exo cyclizations with low to moderate enantiomeric excesses induced by a chiral phosphine ligand if terminal allenes were used.[302] However, with substitution on the allene, the vinyl–gold species generated after the initial exo-cyclized product was trapped intramolecularly leading to methylenecyclobutane structures (equation 114).[303]

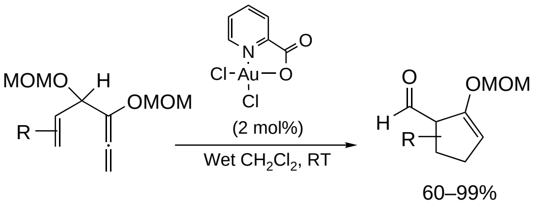


(113)

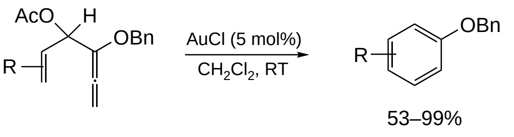


(114)

Other tandem cyclizations have been reported: in the simplest one, a semipinacol ring contraction takes place over the cationic intermediate (equation 115).[304] By changing the protecting groups of the alcohols, the rearrangement does not take place and elimination favors the formation of benzenes (equation 116).[305] The evolution to gold carbenes is also possible (equation 117): in a cyclization of dieneallenes, the isomerization to a gold carbene of the allyl–gold cation, obtained after the attack to the allene, is responsible for the cyclopropanation of the second olefin.[306]



(115)



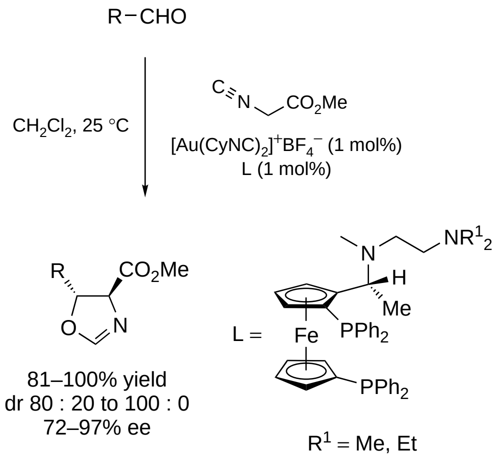
(116)

7 CARBONYL ACTIVATION

7.1 1,2-Additions to Carbonyls and Imines

The Lewis acidity of gold, related to relativistic effects,[11] allows not only the coordination to carbon π-systems but also other functional groups. Among them, the most exploited field is the activation of carbonyls and imines toward different nucleophiles. In these cases, Au(III) species are many times the catalysts of choice over Au(I). An explanation for this may be found in the thermodynamic coordination preference of $AuCl_3$ for aldehydes over other moieties such as alkynes,[11] accounting for the functional group discrimination in these reactions. Nevertheless, Au(I) is still used in some of the transformations described in this section.

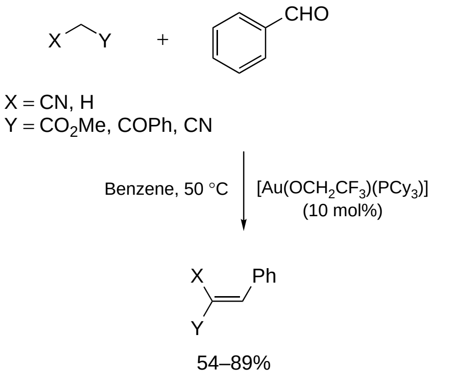
The first reported gold-catalyzed carbonyl activation was, unexpectedly, an asymmetric Au(I)-catalyzed aldol-type reaction in which the enolate of an isocyanoacetate reacted with aldehydes (equation 118) using a cationic gold species generated in situ by ligand displacement.[307] The asymmetric induction was achieved by a secondary interaction of the enolate with a side amino group of the chiral ferrocenyldiphosphine ligand employed, producing oxazolines in high yields and enantiomeric excesses, that were subsequently opened to the corresponding amino alcohols. This methodology was later extended by the authors to α-isocyano Weinreb amides to facilitate the further transformation of the products to aminoaldehydes and aminoacids.[308]



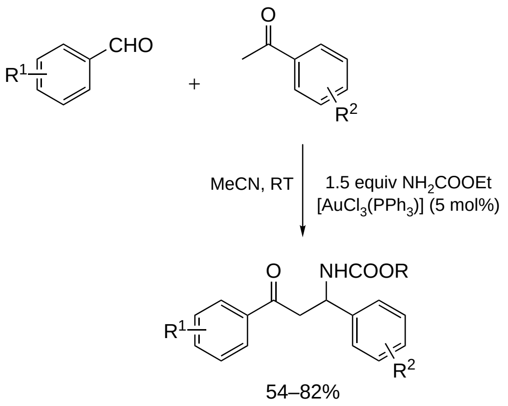
(118)

It is interesting to note that although this was one of the first gold-catalyzed reactions, and despite the great boost in the last few years, gold asymmetric catalysis is still an underdeveloped field.

However, a variety of reactions regarding carbonyl and imine activation by gold have been described. In fact, the formation of imines and enamines from carbonyls is catalyzed by gold species as was shown by Arcadi in the first step of a synthesis of pyridines.[184] Both carbonyl groups and imines can coordinate to gold as a Lewis acid, thus promoting the attack of other nucleophiles present in the reaction medium. The initial examples reported, followed the way outlined by Ito and consisted of gold(I)-alkoxide-catalyzed Knoevenagel condensations with benzaldehyde[309] to give products depicted in equation (119). In this case, Au(I) species showed a higher catalytic activity than those of Au(III). By contrast, Au(III) is preferred in a different case where benzaldimines, formed in situ from benzaldehydes and carbamates, undergo a three-component Mannich-type reaction with acetophenones (equation 120).[310]

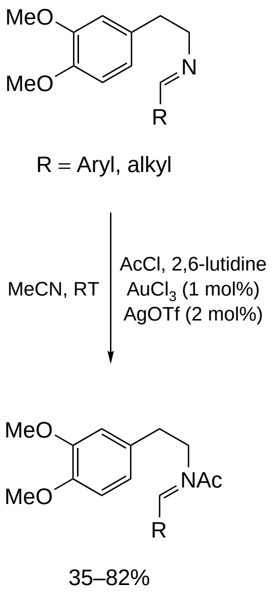


(119)

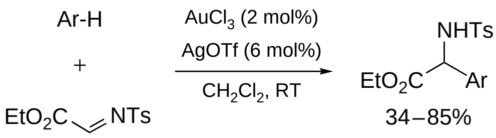


(120)

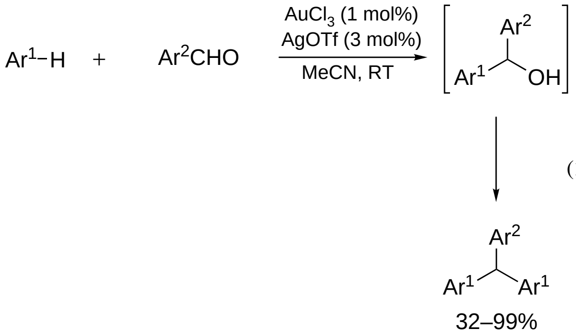
Electron-rich arenes are suitable nucleophiles for this reaction as well. Thus, the addition of arenes to imines has been described in both intra- (equation 121)[311] and intermolecular (equation 122)[312] fashion catalyzed by $AuCl_3$/AgOTf. The yields were increased in the intramolecular version by acylation of the amide intermediate to give acylamides. In the case of addition of electron-rich arenes to carbonyls,[313] a second addition takes place by activation of the benzylic alcohol intermediate (equation 123), a process that is later discussed, to yield products of the type shown in equation (123).



(121)



(122)

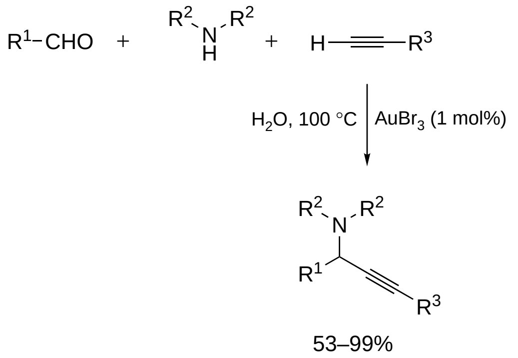


(123)

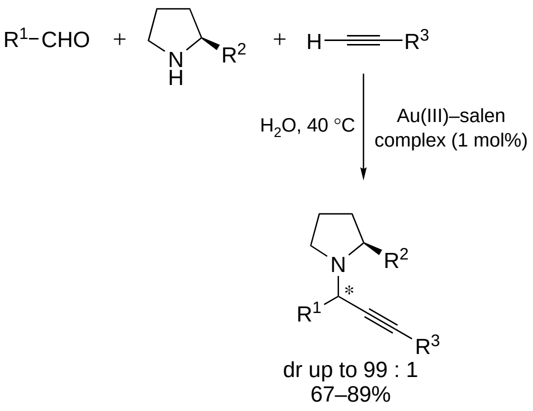
Recently, an intramolecular 1,2-addition to conjugated carbonyls by internal olefins has been reported, in tandem with other nucleophilic addition to the carbocation formed.[314]

Other nucleophiles that have been used in this context are acetylides (alkynes). The addition of those to iminium cations generated in situ from aldehydes and secondary amines accomplishes a gold(III)-catalyzed three-component coupling for the synthesis of propargylamines, as can be observed in equation (124).[315,316] The reactions are performed in water or in tetrahydrofuran (THF) when supported catalysts are employed.[317] Chiral prolinol derivatives as

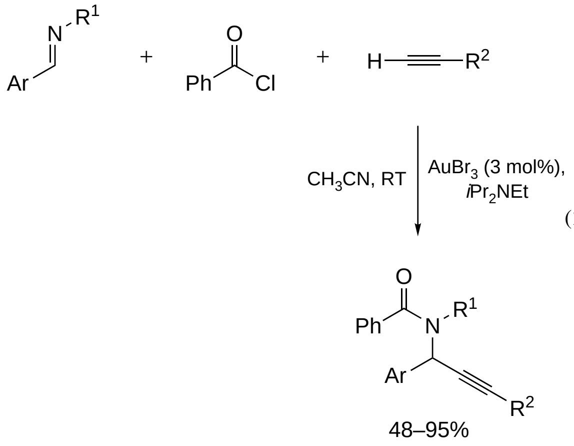
the amine have been applied to a diastereoselective synthesis of propargylamines using Au(III)–salen complexes (equation 125).[318] When primary amines were used, the reactions did not take place[315] but, instead, if the corresponding imines are preformed (equation 126), the alkyne addition can be done by means of an acyliminium, yielding propargylamides.[319]



(124)

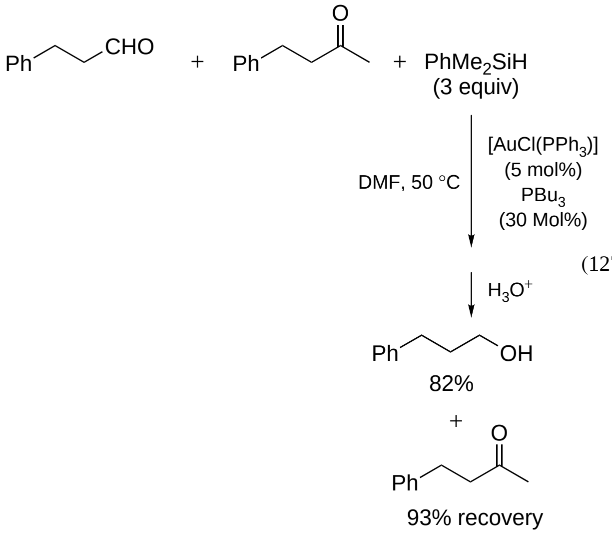


(125)

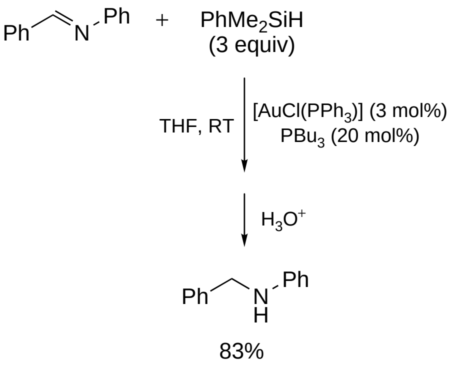


(126)

The last of the nucleophiles discussed in this section is hydride. Aldehyde (equation 127) and aldimine (equation 128) hydrosilylations have been shown to be gold-catalyzed reactions[320,321] and selective over ketones. In these cases, the addition of 20 mol% of PBu_3 is crucial to stabilize the gold(I) catalyst in the reductive medium. After the catalysis step, acidic treatment led to the formation of the alcohols and amines in good yields. In a similar context, a gold-catalyzed hydroboration of imines has been reported.[322]



(127)

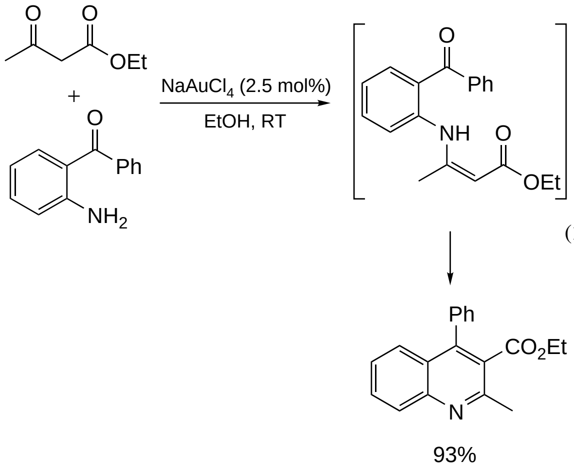


(128)

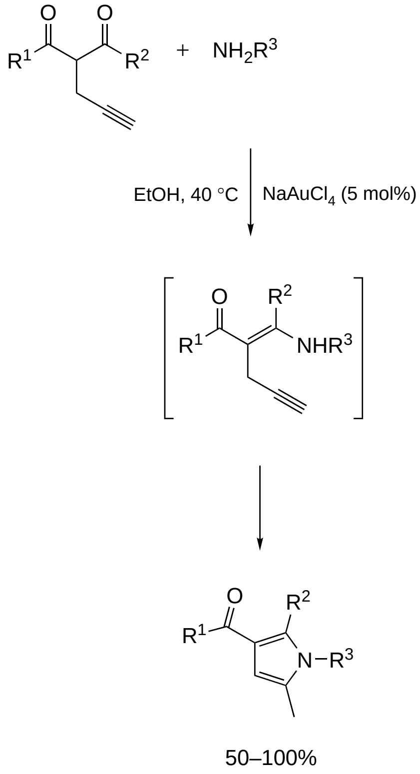
7.2 Additions to 1,3-Dicarbonyl Compounds

When the activated carbonyl is a 1,3-dicarbonyl compound, some tandem reactions have been described.

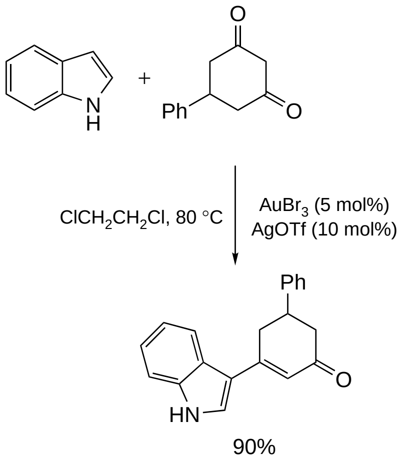
In the simplest of these, β-enaminones are synthesized (equation 129) by the addition of amines to 1,3-diketones or β-ketoesters.[323] The reaction has been applied to the Friedländer synthesis of quinolines by condensation of the enaminone and other carbonyl present in the substrate.[324] Substituted pyrroles in equation (130) can be obtained as well when a propargyl group is present, by addition of the enaminone to the triple bond.[139,325] Alcohols, thiols, and secondary phosphines have been also tested as nucleophiles with good results.[323] A particularly interesting case is found in the condensation of indoles with 1,3-diketones to give substituted indol derivatives in equation (131).[326]



(129)



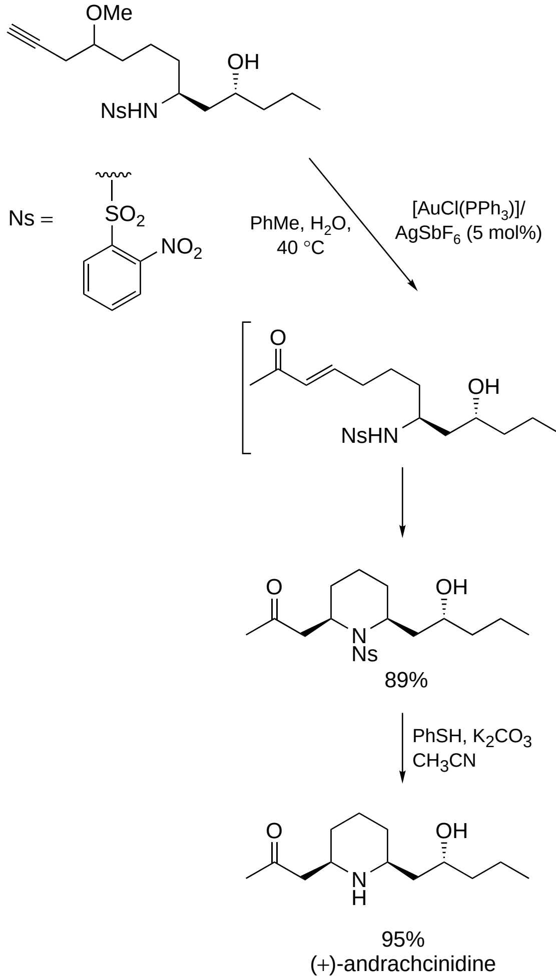
(130)



(131)

7.3 1,4-Additions

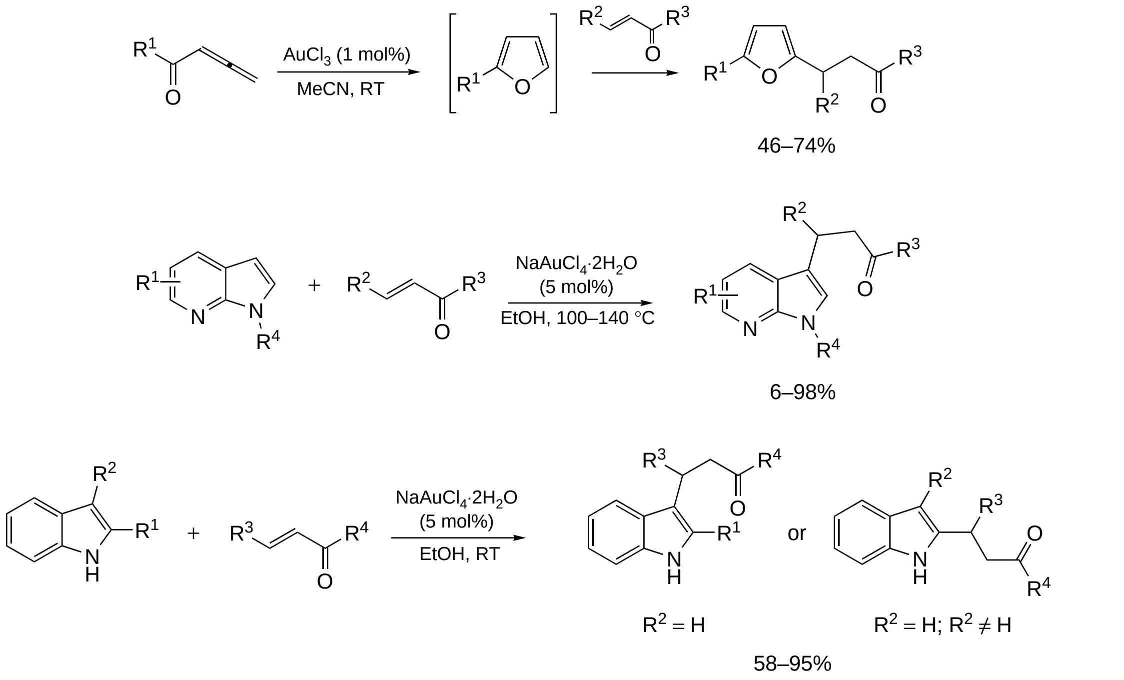
Michael additions to conjugated carbonyls can be catalyzed by gold species. Among them, arene additions are the most studied area but other nucleophiles can attack the gold-coordinated enones as well. In fact, the intermolecular aza-Michael additions of carbamates to enones[327] was reported in 2002 with both Au(I) and Au(III) salts, and in 2007 an intramolecular alkoxide and amide conjugate addition has been developed[70] and applied to the synthesis of (+)-andrachcinidine[70] (equation 132). In the latter case, the enones are formed as intermediates in a previous gold-catalyzed step that is the hydration of an alkyne and methanol loss. Then the cyclization takes place to give piperidines.



(132)

Yet the reaction that attracted more interest has been the conjugate addition of arenes. It was first described by Hashmi in 2000 that enones and furans could react in the presence of $AuCl_3$.[280] In the reported cases, furans were also formed by a gold-catalyzed reaction of allenones (equation 133). Electron-rich substituted benzenes also underwent 1,4-addition with Michael acceptors.[241,264] Later, 7-azaindoles (equation 134)[328] were shown to provide 3-alkylated derivatives. On the other hand, indoles (equation 135)[329] reacted selectively

with enones to give the 2- or 3-substituted derivatives, depending on the substitution pattern of the starting material. Reaction of indoles with enals gave mixtures of 1,2- and 1,4-addition products.[330] Pyrroles have also been submitted to the reaction conditions, but afforded mixtures of disubstituted or trisubstituted compounds in nonselective reactions.[331]



(133)

(134)

(135)

The last examples included in this section are dipolar cycloadditions with dipolarophiles that are conjugated carbonyls. The first one is the 1,3-dipolar cycloaddition of nitrones with methyl acrylate.[332] The reaction is supposed to be catalyzed by both Au(I) and Au(III) species and experiments that discarded the coordination of gold to the nitrone were performed, which may support a carbonyl–Au mechanism, although it still remains elusive. More recently, the enantioselective cycloaddition of münchnones to acrylates catalyzed by a chiral catalyst has been developed.[333]

7.4 Other Processes

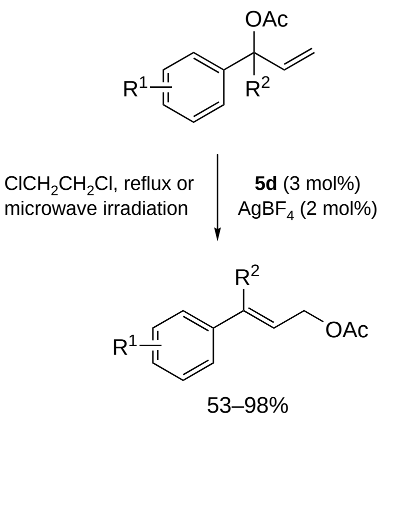
Examples of gold-catalyzed carbonylation of amines and olefins exist related to the activation of carbonyl. The first case involves the formation of carbamates from anilines and CO in the presence of alcohols[334] or the production of acetamides from aliphatic amines.[335] In these examples, Au(I) (usually [AuCl(PPh_3)]) catalysts are preferred. For the carbonylation of olefins, gold(I)–carbonyls are prepared in situ in sulfuric acid media to afford carboxylic acids.[336]

8 ALCOHOL ACTIVATION

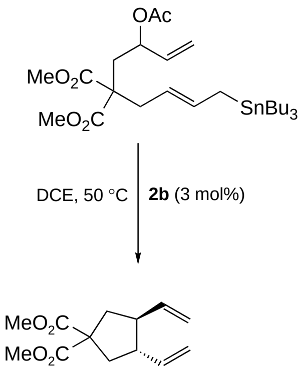
8.1 Substitutions

Allylic carboxylates also react with gold catalysts. These reactions are formally carbonyl activations, but the products observed are closely related to the reactivity shown by allylic or benzylic alcohols that will be discussed in this section. The first examples show an allylic rearrangement to styrenes (equation 136).[337] Nucleophiles such as allyl stannanes have also been added to give substitution reactions and products of intramolecular coupling (equation 137).[338]

The activation of alcohols by gold has just started to be studied in the last few years and is an emerging field in the area. The closest examples to the ones showed for the acetates are the

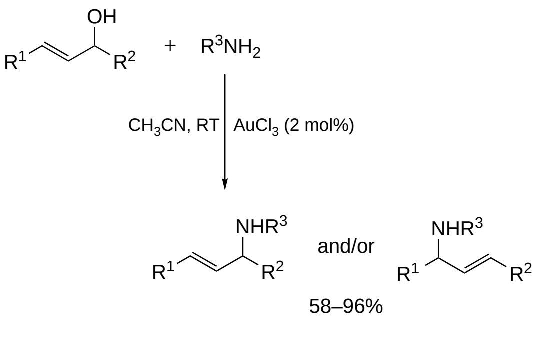


(136)

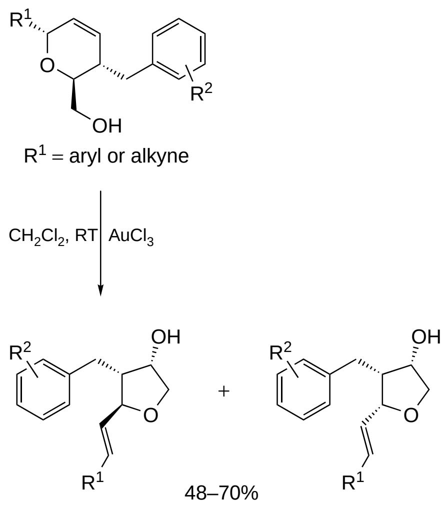


(137)

amination of allylic alcohols and the substitution of benzylic alcohols that was previously outlined. In the first case, anilines and tosylamides act as nucleophiles for the substitution of alcohols (equation 138),[339,340] probably coordinated to gold to increase their leaving ability, yielding amination products. However, the first alcohol substitution was described on propargyl alcohols and different nucleophiles in 2005.[65] In a very recent example, allylsilanes have been used for the substitution of benzylic ethers.[341] Another related example is the isomerization of hydroxyl−allylic ethers described by Porco and Schaus[342] in which a ring contraction takes place by the activation of allyl−propargylic or allyl−benzylic alcohols (equation 139).

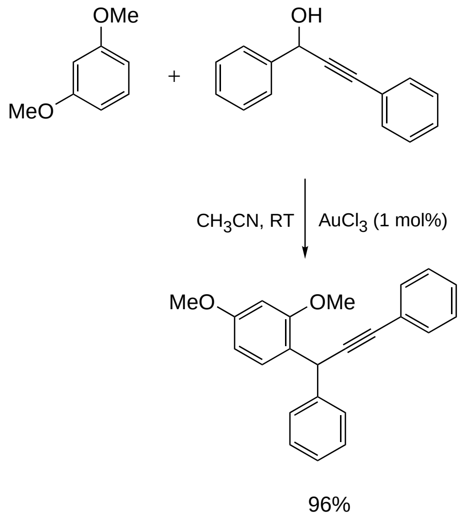


(138)

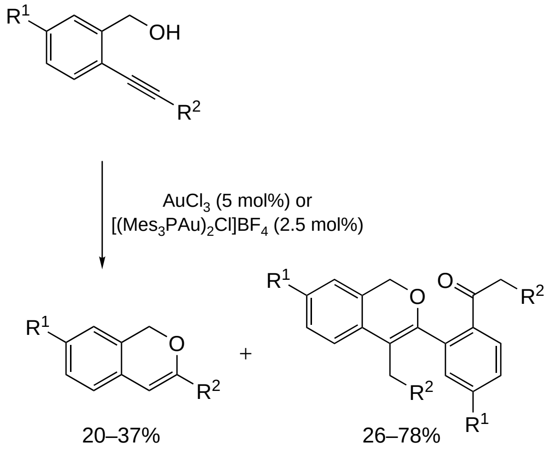


(139)

When benzylic alcohols are the substrates, arenes behave as nucleophiles,[343] as shown in equation (123)[313] and for the analogs in the 1,4-addition.[330] These reactions have been performed with alcohols that are activated by an arene substituent and another group that could be an olefin, an alkyne, or other arene (equation 140). In the case of dimerization reported by Hashmi (equation 141), primary benzylic alcohols[344] produce dimers of the type in equation (141) that arise from the activation of this moiety, together with the expected cyclization products. In a very recently reported example, aryl−alkyl ethers are obtained by reaction with $NaAuCl_4$.[345]



(140)



(141)

A different example of gold-catalyzed alcohol activation is the silylation of primary alcohols. In this reaction, aliphatic, allylic, and benzylic primary alcohols undergo silylation with an Au(I)−xantphos chelated complex.[346]

Other related reactions are the substitutions of aliphatic sulfonate esters by arenes[238] and the epoxide-opening with benzenes[237] catalyzed by gold. In both cases, the aryl groups are the nucleophiles that attack the gold-coordinated sulfonate esters or epoxides, respectively.

8.2 Oxidations

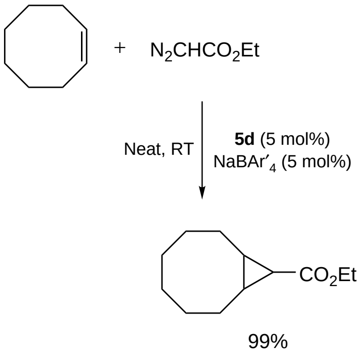
The gold-catalyzed oxidation of alcohols is a less-explored field. In one example, oxygen was used as the oxidant and the authors take advantage of the coordination of benzylic alcohols to an Au(I)-complex generated in situ from AuCl and a diamine anionic ligand.[347]

The rest of the examples of gold-catalyzed homogeneous oxidations are conversions of sulfides to sulfoxides. The early examples by Gasparrini were published in 1983 and 1984 and were reactions in nitric acid under phase-transfer conditions.[348,349] The Au(III) catalysts used were later optimized to tetrabutylammonium tetrabromoaurate.[350] These results were improved by the discovery of a milder method that oxidizes sulfides under ambient conditions with O_2.[351] In this latter case, $HAuCl_4$ and $AgNO_3$ were combined in MeCN to form an $AuCl_2NO_3$(thioether) species that is the active homogeneous catalyst. Recently, the gold-catalyzed oxidation of sulfides with H_2O_2 at room temperature has been reported and complements the previous one.[352]

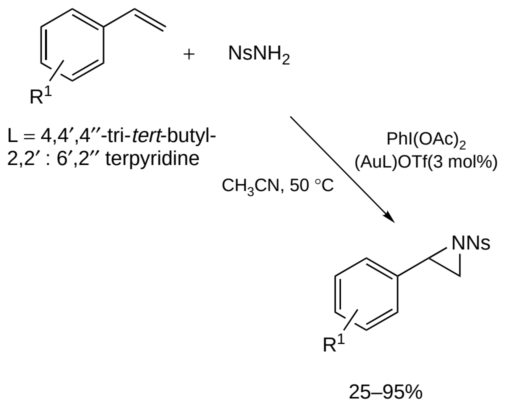
9 OLEFIN ACTIVATION

The coordination of olefins to gold species is well known, despite the preference for alkynes, allenes, and carbonyl groups. This is reflected in the fact that synthetic applications based on olefin activation by gold have been developed to a lesser extent than alkyne or carbonyl activation.

The easiest reactions are those in which the nucleophile is the gold-activated species. Examples of this are Au(I)-catalyzed carbene[122] and nitrene[239] transfers (equations 142 and 143) that convert olefins into cyclopropanes or aziridines, respectively. In the carbene transfer, ethyl diazoacetate is the source of carbene and the active NHC–gold cationic catalyst is generated by chloride abstraction with sodium tetrakis(3,5-bis(trifluoromethyl)phenyl)borate $NaBAr'_4$. The cyclopropanation is competitive with other carbene insertions with active C–H or N–H bonds present in the substrate. For the aziridinations of olefins, nitrene formation is accomplished by the oxidation of sulfonamides with $PhI(OAc)_2$ and the catalyst of choice is a gold-(I) triflate with a terpyridine ligand.

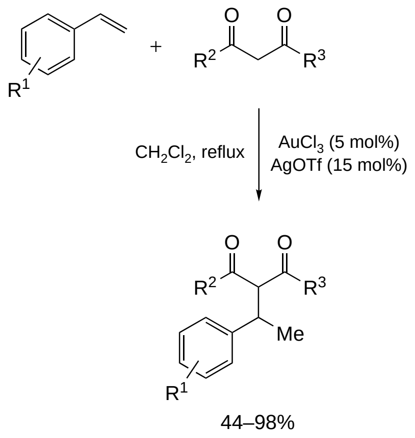


(142)

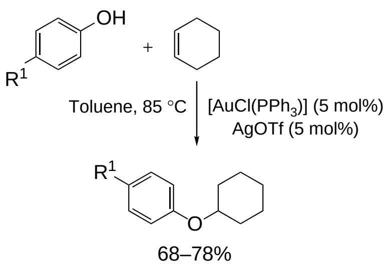


(143)

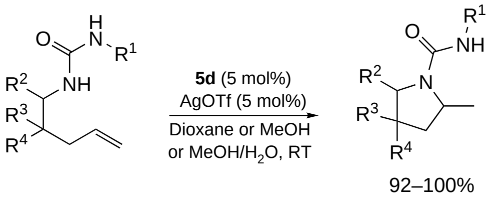
Apart from these two examples, in the rest of the olefin activations, gold coordinates to the olefin, turning it susceptible to nucleophilic attack. The early examples of alkene functionalization by gold catalysis (equation 144) focused on the intermolecular addition of 1,3-diketones to styrenes.[353,354] An intramolecular version with ketoamides to yield pyrrolidinones[355] was later developed and followed by the intermolecular addition of phenols (equation 145) and carboxylic acids to double bonds,[356] a work that included an example of intramolecular addition of an aliphatic alcohol to an olefin.



(144)



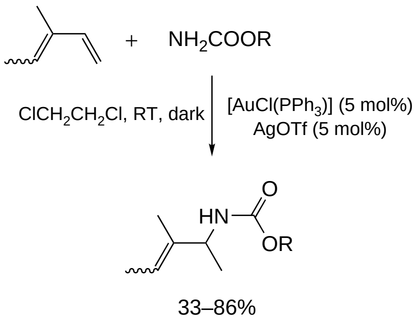
(145)



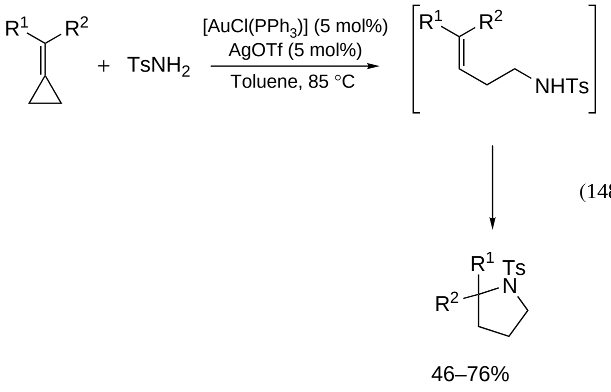
(146)

Hydroamination of olefins is also possible with gold catalysts. In this reaction, the attack comes from a nitrogen nucleophile as a carbamate,[357] a urea,[358] an amide,[359] or a sulfonamide.[360] In the latter case, the reaction can be carried out intermolecularly. While the carbamates, ureas, and amides give only products of intramolecular aminations, the sulfonamides can perform the intermolecular addition. Only the addition of ureas (equation 146) takes place at room temperature, and in the rest of the additions heating is required. The catalysts of choice in all these reactions are cationic gold(I)-species stabilized by phosphines or NHC ligands. The reaction times have been reduced by the use of microwave irradiation.[361] The mechanism of the hydroamination reaction has been studied in detail theoretically.[362]

The intermolecular addition of carbamates to 1,3-dienes (equation 147) under mild conditions has been described as well.[363] The hydrothiolation of 1,3-dienes has also been reported.[364] Other related conjugate additions can be performed over methylenecyclopropanes (equation 148) with sulfonamides and the resulting product cyclizes by a second hydroamination of an olefin, finally yielding cyclic sulfonamides.[365] This behavior is reproduced in a similar reaction for the ring opening of vinylcyclopropanes with sulfonamides.[366] One more example in this group of reactions is the synthesis of dihydrobenzofurans from aryl–allyl ethers.[367]



(147)

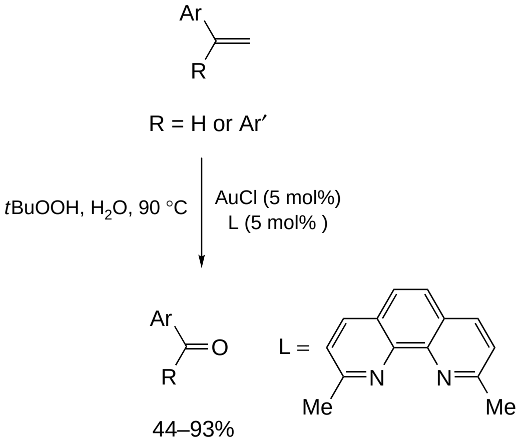


(148)

On the other hand, aniline, phenol, and alcohols have been added to unactivated alkenes using $AuCl_3$,[368,369] but then $CuCl_2$ should be added to the reaction mixture and harder conditions are necessary.

Gold can also behave as a good hydrogenation catalyst. Although its use is more extended as a heterogeneous catalyst, some examples of homogeneous applications have been reported,[370,371] one among them being an enantioselective hydrogenation with a chiral, dinuclear gold(I) chloride.[372] The hydrosilylation of styrene with an Au(III)–salen complex as catalyst[373] and the diboration of olefins have also been studied.[374]

The last example included in this section is an oxidative cleavage of styrenes performed in water with *tert*-butylhydroperoxide as the oxidant (equation 149).[375] In this reaction, the first step is an olefin activation that should be followed by oxidation, although the mechanism is unknown. The catalyst employed is AuCl with neocuproine as the ligand.

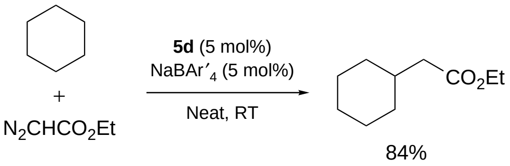


(149)

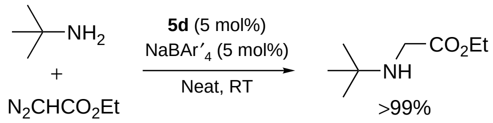
10 ALKANE ACTIVATION (C–H)

A few C–H activations by gold are known.[376] Thus, an initial example observed in nature is the existence of Au atoms in the core of a bacterial protein that oxidizes methane to methanol.[377] In a reaction that tries to mimic this behavior, the formation of alkyl hydroperoxides was achieved with $NaAuCl_4$ or $[AuCl(PPh_3)]$ in acetonitrile solution with H_2O_2 at relatively low temperatures (75 °C).[378] The formed hydroperoxides decomposed partially in the reaction mixture to give the corresponding alcohols and ketones, but were subsequently reduced to the alcohols by different methods. The oxidation of methane by gold–oxygenated complexes has also been studied theoretically.[379]

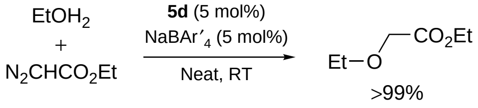
In the carbene insertions to alkane C–H bonds[380] the same concept as for the olefin cyclopropanations is applied. In that work, the gold-catalyzed carbene transfer is now used for insertions into C–H bonds (equation 150), with a selectivity that is influenced by the electronic properties of the ligand and the counterion employed. The carbene and nitrene insertion is not limited to Csp^3–H bonds, but N–H (equation 151), O–H (equation 152),[122] and aryl Csp^2–H bonds react as well (equation 153).[122,243,381]



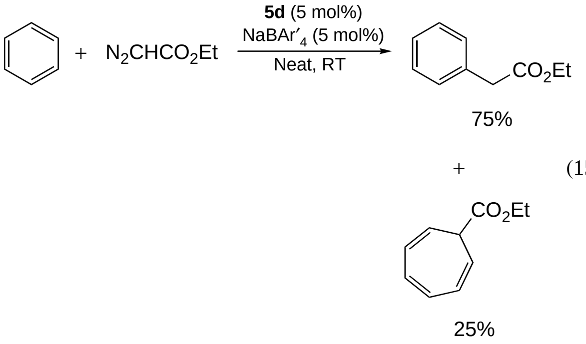
(150)



(151)



(152)



(153)

Aryl C–H bonds are known to be active and thus benzenes undergo auration, which has been exploited as the oxidative coupling of arenes.[382]

11 OTHER ACTIVATIONS

In this section, we would like to mention that gold species can be active against other types of single bonds that are different from C–H. An example of gold-catalyzed dehydrogenative dimerization of trialkyl stannanes[383] shows that M–H bonds may be activated as well. On the other hand, transmetallation from M–C bonds is also possible as observed for boronic acids,[384] a finding that has been applied to the dimerization of those compounds[385] and to the development of the gold(I)-catalyzed Suzuki cross-coupling.[386] In a similar way, gold(I) homogeneous and heterogeneous species have been proposed to be catalytically active in Sonogashira couplings.[387]

1 INTRODUCTION

NHCs were discovered some 40 years ago, when Öfele[1] and Wanzlick and Schönherr[2] independently reported the synthesis of chromium and mercury complexes bearing NHC ligands. But the interest for this class of ligands in the field remained feeble, although in the 1980s, Lappert reported the preparation of various NHC–late TM complexes.[3] It was only when Arduengo isolated the first stable NHC[4] that they caught the attention of coordination and synthetic chemists. Investigations of NHCs stereoelectronic properties[5] showed that NHCs are excellent donor ligands for metals,[6] and the resulting NHC–TM complexes have found numerous applications in catalysis.[7,8] Key transformations such as olefin metathesis[9] and cross-coupling[10] have unquestionably benefited from the use of NHC-based catalysts. Many efforts have focused on the syntheses of new NHCs and NHC–TM complexes;[11] however, the properties of such complexes are still underinvestigated. Here, we intend to provide an overview of the different procedures that have been developed for the synthesis of free carbene and NHC–metal complexes. Because of the wide range of NHC ligands developed so far, we focus our discussion on the commonly used monodentate NHCs, but the synthesis and reactivity of some specific NHCs are also reviewed.[12] Stability of NHC–TM complexes being a feature for their application to catalytic reactions, processes leading to the cleavage of the NHC–TM bond are presented, as well as reactions involving the NHC ligand.

2 SYNTHESIS OF NHC-CONTAINING METAL COMPLEXES

The most common synthetic approach to NHC–metal complexes involves free NHC as an intermediate, either isolated or in situ generated. Numerous other strategies that have been developed are also presented.

2.1 Generation of Free NHCs

The route leading to isolable free NHC originally developed by Arduengo involved the deprotonation of an imidazolium salt using a strong inorganic base.[4] Thus, the sterically hindered IAd (**2**) was generated by proton abstraction of the corresponding chloride salt (**1**) by NaH in THF (equation 1). Catalytic amounts of dimesyl anion (–CH_2SOCH_3) were also added. ^{t}BuOK was also found efficient to deprotonate the NHC precursor. Recently, this procedure has been extended to the syntheses of numerous unsaturated NHCs bearing either alkyl group IDM, ITM,[13] I^{t}Bu[14] or aryl group such as (**3**), IMes,[13] and IPr[15] and saturated carbenes SIMes[16] and SIPr.[15] Deprotonation of imidazolium salts in THF normally requires overnight reaction times. However, reaction time can be drastically reduced (to 30 min) when a mixture of liquid ammonia and THF (5:1) is used as solvent.[17]

The choice of solvent to perform reactions dealing with NHCs is crucial since they react with numerous common

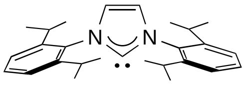
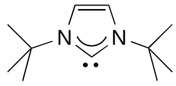
(IMes)

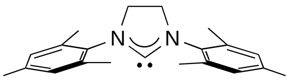


(IPr)

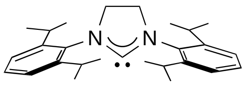


(I^{t}Bu)

(**3**)

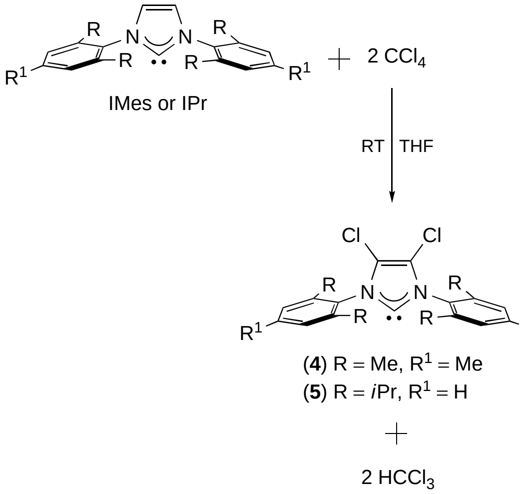


(SIMes)



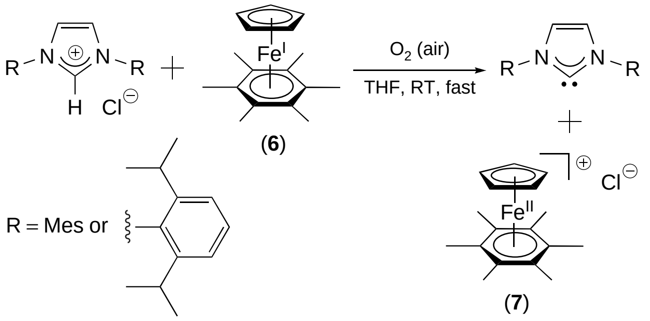
(SIPr)

organic solvents. For instance, IMes and IPr react with carbon tetrachloride leading to the chlorination of the 4- and 5-positions of the imidazole rings, respectively (**4**) and (**5**) (equation 2). These unusual NHCs are exceptionally stable and have been used to synthesize TM-based complexes active in catalysis.[15,18]



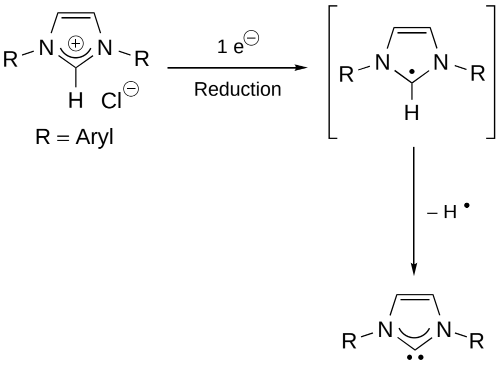
(2)

Recently, Astruc demonstrated that the deprotonation of imidazolium salts could be also achieved by a 19-electron Fe(I) complex (**6**), namely, [Fe(Cp)(η^6-C_6Me_6)], in the presence of oxygen (equation 3).[19] The proposed mechanism, reported in Scheme 1, is a radical transfer from O_2 to the Fe(I) complex (**6**) to give the adduct [Fe^{II}Cp(η^6-C_6Me_6), $O_2^{\bullet -}$] (**8**), in which the $O_2^{\bullet -}$ deprotonates the imidazolium salt. Changing the solvent from THF to pentane, toluene, or ether, in which the imidazolium salts are not soluble, led to the formation of complex (**9**) [Fe^{II}Cp(η^5-$C_6Me_5CH_2$)], which is, in that case, the effective deprotonating agent.



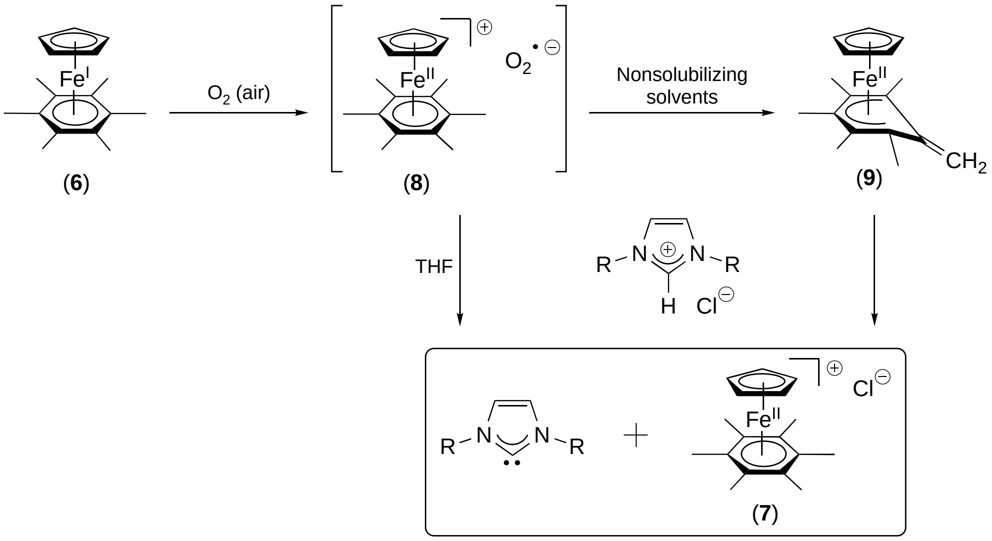
(3)

Alternatively, free NHCs have been obtained from imidazolium salts by electrochemical or chemical reduction.[20] Coulometric analysis showed a single electron event, suggesting that the reduction proceeds via an imidazole radical, with further loss of one radical hydrogen to afford the free carbene (equation 4).



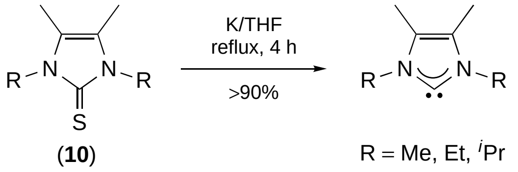
(4)

Although deprotonation of NHC salts have proven to be an efficient synthetic route, the basic reaction conditions can prove incompatible with certain complex synthesis in a one-pot procedure. Thus, other synthetic strategies to generate free carbene have been developed. Khun reported the synthesis of imidazol-2-ylidenes bearing a small alkyl group on the NHC backbone by potassium reduction of the corresponding thiones (**10**) (equation 5).[21] This method has also been applied in the synthesis of benzimidazole derivatives, by reduction of the corresponding sulfones with Na/K alloy at room temperature.[22] Synthesis of unsymmetrically substituted



Scheme 1 Synthesis of free NHC by complex (**6**)

saturated NHCs could be achieved following the same method.[23]



(5)

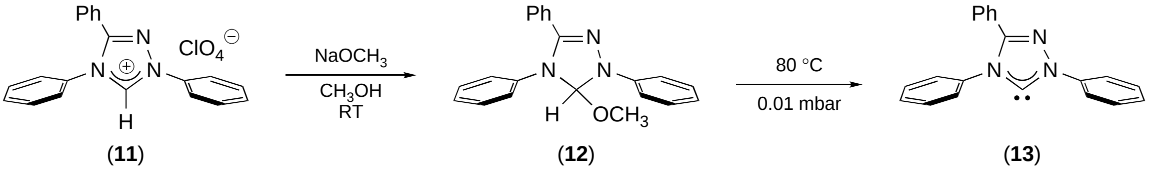
On the other hand, generation of free carbenes can be thermally achieved from ''C-protected NHC''. In 1995, Enders reported the thermal elimination of methanol from 5-methoxy-1,3,4-triphenyl-4,5-dihydro-1*H*-1,2,4-triazole (**12**) affording the corresponding carbene 1,2,4-triazol-5-ylidene (**13**) in quantitative yield (Scheme 2). Methanol adduct (**12**) is easily synthesized from reaction of triazolium perchlorate (**11**) and $NaOCH_3$ in methanol.[24,25]

It may be noted that Grubbs applied this synthetic method to imidazolinylidene Ru complexes. Compound (**14**) was found efficient in releasing free SIMes upon heating at 80 °C.[26] Alternatively, *tert*-butylate SIMes adduct (**15**) could be used as a precursor to SIMes, while isolation of the unsaturated analogs proved unsuccessful.[27] NHC–amine[28] and NHC–chloroform[29] adducts (**16**) and (**17**) were also synthesized, although their uses in complex formation are very limited.

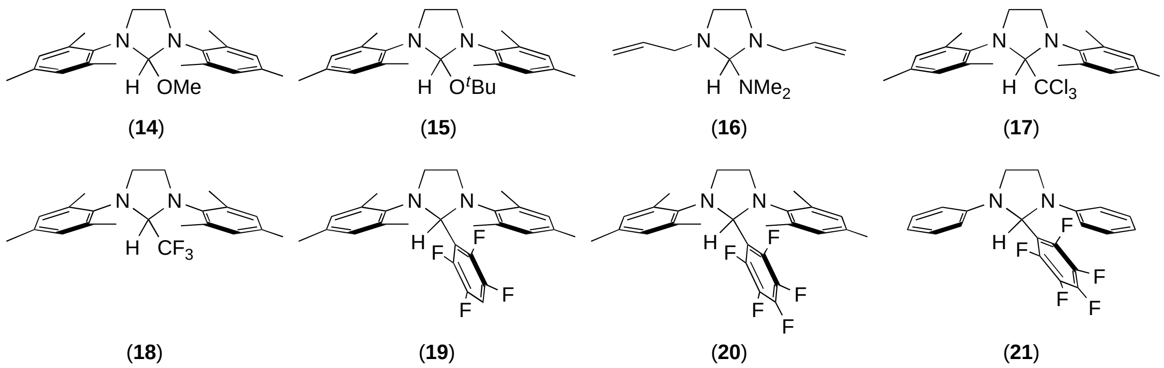
In 2004, Waymouth and Hedrick reported a new generation of NHC adducts, in which the NHC protecting group was substituted by different fluorobenzene or trifluoromethane.[30] Compounds (**18**)–(**21**) were directly generated from the diamine and the corresponding substituted aldehydes. They were found stable at room temperature and easy to handle in air. Notably, the pentafluorobenzene adduct (**20**) exhibited the best reactivity and free IMes was released upon heating at 65 °C.

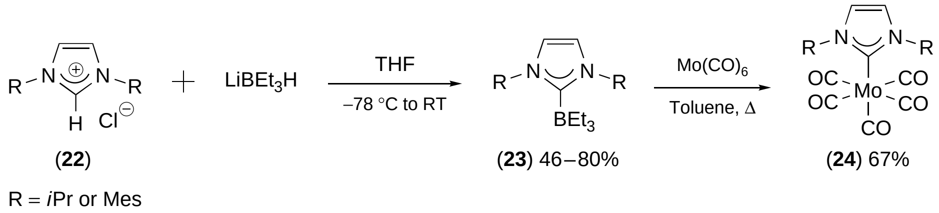
Ito and Yamaguchi found that reaction of alkyl and aryl imidazolium chloride (**22**) with $LiBEt_3H$ afforded the triethylborane–NHC adduct (**23**) (Scheme 3). These compounds proved to be versatile sources of the free carbenes. Indeed, heating a toluene solution of NHC–BEt_3 and the TM complex $Mo(CO)_6$ afforded complex (**24**) [(NHC)$Mo(CO)_5$] in good yield.[31]

Crabtree and coworkers reported the synthesis and the use of air- and moisture-stable *N*,*N*-dimethyl-imidazolium-2-carboxylate (**25**). Upon heating to 75 °C, CO_2 was released from (**25**) and the so-generated free carbene coordinated to different TM complexes, as depicted in Scheme 4. Reaction of (**25**) with $[M(COD)Cl]_2$ (M = Rh or Ir) afforded monocarbene complexes (**26**). Novel biscarbene complex (**27**)

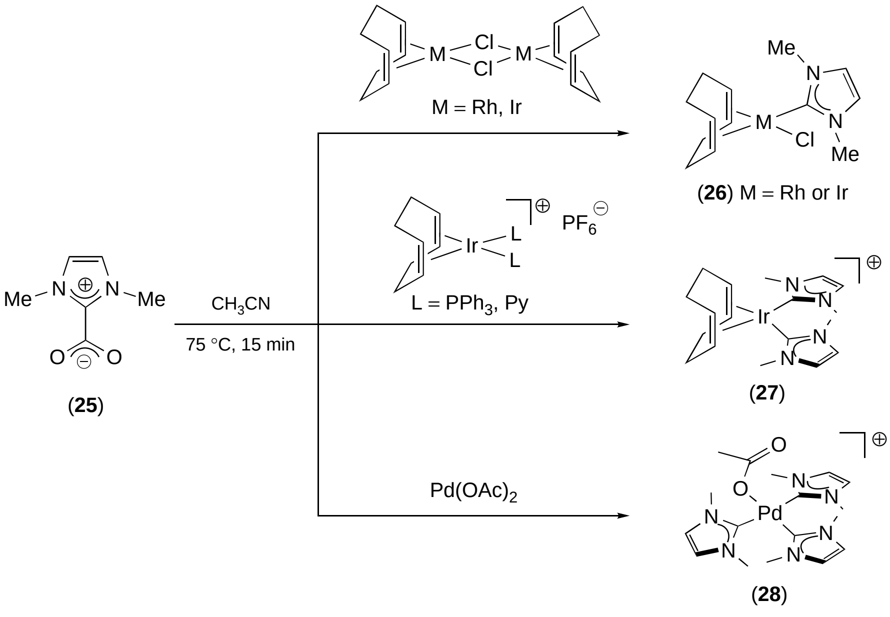


Scheme 2





Scheme 3



Scheme 4 Synthesis of NHC–metal complexes from carboxylate–NHC adduct

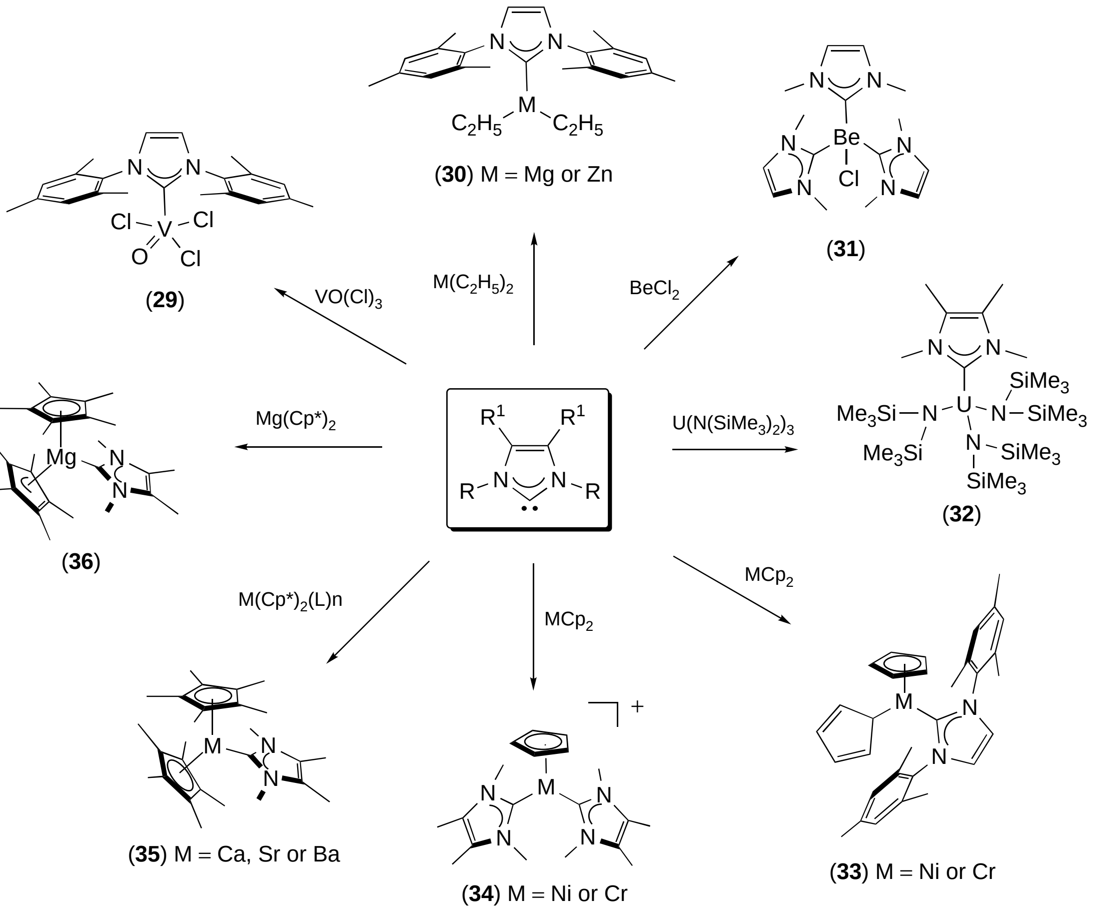
and triscarbene complex (**28**) were synthesized as well, from the same precursor.[32]

2.2 Formation of NHC–TM Complexes

The availability of free carbene as a reagent prompted the development of TM complexes bearing these NHC ligands. Their formation can be achieved using various pathways: either by direct coordination to a metal source or by substitution of another ligand present in the metal coordination sphere.

2.2.1 NHC Addition onto the Metal Center

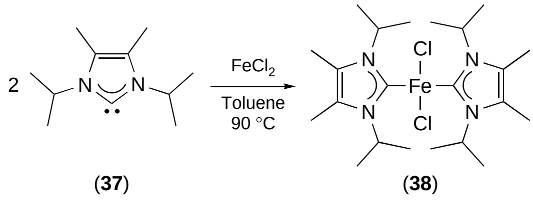
Direct coordination of free carbene to a metallic center is the most straightforward route leading to NHC–metal



Scheme 5 Coordination of free NHC to metal complexes

complex. Some examples involving main group and TM salts are reported in Scheme 5. $VO(Cl)_3$ and diethyl Mg(II) or Zn(II) complexes react with IMes affording complexes (**29**) and (**30**) respectively.[33,34] In a similar manner, beryllium and uranium complexes (**31**) and (**32**) of IDM and ITM can be synthesized.[35,36] Ni and Cr metallocenes $[M(Cp)_2]$ showed different reactivity depending on the steric hindrance of the NHC employed. Reaction with IMes changed the coordination mode of one Cp from η^5 to η^1, giving rise to (**33**). On the other hand, the less sterically demanding ITM afforded complexes (**34**) $[(NHC)_2M(Cp)](Cp)$, in which one Cp was substituted by two carbenes.[37] NHC–metallocene complexes (**35**) of groups 2 and 12 were easily prepared by reaction of $[(Cp^*)_2M]$ with free carbene. When a twofold excess of NHC was used, the biscarbene complex $[(Cp)_2M(NHC)_2]$ was isolated. If M = Mg, coordination of ITM gave rise to (**36**) where one of the two Cp* rings changed its coordination mode from η^5 to η^3.[38]

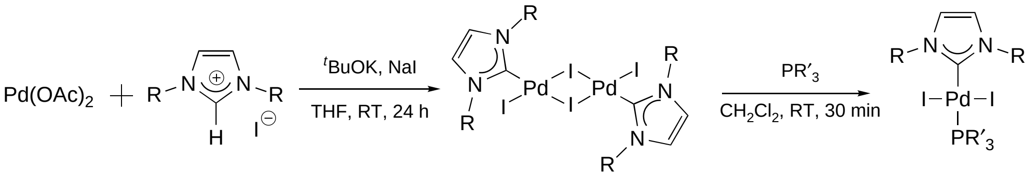
In a similar manner, Fe(II) halides react with free carbene (**37**) to afford *trans*-$[(NHC)_2FeCl_2]$ (**38**) (equation 6).[39]



(6)

As an alternative to the use of free NHC, which requires special handling conditions, the generated in situ carbene from the corresponding NHC salt and a base is often employed. For example, [(NHC)CuCl] complexes were synthesized by treatment of CuCl with NHC salts in the presence of ^{t}BuOK. First reported for IPr,[40,41] this synthetic route was found wide in scope and has been extended to various NHCs.[42] It may be noted that when CuOAc is used as the metal source, the isolated product is [(NHC)Cu(OAc)].[43]

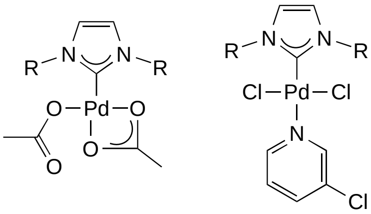
In the same manner, NHC–Pd(II) complexes have been synthesized from $Pd(OAc)_2$ and the in situ generated carbene (Scheme 6).[44] The resulting dimer (**39**) $[(NHC)PdI_2]_2$ can be cleaved with phosphines leading to mixed NHC–PR_3 Pd(II) complexes (**40**).[45]



(39) (40)

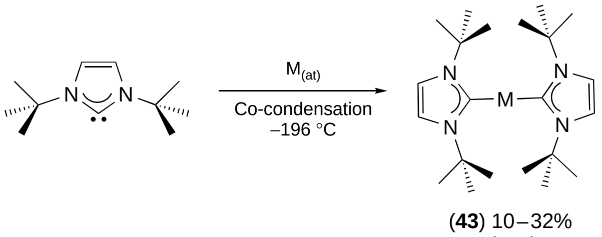
Scheme 6

On the other hand, reaction of $Pd(OAc)_2$ with free NHC in toluene at room temperature afforded the monomer (**41**) [(NHC)Pd(OAc)(κ^2-*O*,*O*-Ac)]. It is worth noting that the mode of formation of the NHC (in situ generated or isolated) led to different products.[46] Recently, Organ reported a procedure for the synthesis of NHC–Pd(II) complexes from $PdCl_2$.[47] $PdCl_2$ and NHC·HCl were heated in neat 3-chloropyridine in the presence of K_2CO_3. The reaction yielded [$PdCl_2$(NHC)(3-ClPy)] (**42**) in quantitative yields.



(**41**) (**42**)

Atypical synthesis of *naked* NHC-containing complexes has been reported by Cloke and coworkers.[48] As shown in equation (7), the co-condensation of nickel, palladium, and platinum vapor with the free NHC, I^{t}Bu, provided two-coordinated homoleptic complexes of Ni(0), Pd(0), and Pt(0) (**43**). Unfortunately, in addition to the poor yield of the isolated product, this original methodology required a metal vapor synthesis apparatus.



(**43**) 10–32%

(7)

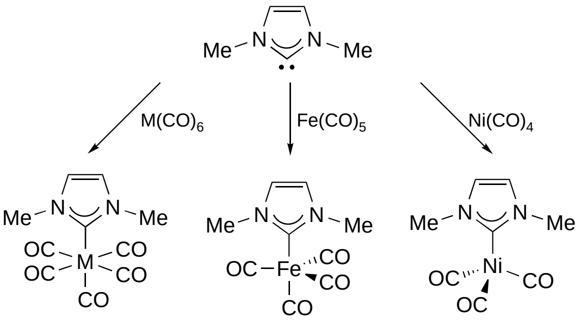
2.2.2 Coordination by Nucleophilic Ligand Substitution

Owing to their particular electronic properties, NHCs are well known to substitute for various ligands bound to TM complexes. Since they are generally easy to synthesize, to handle and commercially available, carbonyl, phosphines, and olefins metal complexes have been widely used as precursors. In the following section, we present the most significant examples of ligand substitution by NHCs.

Carbonyl Substitution. Replacement of one CO by an NHC ligand such as IDM is a common reaction, which has been applied to carbonyl complexes of Cr(0), Mo(0), W(0), Fe(0), Ni(0), and so on. The corresponding IDM–carbonyl complexes (**44**)–(**46**) were easily isolated in good yield as depicted in Scheme 7.[49]

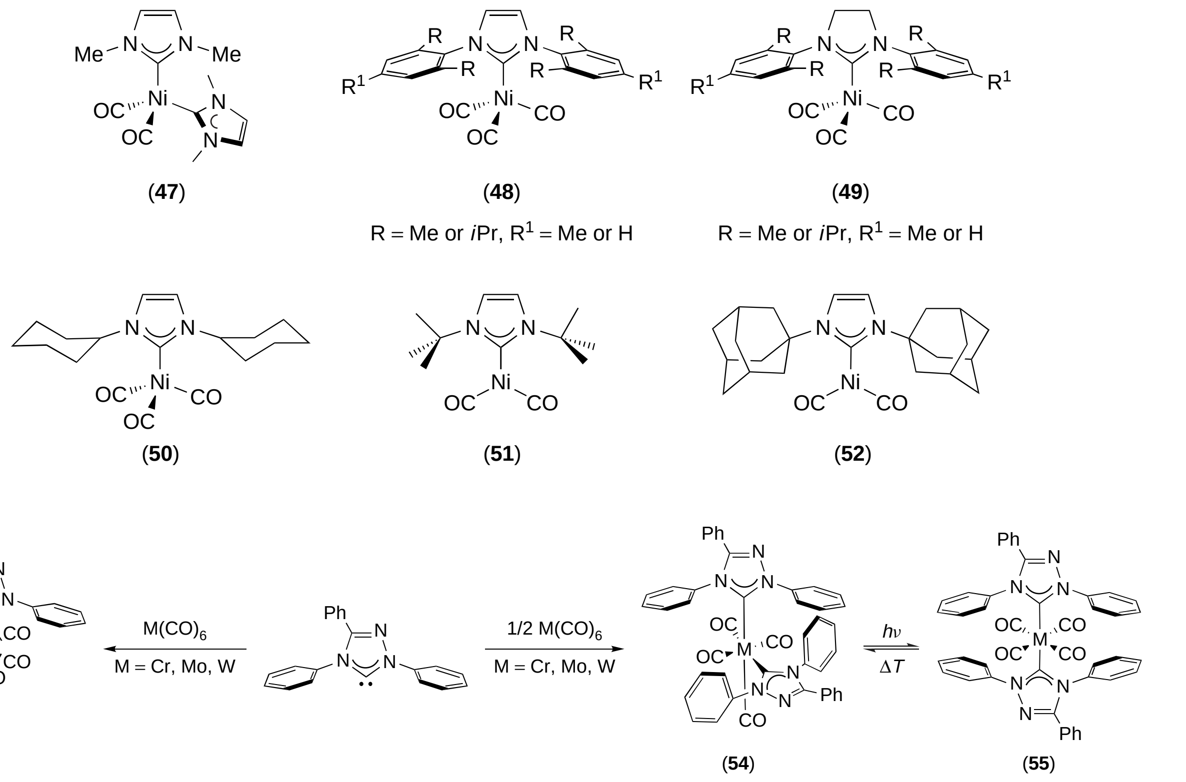
Interestingly, when $Ni(CO)_4$ was treated with two equivalents of IDM, the biscarbene complex (**47**) was formed. Several other NHC–nickel carbonyl complexes have been synthesized following the same route, as also complexes (**48**)–(**50**) containing IMes, IPr, SIMes, SIPr, and ICy, respectively, which have been obtained and characterized.[50] Importantly, when more sterically demanding I^{t}Bu and IAd were used, dissociation of two CO molecules occurred, yielding a rare unsaturated three-coordinated [(NHC)Ni$(CO)_2$] (**51**) and (**52**).[51] These results show that the behavior difference between the various NHC ligands is more a consequence of their steric congestion than of their electronic properties.

Identically, triazole-based carbenes were found to be able to substitute CO, giving rise to mono- or disubstituted carbene carbonyl complexes (**53**) and (**54**) as a function of the reaction stoichiometry (Scheme 8).[52] Reaction between $M(CO)_6$ and one equivalent of triazolylidene led to the formation of cis



(**44**) M = Cr, Mo, or W (**45**) (**46**)

Scheme 7 Substitution of CO ligand in carbonyl complexes by free NHC



Scheme 8

isomer (**54**), which undergoes reversible isomerization to the trans isomer (**55**) upon irradiation.

Piano–stool iron complexes bearing NHC have been obtained by substitution of a CO ligand from [(Cp)Fe(CO)$_2$X] (**56**), as illustrated in Scheme 9.[53] When X was a methyl group, the reaction, performed at room temperature, afforded [(Cp)Fe(CO)(IMes)(Me)] (**57**), while heating the reaction mixture to 60 °C led to the concomitant insertion of CO into the Fe–CH$_3$ bond giving rise to complex (**58**). On the other hand, when X was an iodide, substitution of IMes did not take place at the CO position but for the iodide leading to the cationic complex (**59**) [(Cp)Fe(CO)$_2$(IMes)]$^+$.[54,55]

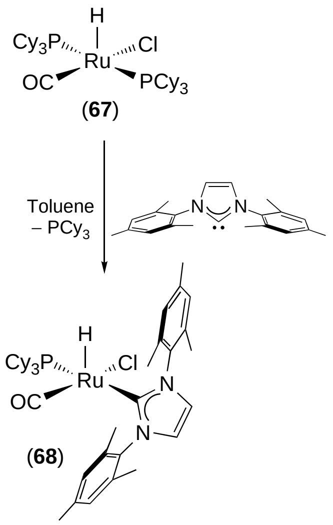
Scheme 10 Synthesis of mono- and biscarbene CpRu complexes

Phosphine Substitution. Owing to their stronger σ-donating properties, NHC ligands are able to displace phosphines in different situations. The large number of phosphine-containing complexes commercially available explains why this synthetic route is one of the most commonly employed nowadays. Synthesis of Ru(Cp) complexes bearing NHC could be achieved, as depicted in Scheme 10, by ligand exchange from [(Cp)Ru(Cl)(P)(L)] (**60**)–(**62**) with P = phosphine and L = phosphine, CO, and CPh_2 respectively. When only one phosphine was in the coordination sphere of Ru complexes (**60**) and (**61**), monocarbene complexes (**63**) and (**64**) were isolated. Interestingly (and as expected), for (**63**) where both carbonyl and phosphine ligands were present, ICy substituted for the phosphine rather than for the CO. When L was a phosphine, mono- (**65**) or di-substituted (**66**) ICy complexes were synthesized as a function of the stoichiometry of the reaction.[56]

Treatment of the Ru hydride [RuHCl(CO)(PCy_3)] (**67**) with a free carbene such as IMes proceeds by the easy and selective phosphine displacement and formation of complex (**68**) (equation 8).[57] At the time of this article, this synthetic pathway has been extended to analogs [(IPr)RuHCl(PCy_3)],[58] [(IMes)RuHCl(PPh_3)], and [(SIMes)RuHCl (PPh_3)].[59]

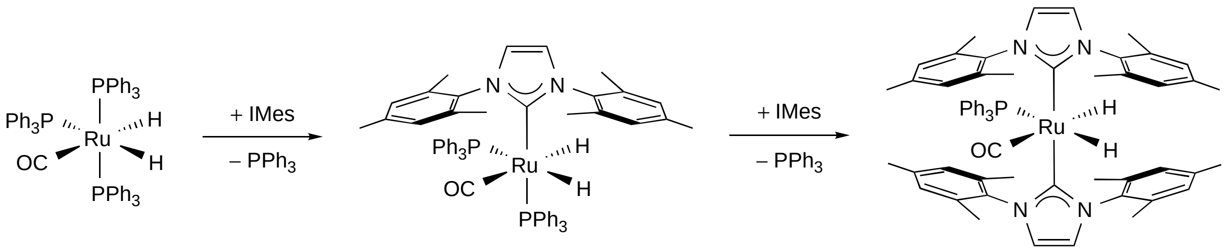


(**67**)

(**68**)

(8)

In the dihydride Ru complexes (**69**), [$RuH_2(CO)(PPh_3)_3$] (Scheme 11), a threefold excess of IMes led to the sequential formation of the mono-substituted IMes complex (**70**) and of the bis-substituted complex (**71**).[60] It may be noted that substitution neither of the third phosphine nor of the carbonyl ligand was observed.



(**69**) (**70**) (**71**)

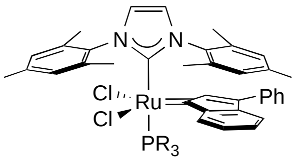
Scheme 12 Substitution of phosphine ligands in first-generation Grubbs catalyst

In 1998, Herrmann reported that first-generation Grubbs catalyst $[RuCl_2(PCy_3)_2(CHPh)]$ (**72**) (Scheme 12) underwent substitution of the two phosphines by two equivalents of alkyl carbene affording complex (**74**).[61] On the other hand, when only a slight excess of the free carbene was added monosubstitution of phosphine was achieved, and complex (**73**) was obtained.[62,63]

Reaction of (**72**) with aryl *N*-substituted NHC, yielding second-generation metathesis catalysts, was reported in 1999 by Nolan *et al.*[64] and Grubbs *et al.*[65] Substitution of one phosphine in (**72**) by IMes afforded $[Cl_2Ru(IMes)(PCy_3)(CHPh)]$ in excellent yields. Even in the presence of a 10-fold excess of IMes, only one phosphine underwent substitution.[64] Since then, this synthetic route has been extended to a number of carbenes, for instance, SIMes, for which the free carbene has been generated in situ from the methanol-protected NHC (**14**),[26] IPr,[66] SIPr[67] generated either from the *tert*-butanol-protected NHC[68] or by in situ deprotonation of IPr·HCl salt,[69] SIAd,[70] as well as unsymmetrically substituted NHC.[70,71] Very recently, Grubbs reported that various $[(NHC)RuCl_2(PCy_3)(CHPh)]$ could be obtained from the reaction of precursor (**72**) and 2-(pentafluorophenyl)imidazolidines, such as (**20**), under mild thermolytic conditions.[72] Ru−indenylidene complexes (**75**) have been synthesized with the same synthetic procedure by a phosphine substitution of $[Cl_2Ru(PR_3)_2(Ind)]$ (Ind = indenylylidene).[73]



(**75**)

Substitution of PCy_3 by NHC also occurred for catalyst (**76**) developed by Hoveyda (Scheme 13).[74] Isolation of reaction intermediate (**77**) showed that SIMes first substituted the more labile coordinative oxygen and then the chelation of the oxygen released PCy_3 from the Ru center affording (**78**). It is worth noting that the same reaction led to poorer yield when PPh_3 was used as phosphine.[75]

In the same manner, phosphine substitution from $[Pd(PR_3)_2]$ complexes have proven very useful in the synthesis of biscarbene Pd(0) complexes as depicted in equation (9). Reaction of $[Pd(Ptol_3)_2]$ (**79**) with two equivalents of IMes, I^{t}Bu, and ICy afforded the corresponding $[(NHC)_2Pd]$ products (**80**). A mixture of starting material and monosubstituted complex was observed when only one equivalent of free NHC was added.[76]

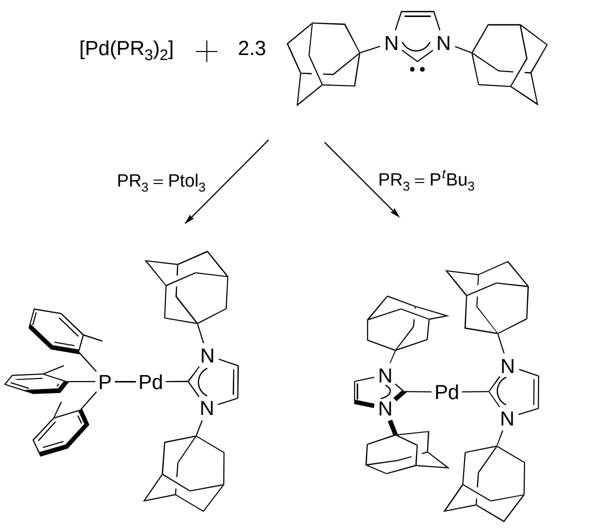
(**76**) (**77**) (**78**)

Scheme 13

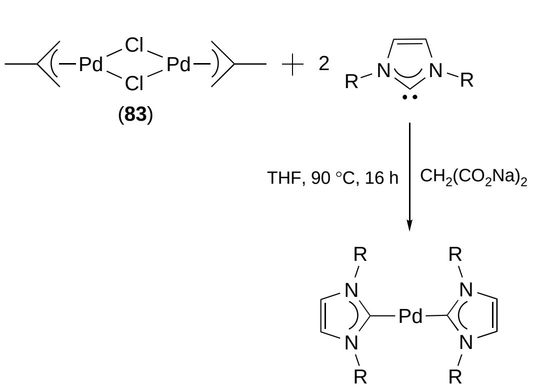


(**81**) (**82**)

Scheme 14 Influence of phosphine ligand in the synthesis of sterically hindered NHC–Pd complexes

On the other hand, using sterically hindered IAd, the mixed NHC–phosphine complex (**81**) can be isolated in good yield (Scheme 14).[77] To achieve the substitution of both phosphines affording (**82**), it was necessary to start from $[Pd(P^tBu_3)_2]$, highlighting how the choice of the leaving ligand controls the outcome of the reaction. However, Cloke and Caddick reported that careful control of reaction stoichiometry enabled the synthesis of $[(I^tBu)Pd(Ptol_3)]$ from $[Pd(Ptol_3)_2]$ (**79**).[78]

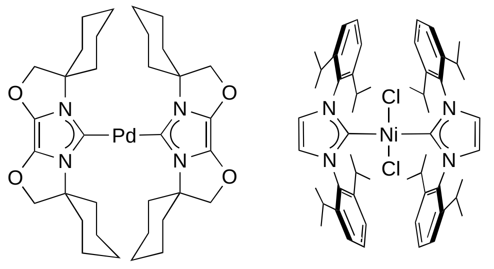
In this context, it is worth reporting that another route to bis-NHC–Pd(0) complexes has proven efficient.[79] A Pd(II) source, such as the dimer $[Pd(2\text{-methylallyl})Cl]_2$ (**83**) (equation 10) reacted with sodium malonate in the presence of free NHC ligand. Reduction of Pd(II) to Pd(0) and coordination of two NHCs afforded $[(NHC)_2Pd]$ in quantitative yield. This route proved very useful for the synthesis of catalyst (**84**) developed by Glorius *et al.*[80]



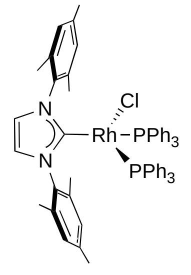
(**84**) (10)

Similarly, $[(NHC)_2Ni(II)Cl_2]$ complexes (**85**) were synthesized from the corresponding $[(PPh_3)_2NiCl_2]$ by simple substitution of two phosphines by two NHC ligands.[81,82]

Wilkinson's complex also underwent substitution of phosphines by IMes. The reaction afforded $[(IMes)RhCl(PPh_3)_2]$ (**86**), in which the two phosphines are in cis, in contrast to the general behavior of $[(L)RhCl(PPh_3)_2]$-type derivatives that usually adopt a trans geometry.[83]



(**84**) (**85**)

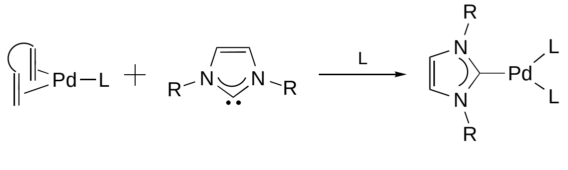


(**86**)

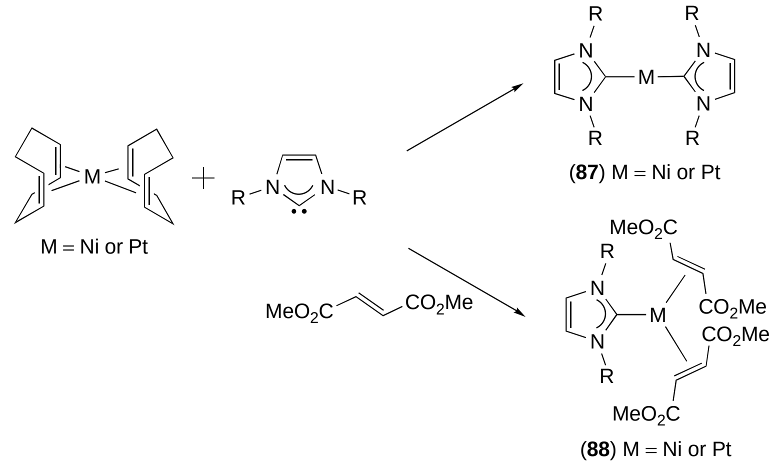
Olefin Substitution. Coordinated olefins are generally labile ligands and their substitution is easily achieved by a more donating ligand. Ni(0) and Pt(0) biscarbene complexes (**87**) were prepared from the corresponding $[(COD)_2M]$ complex by simple substitution (Scheme 15).[84] When the reaction with IMes or SIMes was carried out in the presence of two equivalents of DMFU, the monocarbene diolefin complexes $[(NHC)M(DMFU)_2]$ (**88**) were obtained.[85,86]

To obtain the Pd(0) analog of (**88**), it was necessary to use $[(^tBuDAB)Pd(DMFU)]$ as starting material, as the reaction using the diolefin complex $[Pd(dba)_2]$ gave a complex mixture of products owing to interactions of free NHC with the dba ligand. Reaction of $[(^tBuDAB)Pd(DMFU)]$ with two equivalents of IMes and an excess of DMFU yielded $[(IMes)Pd(DMFU)_2]$ (**89**). In this case, the free carbene displaced the chelating diamine.[86]

Usually, NHC palladium diolefin complexes, similar to (**89**), have been synthesized according to equation (11). The Pd(0) precursor bearing diolefin, for instance, nbd, COD, etc., reacted with NHC in the presence of an excess of a ligand L.

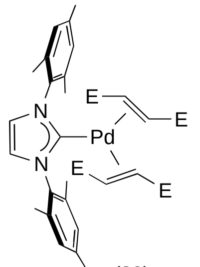


(11)

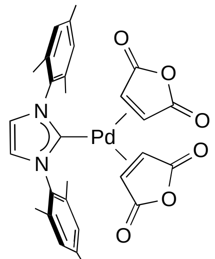


Scheme 15 Synthesis of Ni(0) and Pt(0) NHC complexes

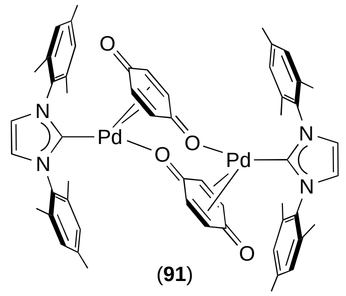
Hence, complex (**90**) was obtained by reaction of [(nbd)Pd(ma)] with one equivalent of IMes and one equivalent of ma.[87] NHC-naphthoquinone and benzoquinone dimers (**91**) and (**92**) were prepared in the same manner from naphtylquinone- and benzoquinone-palladium derivatives.[88] Small NHCs such as ITM can give rise to biscarbene complexes (**93**) and (**94**). Indeed, displacement of COD in [Pd(COD)(alkene)] complex by two equivalents of ITM



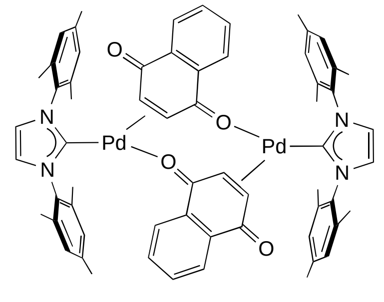
(**89**)
E = CO_2Me



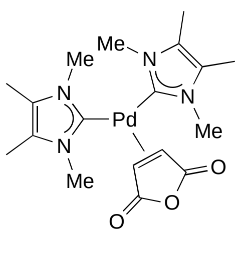
(**90**)



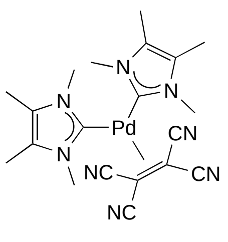
(**91**)



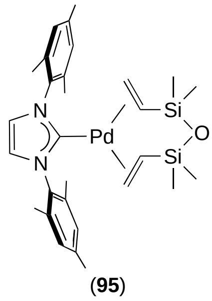
(**92**)



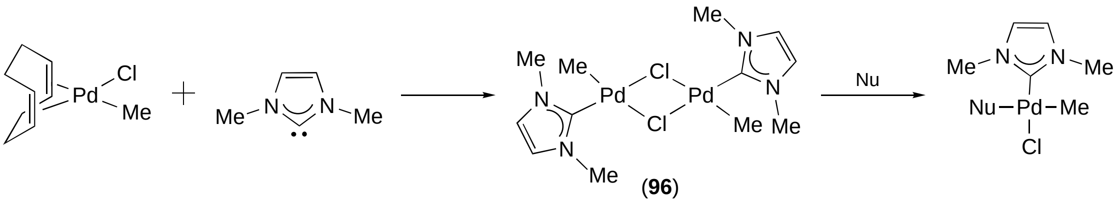
(**93**)



(**94**)



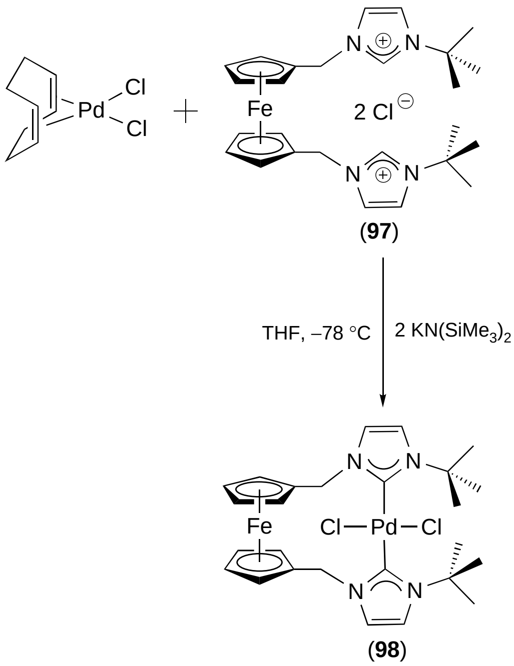
(**95**)



Scheme 16

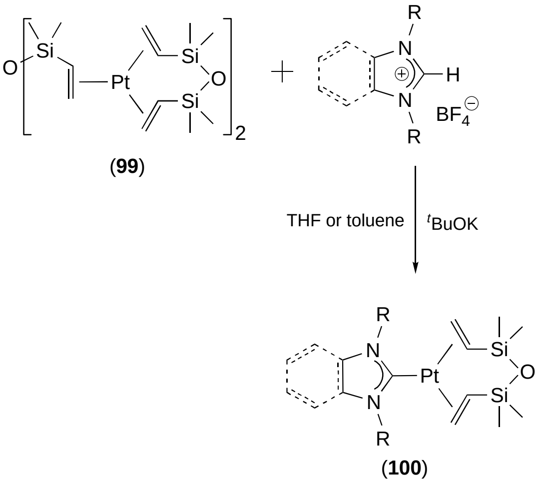
gave the corresponding biscarbene–alkene complex in good yield.[89] Substitution by an NHC of dae ligand from [$Pd_2(dae)_3$] in the presence of DVTMS afforded monocarbene Pd complexes [(NHC)Pd(DVTMS)] such as (**95**).[90,91] Substitution of COD was also found efficient for the preparation of Pd(II) alkyl complexes. Reaction of [MePdCl(COD)] with IDM gave the dimer [$MePdCl_2$(IDM)] (**96**)[92] that was subsequently opened with a range of nucleophiles (Scheme 16).[93]

Treatment of [$PdCl_2$(COD)] with ferrocenyl bis-NHC (**97**) yielded complex (**98**), in which an isomerization cis/trans was observed (equation 12). It is worth noting that the free carbene was generated in situ using the strong base $KN(SiMe_3)_2$.[94]



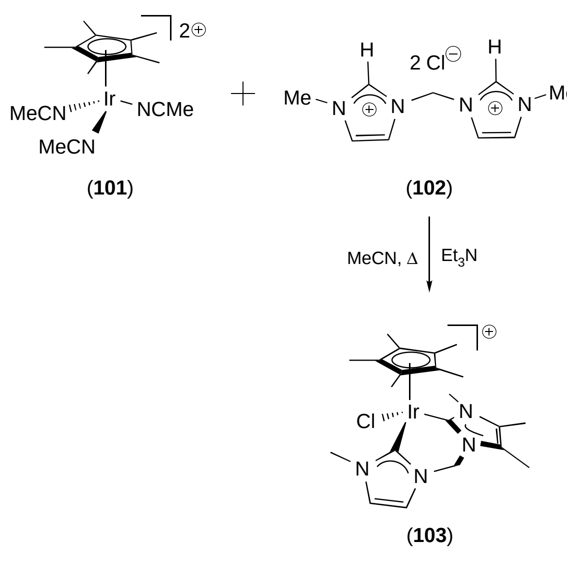
(12)

NHC–Pt(0) complexes were synthesized from Karstedt's catalyst (**99**) (equation 13).[95] Substitution of DVTMS by two equivalents of in situ generated NHC led to the formation of a series of [(NHC)Pt(DVTMS)] complexes (**100**). The first time, this was developed for ICy, I^{t}Bu, and IDM; subsequently, this synthetic procedure was efficiently applied to numerous imidazolylidene and benzimidazolylidene derivatives independent of their *N*-substituents.[96,97]



(13)

Substitution of Other Ligands. A variety of other ligands were found to be easily displaced by NHC ligands. We report here some significant examples. Substitution of pyridine in [Ir(COD)Py_2] by SIMes gave [(SIMes)Ir(COD)Py].[98] The steric bulk of SIMes allowed for substitution of only one pyridine.[99] Reaction of biscationic complex [Ir(Cp*)$(CH_3CN)_3]^{2+}$ (**101**) with bisimidazolium salt (**102**) in the presence of triethylamine led to the displacement of two acetonitrile molecules and formation of cationic complex (**103**) (equation 14).[100]



(14)

Owing to the lability of acetonitrile ligands, $[Cu(MeCN)_4]X$ ($X = PF_6$ or BF_4) was found to be a convenient starting material for the synthesis of cationic NHC–Cu(I) complexes.[101] In this case, the in situ formation of NHC from the corresponding chlorinated salts was found more suitable to isolate cationic biscarbene complexes $[(NHC)_2Cu]X$. Reaction of Pd(II) precursor $[PdCl_2(PhCN)_2]$ with one equivalent of IPr afforded the dimer $[(IPr)PdCl]_2$.[102]

By displacement of THF, NHC–Ln complexes have been synthesized using $[LnCl_3(THF)_n]$ as a metal source. Depending on the reaction stoichiometry, several NHCs could be introduced onto the metal center.[103]

In the same manner, dimethylsulfide substitution proved to be a practical procedure for the preparation of NHC−gold complexes. Good yields were obtained for the synthesis of monocarbene Au(I) complexes (**104**) from $[(Me_2S)AuCl]$ and one equivalent of free NHC (Scheme 17).[104,105] The steric hindrance of NHCs was found to be of critical importance, since NHCs with smaller nitrogen substituents such as Mes, *iso*-propyl or *n*-butyl led to a lower yield and formation of a by-product identified as the biscarbene complex $[(NHC)_2Au]^+ Cl^-$. Fortunately, the silver-mediated transmetallation was an efficient alternative route for these NHCs (see Section 2.6).[105,106] When the same reaction was performed with two equivalents of in situ generated NHCs, the cationic biscarbene complex (**105**) $[(NHC)_2Au]X$ (X = Cl, Br, or PF_6) was obtained as the only product.[107]

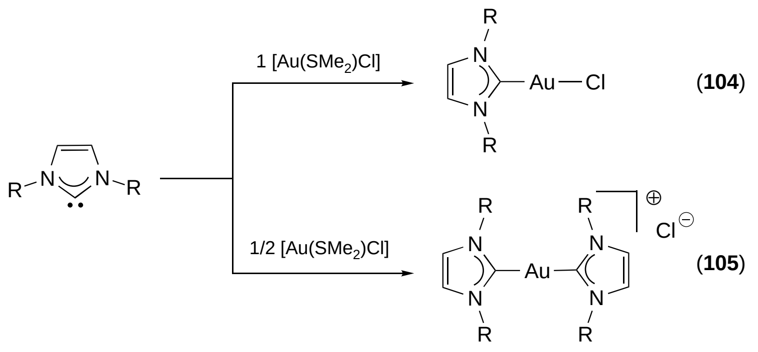
Surprisingly, cationic complexes of Cu(I) and Ag(I), namely, $[(NHC)_2M](CF_3SO_3)$, have been prepared by substitution of anionic ligand of $M(CF_3SO_3)_2$ with two equivalents of free carbene.[108]

The NHC·HCl was able to react with a chelate *O*, *C*-acetylacetonate (acac) from $[Pd(acac)_2]$ (**106**), giving rise to [(IPr)Pd(acac)(*C*-acac)] (**107**) that was converted into [(IPr)PdCl(acac)] (**108**) by addition of HCl (Scheme 18).[109]

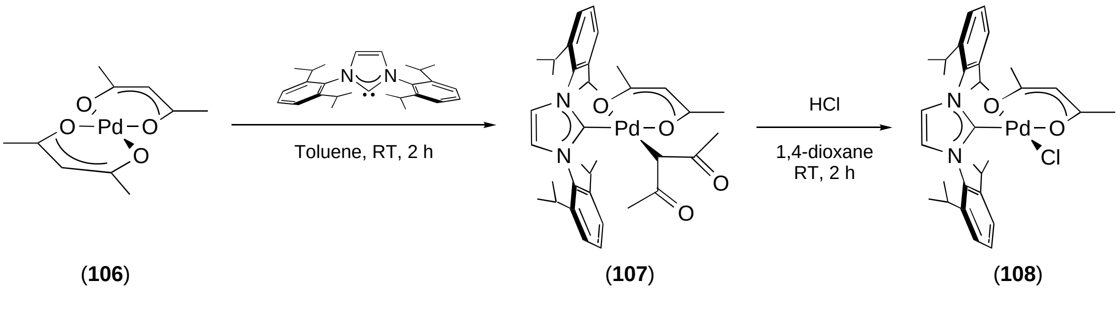
2.2.3 *Cleavage of Dimeric Metal Complex*

Group 10 TM complexes (**110**) bearing allyl ligand were synthesized by breaking the corresponding dimer $[MCl(R^1,R^2\text{-allyl})]_2$ (**109**) with two equivalents of free NHC ligand (equation 15).[110,111] Aryloxy dimer $[Ni(allyl)(OAr)]_2$ (Ar = 2,6-di-*iso*-propylphenyl) has also been employed for the preparation of NHC−allyl Ni complexes.[112] Since the [(NHC)PdCl(allyl)] complexes exhibited an excellent activity in palladium-catalyzed cross-coupling reactions,[113] this series was extensively studied with special attention to allyl substituent effects.[114,115]

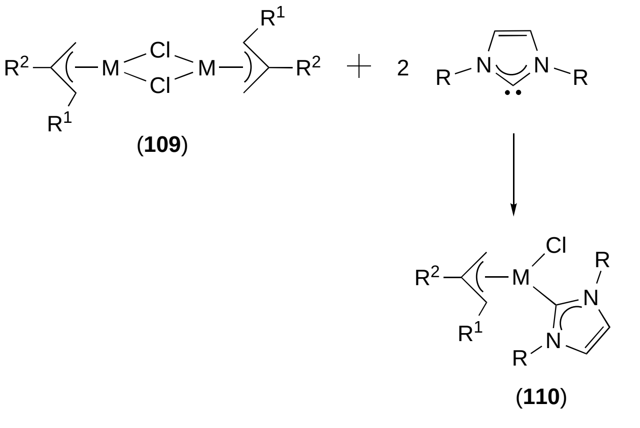
Dixneuf and coworkers reported the synthesis of Ru-η^6arene derivatives from dimeric $[Cl_2Ru(\eta^6\text{-arene})]_2$ (**111**) and dimeric carbene such as (**112**) as the source of NHC, as illustrated in Scheme 19.[116] Using different η^6-arene dimers, complexes (**113**) were isolated in good yields. When (**114**) was used as an NHC source, the expected product (**115**) was



Scheme 17 Synthesis of mono- and biscarbene Au(I) complexes

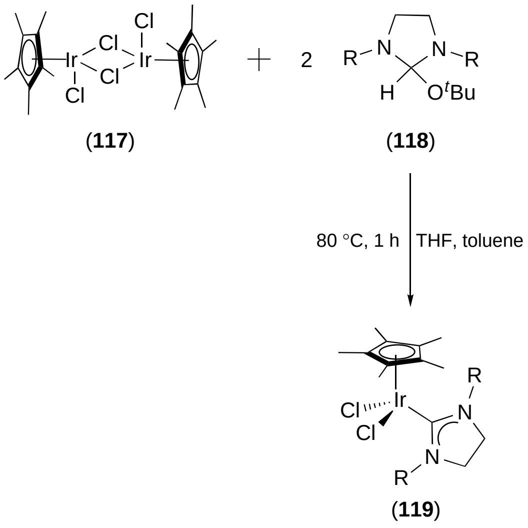


Scheme 18



M = Ni, Pd or Pt; R1 = H, Me or Ph; R1 = H or Me

(15)

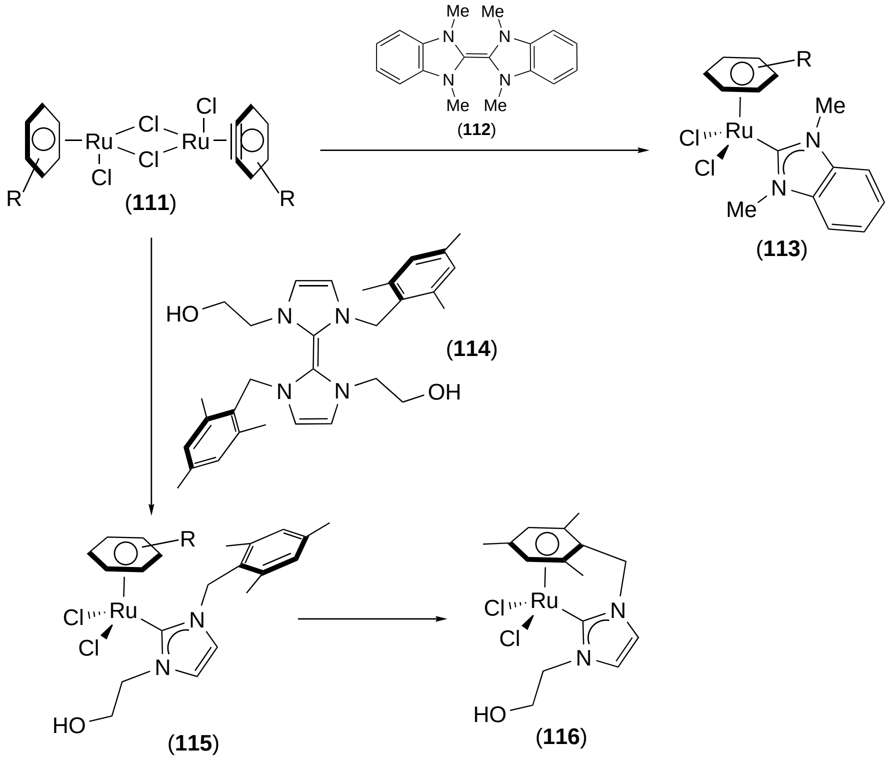


(16)

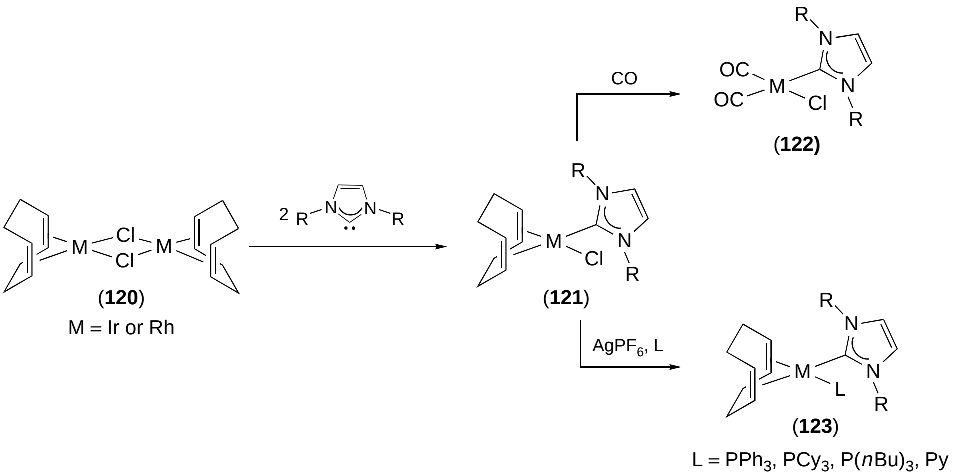
observed but it proceeded rapidly to lead to the chelate complex (**116**).[117] The flexibility of the benzyl group allowed for the C–H activation of its aromatic group and the substitution of the initial η^6-arene. It may be noted that no coordination of hydroxyl function was detected.

Cp*Ir(III) complexes were easily synthesized in good yields from the dimer $[IrCl_2(Cp^*)]_2$ (**117**) and the free carbene (equation 16).[118] This procedure proved efficient for a large range of carbenes, which can also be added to the reaction mixture in their protected form (**118**).[119]

A widely used precursor for Rh(I) and Ir(I) in coordination chemistry is the $[MCl(COD)]_2$ dimer (**120**). In the presence of either free NHC or in situ generated carbene from the alcohol adduct or the combination imidazolium salt and base, the dimer was cleaved giving rise to [(NHC)MCl(COD)] (**121**) (Scheme 20).[120] The presence of labile COD allowed for further modification of the metal coordination sphere. For example, under CO atmosphere the COD ligand was rapidly removed, leaving two CO binding the metal center.[121] The



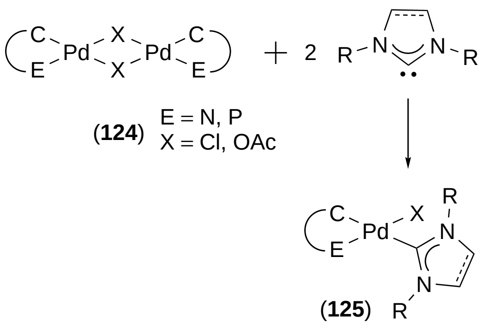
Scheme 19 Breaking of $[RuCl_2(\eta^6\text{-arene})]_2$



Scheme 20 Cleavage of $[MCl(COD)]_2$ dimer by free NHC

chloride has also been substituted by phosphines or pyridine in the presence of silver salts producing (**123**).[122]

NHC–palladacycle complexes (**125**) have been obtained, as depicted in equation (17), from the corresponding dimer (**124**) and two equivalents of NHC ligand. Conveniently, this route was found compatible with diverse functions and so aminopalladacycles[123] and phosphapalladacycles[124,125] have been prepared.

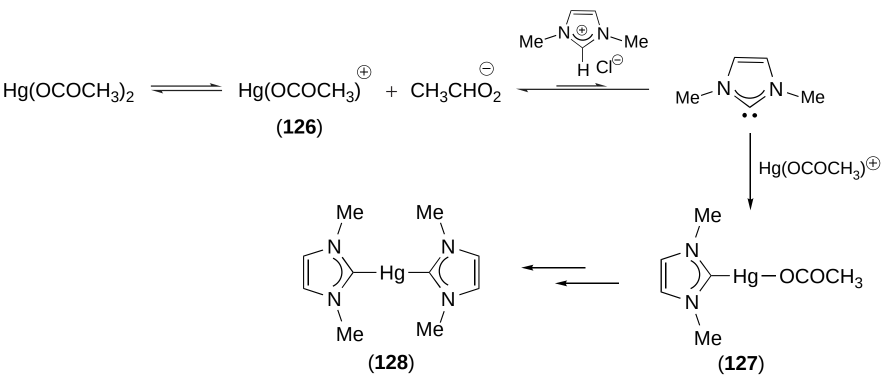


(17)

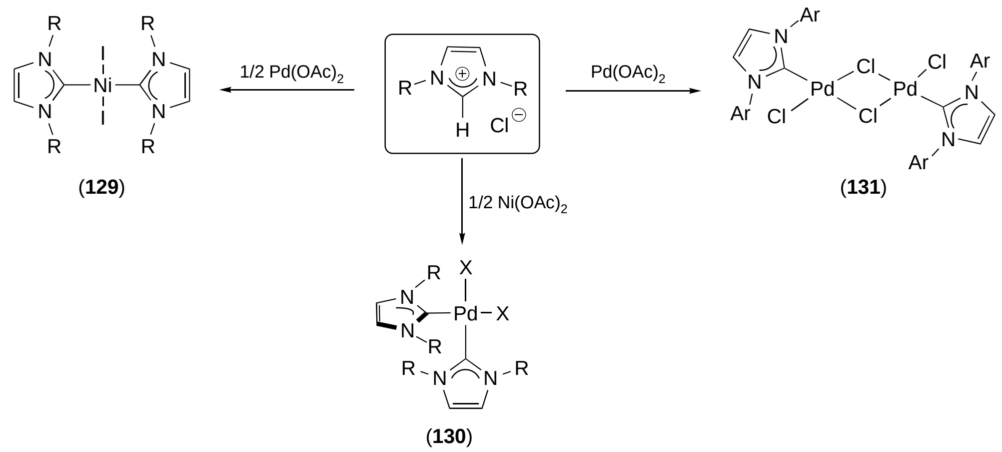
For sterically hindered NHCs, monocarbene complexes were obtained, while with smaller NHC this reaction gave biscarbene complexes.[126] In the case of the smaller IDM, it was even possible to obtain the triscarbene complex, via palladacycle opening.

2.3 Acid–Base Reactions with Imidazolium Salts

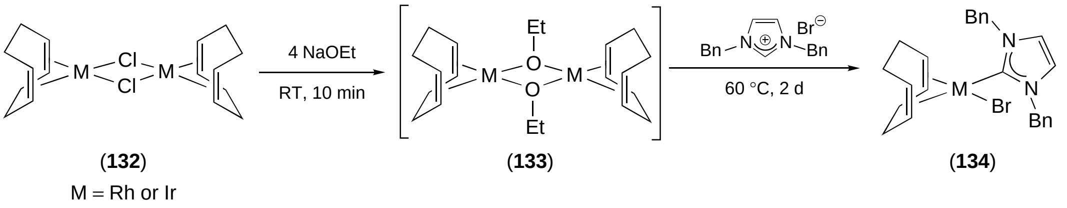
Since the synthesis of NHC–TM complexes was initially achieved by in situ formation of NHC from azolium salt in the presence of base followed by coordination to a metal center, a simpler procedure would be useful. In 1996, Arduengo reported the synthesis of $Hg(IDM)_2$ (**128**) from $Hg(OAc)_2$ and IDM·HCl salt.[127] The mechanism of this reaction is depicted in Scheme 21. Dissociation of one acetate ligand generates $[Hg(OAc)]^+$ (**126**) and the mildly basic acetate anion drives the deprotonation of the imidazolium salt. Thus, the newly formed NHC coordinated promptly (**126**) and led to $[(IDM)Hg(OAc)]^+$ (**127**).



Scheme 21 Proposed mechanism for the formation of $[Hg(IDM)_2]$ (**128**)



Scheme 22 Synthesis of TM complexes from imidazolium salt and acetate-containing metal precursors

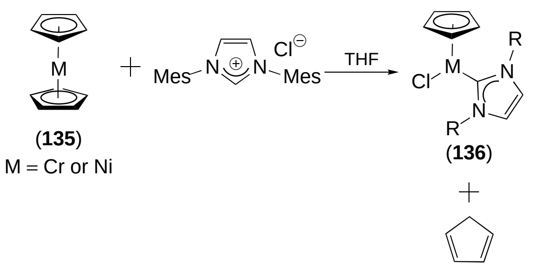


Scheme 23

This procedure has been applied in the synthesis of other complexes from acetate-containing metal source such as $Ni(OAc)_2$[81,128] and $Pd(OAc)_2$,[129,130] as depicted in Scheme 22. The reaction, involving two equivalents of NHC·HI salts, yielded the corresponding complexes: *trans*-$[NiI_2(NHC)_2]$ (**129**) and *cis*-$[PdX_2(NHC)_2]$ (**130**). Complexes of benzimidazolin-2-ylidene have been synthesized in an analogous manner.[131] Interestingly, a reaction carried out of with one equivalent of imidazolium salt and $Pd(OAc)_2$ afforded the $[PdX_2(NHC)]_2$ dimer (**131**).[132,133]

Instead of acetate complexes, ethoxide-containing metal precursors (**133**) have been used with imidazolium, benzimidazolium, or triazolium bromide salts affording [MBr(COD)(NHC)] (**134**) in quantitative yields (Scheme 23).[134,135] The ethanolate dimer was generated in situ from the corresponding chloride dimer (**132**) by addition of sodium ethoxide. Complex (**133**) was not isolated but its formation proposed as indicated by the color change of the solution. Subsequent addition of imidazolium salt afforded complex (**134**). Bridged hydroxy groups have also been found competent to carry out the deprotonation. For instance, reaction of $[(PPh_3)Pd(R)(\mu\text{-}OH)]_2$ (R = Ph, CH_3) with IPr·HCl salt gave $[(PPh_3)PdCl(R)(IPr)]$ in moderate yields.[136]

Unexpectedly, Tilset observed that coordinated Cp ligands deprotonated imidazolium and imidazolinium salt.[137] $[(Cp)_2Cr]$ (**135**) reacts with IMes·HCl to give [(IMes)CrCl(Cp)] (**136**) and cyclopentadiene (equation 18).



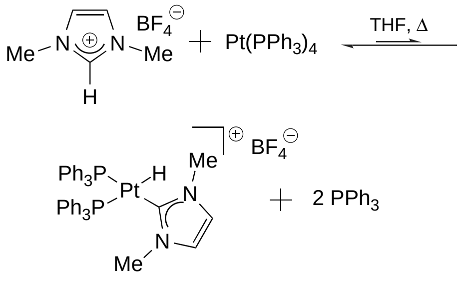
(18)

When $[(Cp^*)_2Cr]$ was used as the starting material, no product was detected. According to the authors, the absence of reactivity in the latter case could be explained by the higher steric hindrance of the Cp* ring, which would prevent the coordination of IMes. This procedure was extended subsequently to the synthesis of Ni analogs with both saturated and unsaturated aryl-substituted NHCs.[138,139]

2.4 Oxidative Addition of Imidazolium Salts onto the Metal

Although oxidative addition of C–Cl bond of thiazole, benzothiazole, and oxazole was reported as a feasible access to NHC–TM complexes by Stone in 1974,[140] this approach remained unexplored in the following 25 years. In 2001, Cavell and Yates demonstrated, with combined theoretical and experimental studies, that oxidative addition of the C–H bond

of imidazolium salts to Pt(0) was energetically favored.[141] Indeed, reaction of $Pt(PPh_3)_4$ with IDM·HBF_4 afforded the oxidative addition product (**137**) [(IDM)PtH$(PPh_3)_2$] in 15% yield. The oxidative addition of the imidazolium salt was shown to be an equilibrium reaction (equation 19).



(**137**)

(19)

Tuning the platinum precursor improved the yield to 63% using the unsaturated $[Pt(PR_3)_2]$ ($PR_3 = PPh_3$ or PCy_3) as the starting material. Displacement of two phosphines from the coordination sphere of Pt drove the equilibrium to the formation of the expected product. Following Stone's work, oxidative addition of C–I bond was also studied, and it was found that ITM·BF_4 reacted smoothly with $[Pt(PPh_3)_4]$, affording [(ITM)PtI$(PPh_3)_2$] in 89% yield. Although showing a reactivity close to the one displayed by Pt(0) complexes, Pd(0) (**138**) treated with iodoimidazolium cation (affording complex (**139**), Scheme 24) did not react with imidazolium salts. When a four-fold excess of imidazolium salt was used to drive the equilibrium, decomposition of (**138**) to palladium black occurred.[142]

Further investigations by Crabtree showed oxidative addition of imidazolium C–H bond possible for Pd(0).[143] Reaction of pyridine-substituted imidazolium salts (**140**) (Scheme 25) with Pd_2dba_3 afforded the neutral or cationic complexes (**141**) and (**142**). Apparently, the geometry cis/trans of the formed complex is a function of the steric pressure of the NHC–nitrogen substituents. Remarkably, this behavior is not related to the pyridine moiety, which could act as a base, since the oxidative addition of benzimidazolium salts to $[Pd_2dba_3]$ affording $[(NHC)_2PdCl_2]$ was achieved in moderate yield.[144]

Oxidative addition of imidazolium salts to NHC-containing complexes of Ni and Pt has also been reported. IDM·HI reacted with [(NHC)Pt$(DMFU)_2$] to give the biscarbene hydride complex [(NHC)(IDM)PtHI].[85] Reaction of IDM·HBF_4 salt with the homoleptic $[(IMes)_2M]$ (**143**) (M = Ni or Pd) afforded the triscarbene hydride complex $[(IMes)_2$(IDM)MH] (**144**) (equation 20). This metal hydride exhibited a remarkable stability both in solution and in solid state. This stability is certainly due to the steric bulk of NHCs that shields and protects the hydride function.[145]

Recently, Fürstner extended the method of Stone to chloroimidazolinium salts.[146] Oxidative addition of 2-chloro-1,3-dimethylimidazolinium hexafluorophosphate (**145**) onto $Pd(PPh_3)_4$ gave the cationic [(NHC)PdCl$(PPh_3)_2]PF_6$ (**146**) in 72% yield (equation 21).

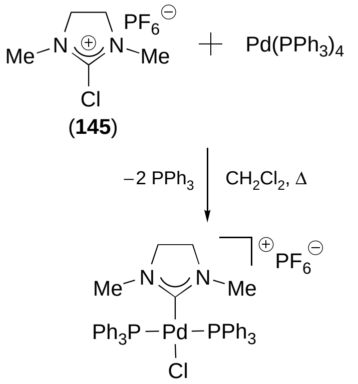
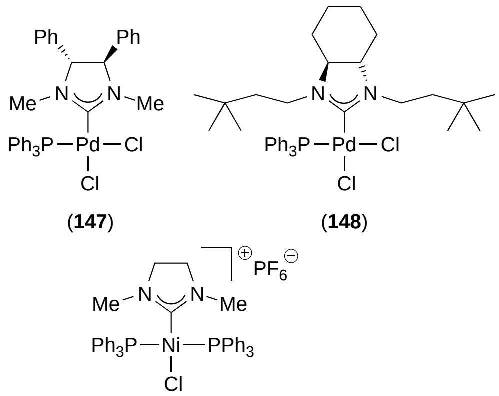
(143) (144) (20)



(145) (146) (21)

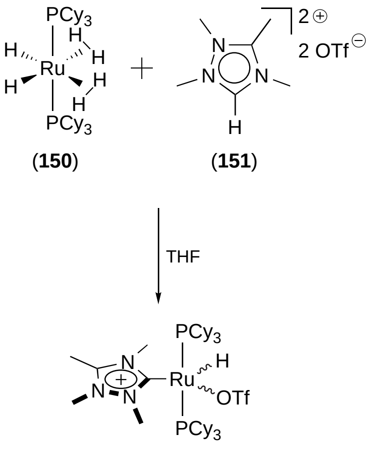


(147) (148) (149)

When the counteranion of the imidazolium salt was a chloride, the neutral $[(NHC)PdCl_2(PPh_3)]$ complex was obtained, the chloride triggering PPh_3 displacement from the metal coordination.[147] This route proved successful also for chiral NHC-containing palladium complexes (**147**) and (**148**). The cationic nickel analog (**149**) has been synthesized from reaction of $[Ni(COD)_2]$ and 2-chloro-1,3-dimethylimidazolidinium salts in the presence of two equivalents of PPh_3.

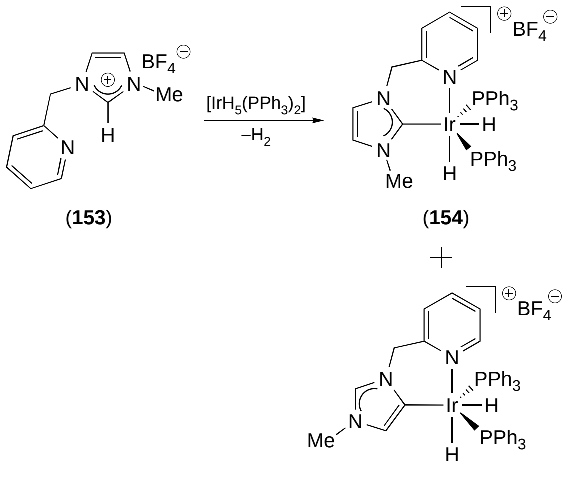
2.5 Reaction of Imidazolium Salts with Metal Hydrides

In 1968, Öfele reported that heating the adduct $[IDMH][HCr(CO)_5]$ at 120 °C yielded the NHC–Cr carbonyl complex $[(IDM)Cr(CO)_5]$.[1] Forty years later, reactions using metal hydrides to synthesize NHC–TM complexes are still scarcely used. Nonetheless, Sabo-Etienne and Chaudret synthesized a mixture of stereoisomers of the Ru complex (**152**) from $[RuH_2(PCy_3)_2(H_2)_2]$ (**150**) and tetramethyltriazoilum triflate (**151**) (equation 22).[148]



(150) (151) (152) (22)

Crabtree and Faller developed a similar route using $[IrH_5(PPh_3)_2]$ and the imidazolium salt (**153**) (equation 23).[149] Whereas the expected product (**154**) has been isolated, another complex was formed and identified as (**155**), showing an unusual chelation of the imidazolium moiety. Using benzimidazolium salts, because of the protection of the C4 and C5 positions, only the expected complex was observed.



(153) (154) (155) (23)

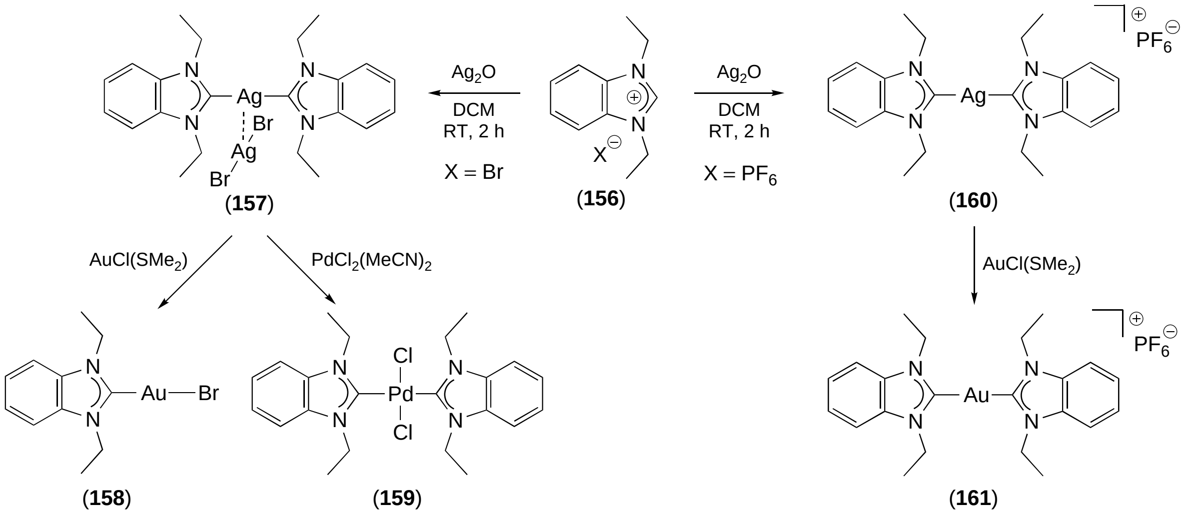
2.6 Synthesis by Silver-mediated Transmetallation

NHC transmetallation can be mediated by different TMs; however, only Ag–NHC complexes are commonly used for TM-complex synthesis.[150,151] The straightforward synthesis of NHC–Ag complexes, their high stability, and their tolerance to functional groups explain the success of this procedure. Other TM-mediated transmetallation are presented in Section 3.1.4.

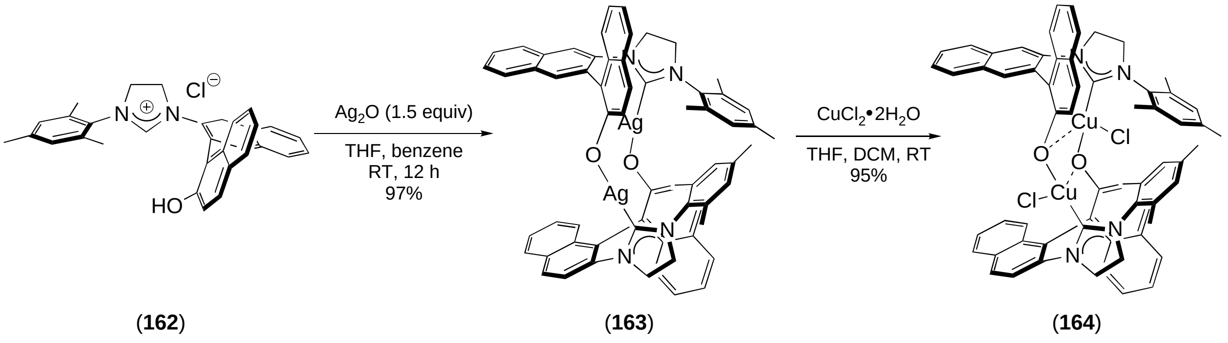
The first synthesis of NHC–Ag complex was performed by Arduengo from $Ag(CF_3SO_3)_2$ and free carbene,[108] but later Lin developed a much easier procedure.[152] This procedure has the advantage that it does not require the synthesis and isolation of the free carbene. It was found to be non-air-sensitive and is carried out using mild reaction conditions. As depicted in Scheme 26, reaction of benzimidazolium salts (**156**) with Ag_2O in air and at room temperature afforded cationic biscarbene complex (**157**) (X = Br) or (**160**) (X = PF_6). These Ag-based complexes proved to be very efficient transmetallating agents. Indeed, reaction of $[Ag(NHC)_2](AgBr_2)$ (**157**) with $[AuCl(SMe_2)]$ gave the monocarbene complex [AuBr(NHC)] (**158**), while with $[PdCl_2(MeCN)_2]$ the palladium complex $[PdCl_2(NHC)_2]$ (**159**) was obtained. Interestingly, with PF_6 as counteranion, both NHCs were transferred to $[AuCl(SMe_2)]$ yielding the biscarbene complex (**161**).

Both the presented synthetic routes to NHC–Ag complexes and the subsequent NHC transmetallation were found to be very tolerant to the NHC steric hindrance. For example, Nolan reported the synthesis of a large library of [AgCl(NHC)] complexes.[153] Compatibility with functional groups was also demonstrated, since Hoveyda used this procedure for the synthesis of Cu(II) catalyst bearing an aryloxy-containing NHC.[154] As depicted in Scheme 27, treatment of salt (**162**) with Ag_2O led to the formation the dimeric complex (**163**). The resulting dimer has been used as an NHC transfer agent for the synthesis of NHC–Cu(II) dimer (**164**).

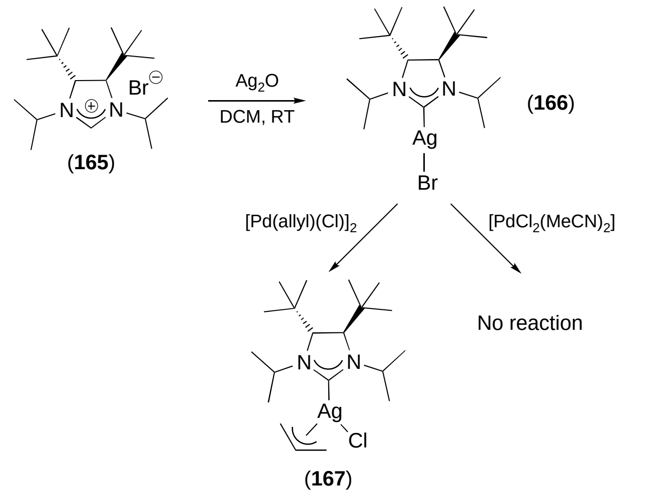
The transmetallation process was found competent for several metals – for instance, Crabtree and coworkers reported the transmetallation of $[Ag(NHC)_2](AgCl_2)$ to Rh(I) and Ir(I).[155] Owing to its mild reaction conditions, this procedure for the synthesis of NHC-containing complexes has found



Scheme 26 Synthesis of several NHC–Ag complexes and their reactivity in transmetallation reactions



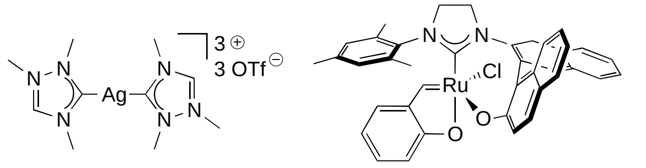
Scheme 27



Scheme 28 Importance of metal source in transmetallation process

special use for the transfer of chiral NHC ligands. Complex (**166**) was synthesized from the chiral salt (**165**) and Ag_2O without racemization of chiral centers (Scheme 28).[156] Complex (**166**) has been used to transfer the chiral NHC to [(allyl)$PdCl_2$] affording the Tsuji–Trost catalyst (**167**). However, the importance of the metal source should not be disregarded, since reaction with [$PdCl_2(MeCN)_2$] did not lead to the expected product.

Recent investigations demonstrated that it is not necessary to isolate the NHC–Ag complexes.[105,157] For example, several NHC–Au(I) complexes have been synthesized by mixing the carbene salt, Ag_2O, and [AuCl(SMe_2)] in a one-pot reaction. A few other silver bases have been employed, such as Ag_2CO_3[158] or AgOAc.[159] AgOAc has been used as a precursor to synthesize bistriazolium Ag(I) complexes (**168**), and $AgCO_3$ to prepare the Ru-based enantioselective metathesis catalyst (**169**).[160]



(**168**) (**169**)

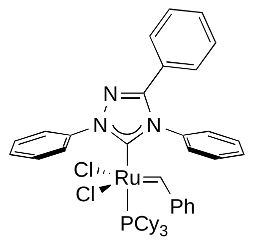
3 STABILITY AND REACTIVITY OF NHC-CONTAINING METAL COMPLEXES

Compared to phosphine ligands, NHCs are well known to significantly improve the stability of transition metal complexes, allowing for major advances in the field of catalysis. Even if the metal–NHC bond was considered for a while as inert and the NHC ligand as noninterfering, numerous reports mentioned different behaviors of these complexes.[161] In this section, we present an overview of NHC–TM complexes, focusing on the stability of the metal–NHC bond and the reactivity of the complexes involving the NHC ligand itself.

3.1 Stability of NHC–TM Complexes

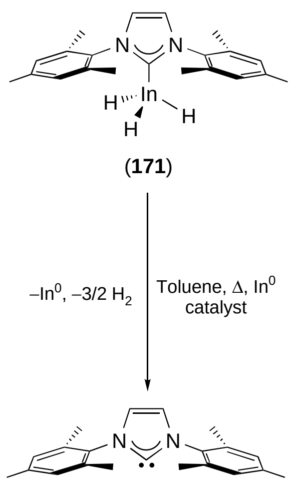
3.1.1 NHC–TM Bond Cleavage

Till now, triazolylidene and thiazolylidene have been scarcely studied as TM ligands, although they find numerous applications in organocatalysis.[162,163] The stability of complexes binding these types of NHC has not been extensively reported and could explain why their use remains scarce. As an example, metathesis ruthenium-based catalyst (**170**) first synthesized by Fürstner exhibited a moderate activity in metathesis transformations in relation to its poor stability in solution.[68] This problem of reactivity/stability has been pointed out in others reports.[27,164]



(**170**)

The stability of trihydride complex (**171**) has been found to be a remarkable feature.[165] Complex (**171**) is stable under inert atmosphere up to 115 °C in the solid state and in toluene solution at room temperature for months. It was observed that when the toluene solution was heated at 100 °C, no decomposition occurred until indium(0) traces appeared. In the presence of catalytic amount of indium(0), complex (**171**) decomposed entirely in a few minutes, freeing the free carbene, IMes (equation 24).

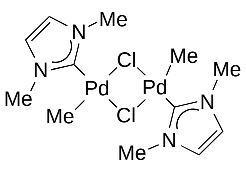


(24)

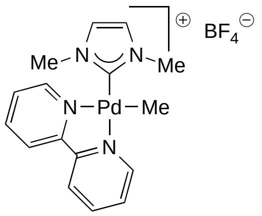
3.1.2 Redox Processes

NHC–TM complexes can be involved in redox processes, especially reductive elimination, leading to the cleavage of the NHC–TM bond and so to the decomposition of the complex. This subject has been comprehensively reviewed by Cavell and McGuinness.[166]

In 1998, Cavell *et al.* reported that some NHC–Pd complexes such as (**96**) and (**172**) were found moisture- and temperature-sensitive and needed to be stored under inert atmosphere below 5 °C.[92] Moreover, under atmospheric pressures of CO, (**96**) and (**172**) were quickly decomposed to Pd(0) and organic products.

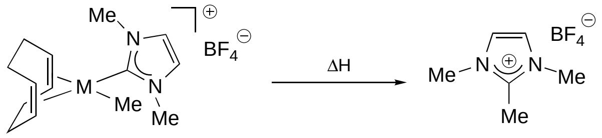


(**96**)



(**172**)

Investigations on the decomposition of complex (**173**) allowed for the identification of degradation products (equation 25).[93] The only detectable products were found to be 1,2,3-trimethylimidazolium salt (**174**), free COD, and Pd(0).



(**173**) (**174**) (25)

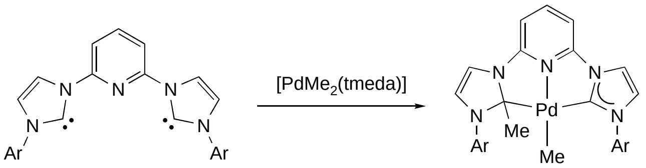
+

COD

+

Pd(0)

To explain this degradation, two different reaction pathways have been proposed (Scheme 29). The reaction may proceed by concerted reductive elimination or alternatively by migratory insertion, giving the intermediate (**175**) and subsequent heterolytic cleavage. Kinetic studies and DFT calculations supported the second proposed pathway.[142,167] An interesting clue supporting the migratory insertion is shown in equation (26). Danopoulos reported that reaction of the biscarbene (**176**) with [Pd(Me)$_2$A(tmeda)] did not allow for the isolation of the expected biscarbene complex but led solely to complex (**177**). Complex (**177**) was formed by a facile migratory insertion reaction and was stable enough to avoid decomposition into imidazolium salt.[168]

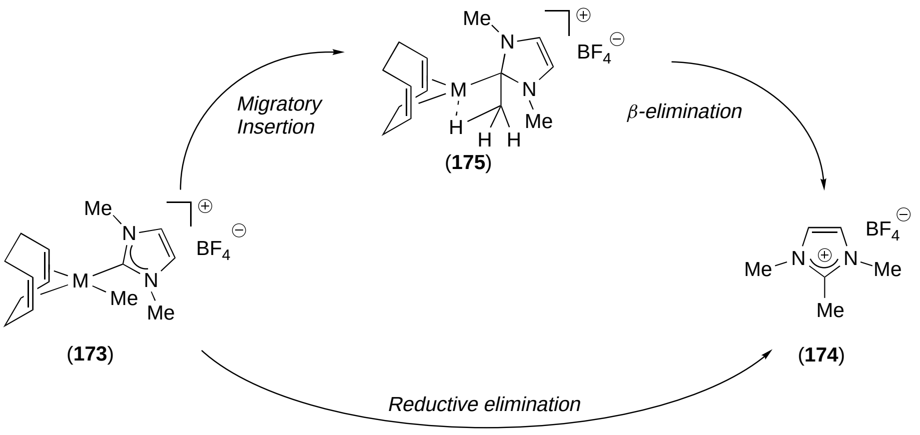


(**176**) (**177**)

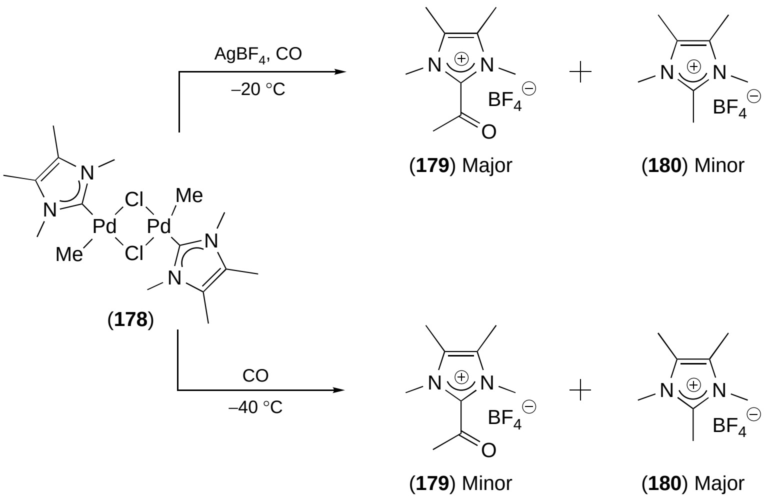
(26)

Reactivity and stability of methylpalladium complexes have been examined with CO also, and facile reductive elimination was observed.[169] Reaction conditions were found to drive the formation of the degradation products (Scheme 30). Whereas, in the presence of silver salt, the 2-acylimidazolium salt (**179**) was observed as the major product, in its absence, complex (**178**) was degraded mostly into methylimidazolium salt (**180**). These results indicated that in the presence of silver salt, a coordination site of the palladium was free and led to the easiest coordination of CO, which is the key step for the carbonylation occurring before the degradation.

The stability of NHC-containing methylpalladium complexes was found dependent on different parameters such as the chelate bit-angle, but the chelating ligands itself appears

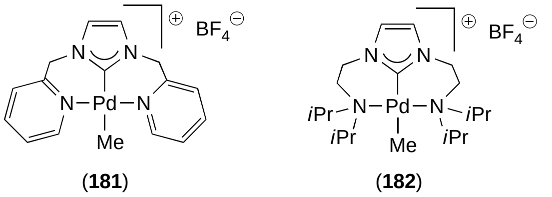


Scheme 29



Scheme 30

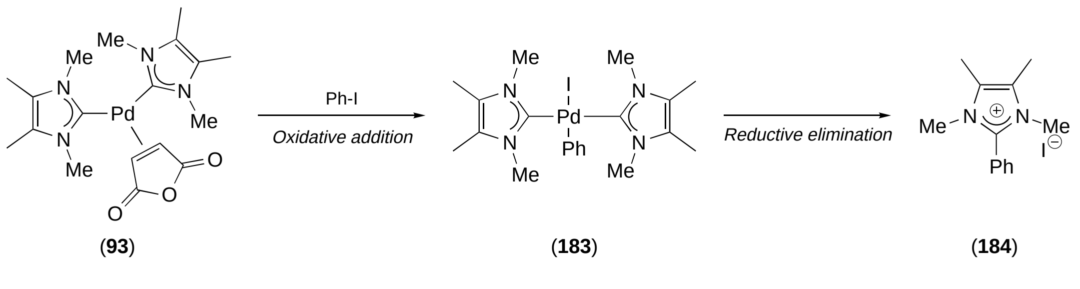
to be an even more important factor. As an example, complexes (**181**) and (**182**) binding amine functions exhibit totally different thermal stabilities.[170] Whereas (**181**) was found to be one of the most stable methylpalladium complexes, the decomposition of (**182**) occurred rapidly at room temperature. The most rigid structure and the more donating pyridine appeared to be crucial for the high stability of (**181**).



Further investigations on reductive elimination processes showed that this reductive elimination could be the side reaction leading to degradation of active species in C–C cross-coupling reactions. As illustrated in Scheme 31, palladium-based catalyst (**93**) underwent oxidative addition in the presence of iodobenzene, providing the reaction intermediate (**183**), which could be involved in the catalytic cycle but also affords the imidazolium salt (**184**) by direct reductive elimination.[171] Since then, a few other examples of reductive elimination processes leading to the degradation of the catalytic species have been reported.[136,172] It is noteworthy that similar redox processes leading to the cleavage of the NHC–TM bond have also been reported with other group 10 metals: nickel[128,171,173] and platinum.[141]

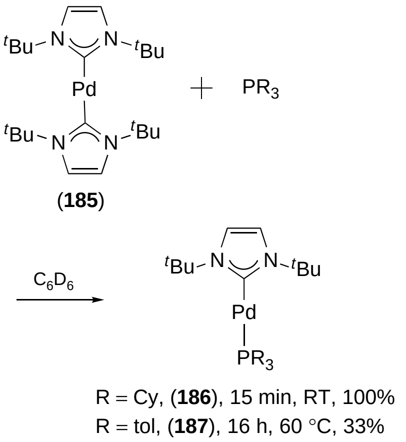
3.1.3 Ligand Substitution

The lability of the NHC ligands is unexpected. However, few examples of NHC substitution have been reported in the literature. Caddick and Cloke described that phosphines and free carbenes can replace coordinated NHC ligands in palladium-based complexes to give mixed NHC–phosphines complexes (equations 27–29).[78] Treatment of (**185**) with PCy_3 at room temperature resulted in a quantitative conversion to the mixed complex (**186**). Similar behavior was observed with the more sterically hindered $P(tol)_3$ with a lower conversion and requiring harsher reaction conditions. Ligand redistribution reaction between (**188**) and $P(tol)_3$ was also found to occur to give (**189**) in poor but isolable yield (equation 28). This same redistribution reaction was carried out with free I^tBu instead of the phosphine and yielded, at room temperature, the two-coordinated mixed NHC–palladium complex (**190**). These experiments demonstrated that ligand

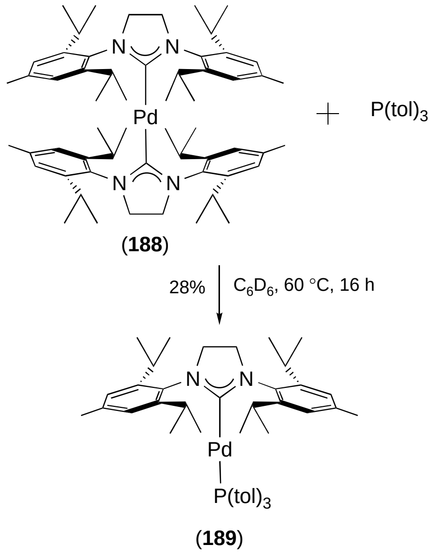


Scheme 31

substitution between phosphine and NHC are probably driven by steric effects.

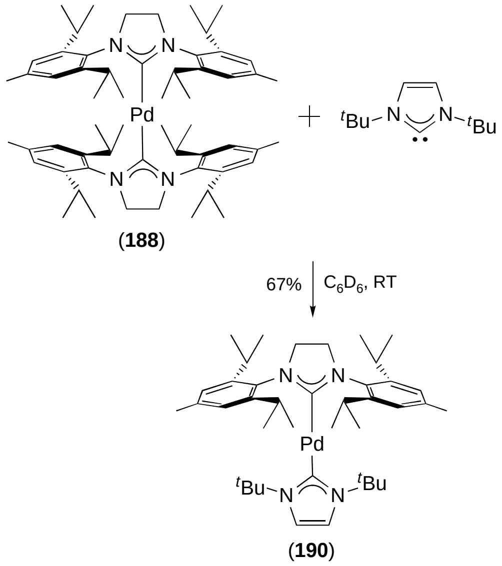


(27)



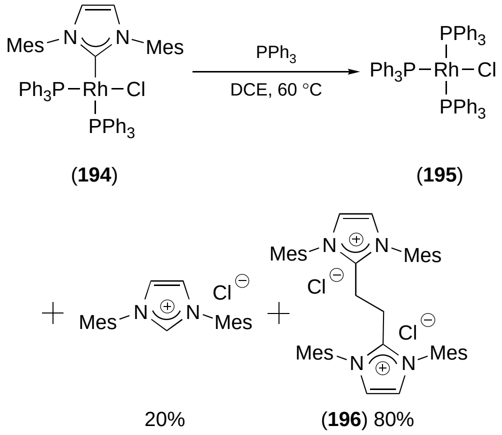
(28)

Displacement of phosphine by NHC ligand is not always obvious, mainly for steric reasons. For instance, during the reaction of $[CpCo(PPh_3)Me_2]$ with free IPr, an equilibrium between the NHC- and phosphine-containing complexes, (**191**) and (**192**), respectively, was observed (Scheme 32).[174] Moreover, addition to the reaction mixture of the less sterically demanding trimethylphosphine led to the formation of the more stable five-coordinated complex (**193**).



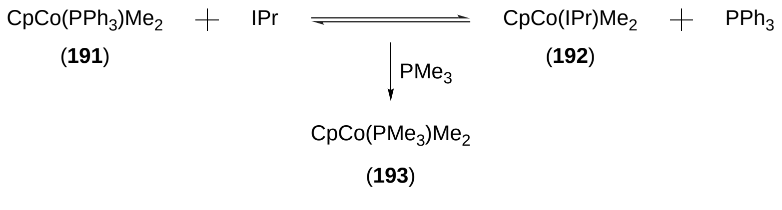
(29)

Another example of ligand substitution is an analog of Wilkinson's catalyst $[RhCl(PPh_3)_3]$ (**195**), in which one of the phosphines was replaced by an IMes ligand, complex (**99**).[175] As illustrated in equation (30), (**194**) underwent cleavage of the Rh−IMes bond when treated with triphenylphosphine in hot DCE to quantitatively yield Wilkinson's catalyst. The corresponding salt IMes·HCl and a dimer (**196**) formed from a double S_N2 reaction involving the solvent. Two molecules of the carbene were also formed during this reaction.



(30)

Recently, Arnold *et al.* reported on the synthesis and stability of f-block NHC-containing complexes.[176] The



Scheme 32

reactions of some yttrium and zirconium complexes with phosphine oxides are illustrated in equations (31–34).[177] Whereas (**197**) is decomposed, chlorine substituted (**198**) afforded six-coordinated adduct (**199**). On the other hand, zirconium analog (**200**) exhibited excellent stability under comparable conditions (pyridine was used because of the poor solubility of (**200**) in benzene). These experiments confirmed the better lability of the Y–NHC bond compared to Zr–NHC bond. A special reactivity was observed for mono-NHC complex (**201**); triphenylphosphine oxide succeeded in displacing the carbene, while neither triphenylphosphine, trimethylamine oxide, THF, nor diethylether reacted.[178]

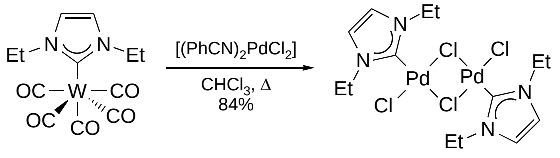
(34)

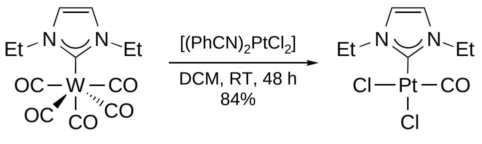
3.1.4 Transmetallation Processes

Silver–NHC complexes have been shown as excellent NHC delivery agents.[150,151] Few examples of transmetallation using distinct late TMs have been reported. Tungsten pentacarbonyl NHC complex (**203**) was found efficient to transfer easily its NHC ligand to palladium (equation 35) and platinum (equation 36) yielding, respectively, palladium dimer (**204**) and platinum complex (**205**) with carbonyl ligand transfer.[179] This is to be noted, as chromium and molybdenum analogs of (**203**) exhibited similar reactivity.



(**203**) (**204**)

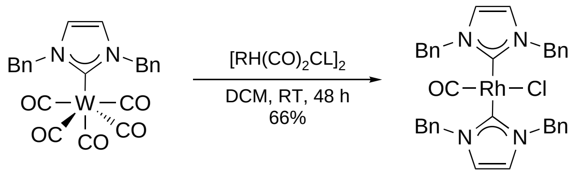
(35)



(**203**) (**205**)

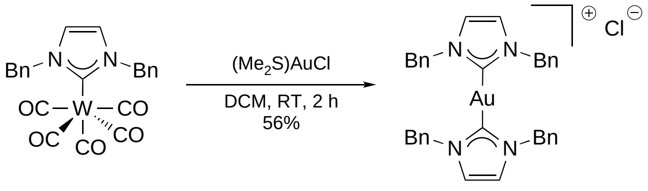
(36)

Transmetallation from tungsten to rhodium and gold has also been found possible.[180] As depicted in equation (37), substitution of a carbonyl ligand from a rhodium center by an NHC occurred in the reaction with $[Rh(CO)_2Cl]_2$ to form biscarbene complex (**207**). In an analogous manner, tungsten complex (**206**) reacted rapidly with $[AuCl(SMe_2)]$ at room temperature to afford, in moderate yield, the biscarbene gold complex (**208**) (equation 38). Even if tungsten, molybdenum, and chromium carbonyl complexes showed an excellent ability to transfer NHC ligand, they are not widely used because of their poor stability. Oxidation with metal or molecular oxygen takes place extremely rapidly in these systems, yielding the



(**206**) (**207**)

(37)



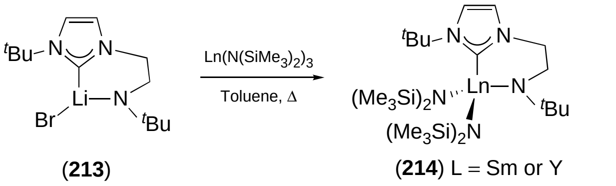
(**206**) (**208**)

(38)

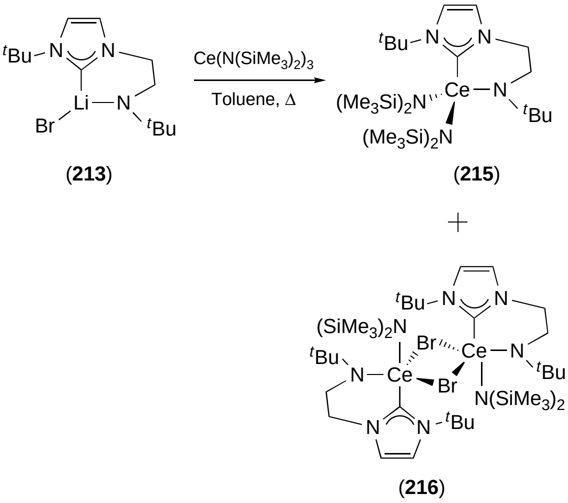
corresponding imidazolium salt or cyclic urea. For this reason, NHC transfer from tungsten to gold and silver affording biscarbene complexes has been observed, but their subsequent decomposition could not be avoided.

Hollis and coworkers reported also on a transmetallation process from zirconium to rhodium.[181] As illustrated in Scheme 33, imidazolium salt (**209**) reacted instantaneously with $Zr(NMe_2)_4$ to generate the biscarbene pincer (**210**) with orthometallation of the phenyl group. The biscarbene pincer was not isolated, but reacted with $[Rh(COD)Cl]_2$. The Rh(III) complex (**211**) was isolated in equilibrium with the dimer (**212**).

Lithium(I) NHC adducts are extremely rare, but some examples have been isolated as stable crystalline solids when a functional group is involved for their stabilization, the amino group, for instance.[176] Since these showed to be effective in transmetallation processes, they represent an interesting alternative to the expensive silver complexes. As an example, Arnold reported the synthesis of covalently tethered lanthanide carbene complexes (**214**) using adduct (**213**) as source of NHC (equation 39).[178] Using (**213**) and the same methodology, unusual cerium complexes (**215**) and (**216**) were isolated and characterized (equation 40).[182]



(39)

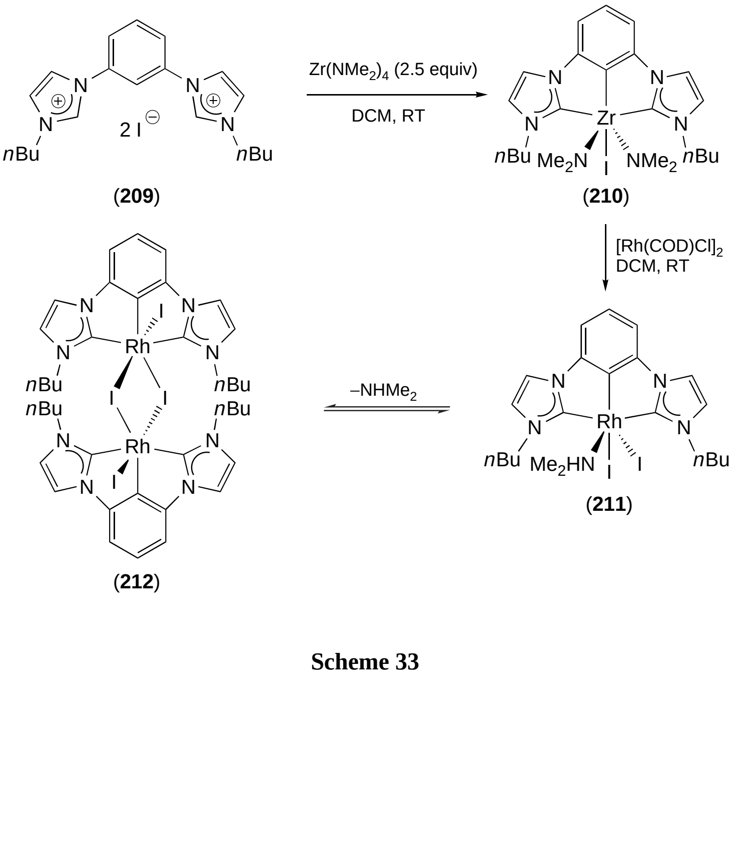


(40)

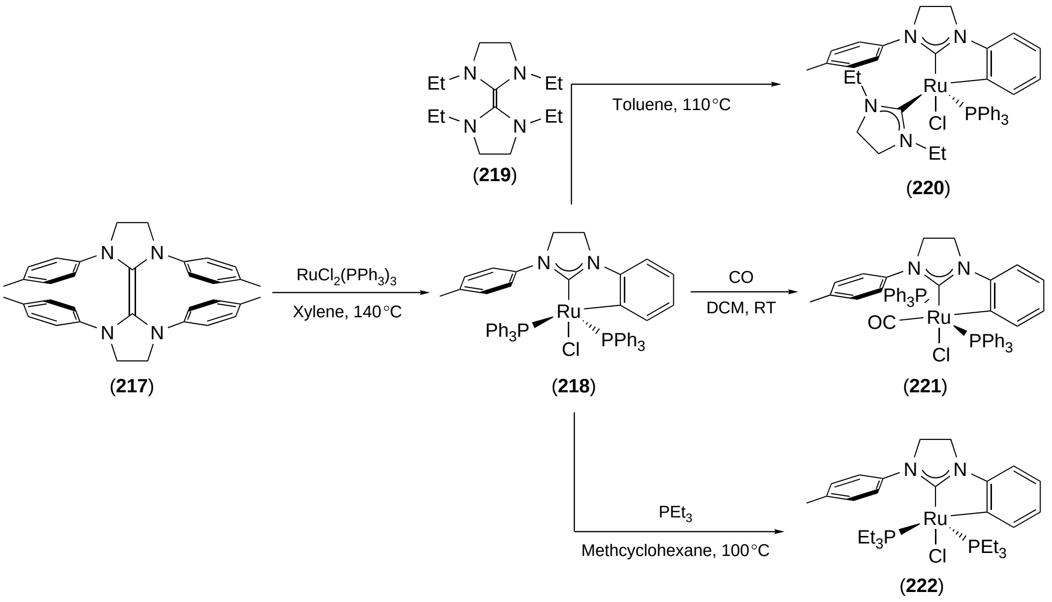
3.2 C–H Activation – Metallation Processes

The selective activation and functionalization of C–H bonds has attracted much attention in recent years.[183] In spite of the common proposal, which postulates that NHC ligands coordinated to TM are relatively inert, several examples of C–H activation processes involving NHCs have been reported. Because of the high electron-donating property of NHCs, some TM–NHC complexes have been found to undergo facile intramolecular C–H bond activation.

The first examples of C–H activation of an NHC ligand by TMs were reported by Hitchcock and Lappert and centered on ruthenium[184,185] and iridium.[186] $[RuCl_2(PPh_3)_3]$ reacted with the dimeric carbene (**217**) in xylene at 140 °C to give the five-coordinate monocarbeneruthenium (II) complex (**218**),



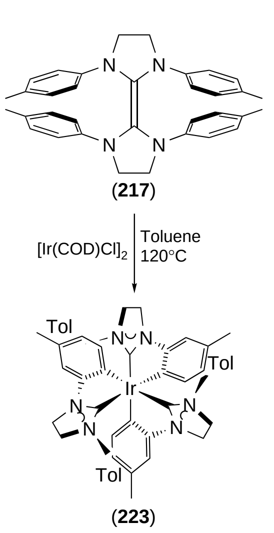
Scheme 33



Scheme 34

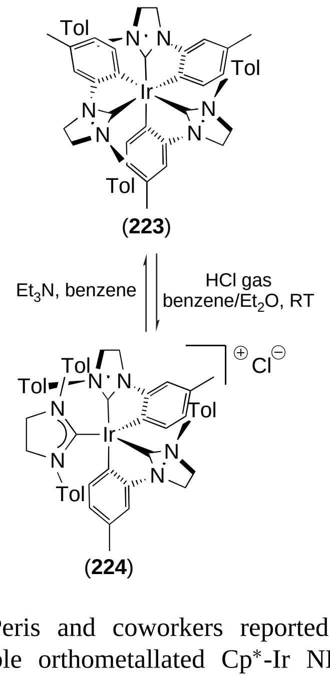
containing a five-membered metallacycle (Scheme 34). It should be pointed out that with smaller *N*-substituents (methyl or ethyl group) tetracarbeneruthenium (II) complexes were obtained.[187] Studies of the stability and reactivity of (**218**) showed that a small NHC could substitute for a phosphine ligand using the dimer (**219**) to yield the biscarbene (**220**). Moreover, reaction with carbon monoxide resulted only in CO binding to the metal center to yield the six-coordinated species (**221**). The treatment of (**218**) with more sterically hindered ligand such as PEt_3 led to the five-coordinated complex (**222**).

Different from the ruthenium system previously discussed, $[Ir(COD)Cl]_2$ reacted with the electron-rich olefin (**217**) to afford the homoleptic organoiridium tricycle complex (**223**) with an increase of the iridium oxidation state from (I) to (III) (equation 41). This spontaneous orthometallation process



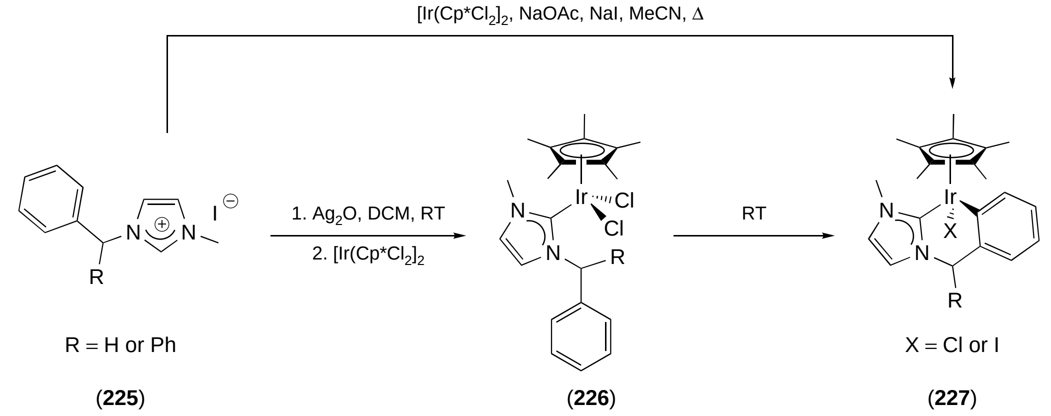
(41)

could be reversed by anhydrous HCl leading to the scission of one of the Ir–C bonds (equation 42). Dehydrochlorination of salt (**224**) using basic conditions caused the orthometallation and the reformation of complex (**223**).



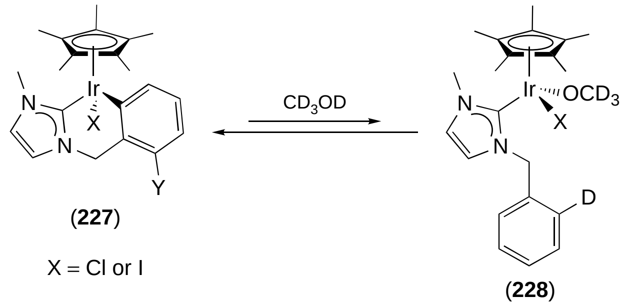
(42)

Recently, Peris and coworkers reported the synthesis of highly stable orthometallated Cp*-Ir NHC complexes and a catalytic application in the deuteration of organic molecules.[188,189] Complexes (**227**) were synthesized from imidazolium salt (**225**) and $[IrCp^*Cl_2]_2$ as metal precursor either by a one-step procedure with sodium iodide to minimize the mixture I versus Cl or by transmetallation from the corresponding silver carbene affording (**226**) followed by the C–H activation of the phenyl ring by the iridium



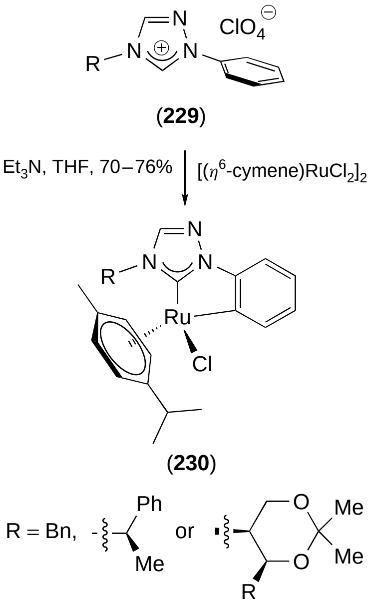
Scheme 35

center (Scheme 35). The easy orthometallation that occurs at room temperature allows for an evaluation of the performance of (**227**) in C–H activation reactions. As depicted in equation (43), refluxing (**227**) in methanol-d_4 led to quantitative deuteration of the ortho position of the phenyl group. The dynamic metallation/demetallation equilibrium process was confirmed by high levels of deuteration of organic molecules obtained when this catalyst is engaged in reaction with deuterated methanol at 100 °C.

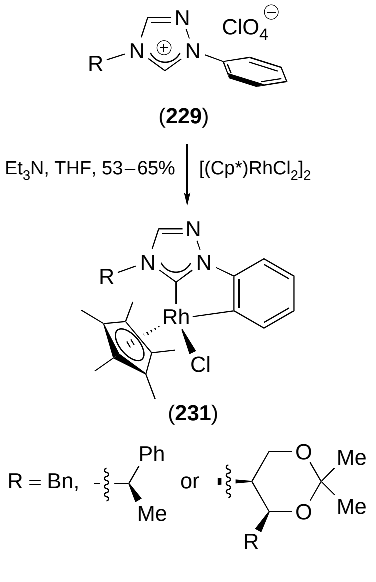


(43)

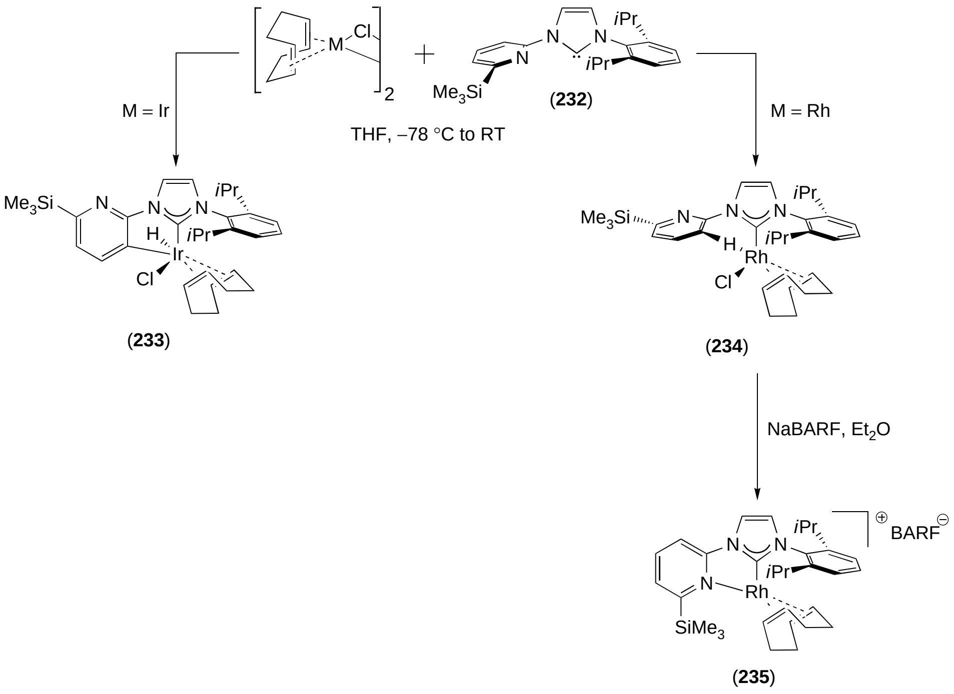
Two C–H activation examples have been reported using triazolium salt (**229**) as NHC ligands.[44,190] With the aim of introducing chirality into a catalyst to generate a stereogenic metal center, Enders synthesized ruthenium and rhodium complexes (**230**) and (**231**) containing chiral orthometallated *N*-phenyltriazolylidene ligands (equations 44 and 45). In situ deprotonation of the corresponding triazolium salts and reaction of these carbenes with dimeric complexes $[(\eta^6\text{-cymene})RuCl_2]_2$ and $[Cp^*RhCl_2]_2$ afforded, respectively, mononuclear complexes (**230**) and (**231**) with the orthometallated phenyl group as chelating ligand. Because of their pseudotetrahedral structures, these complexes possess diastereomeric forms that can be separated by simple silica-gel chromatography. In the case of the rhodium-based complexes, the diastereomeric excesses were lower than ruthenium analogs because of slow epimerization that occurs in solution.



(44)



(45)



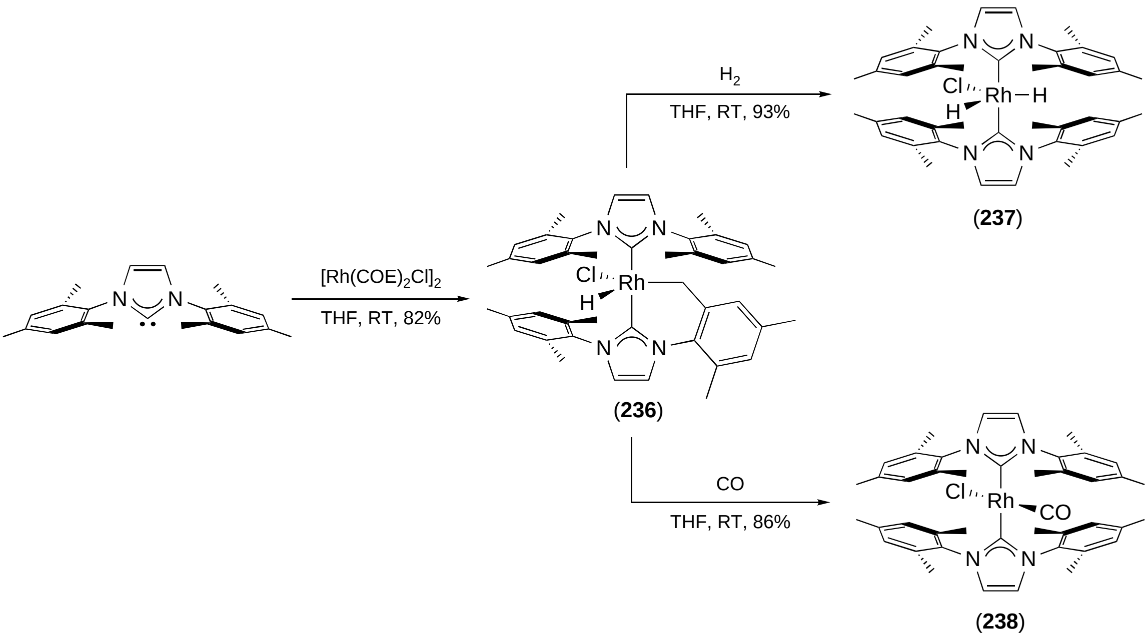
Scheme 36

The reactivity of iridium is often associated with that of rhodium; however, as shown in Scheme 36, iridium is more favorable toward activating the C–H bond and so this metal has been widely used for this reaction. Reaction of $[Ir(COD)Cl]_2$ with one equivalent of the pyridine-functionalized NHC (**232**) gave in quantitative yield the complex (**233**) by cleavage of the metallic precursor dimer and orthometallation of the pyridine moiety (Scheme 36).[191] In contrast, the same reaction carried out with $[Rh(COD)Cl]_2$ as the metal source afforded (**234**), for which a strong interaction between the rhodium center and the *ortho* hydrogen of the pyridine was observed. Treatment of (**234**) with a sodium salt did not lead to a C–H activation, but led to the coordination of the pyridine onto the metal center yielding the air stable (**235**).

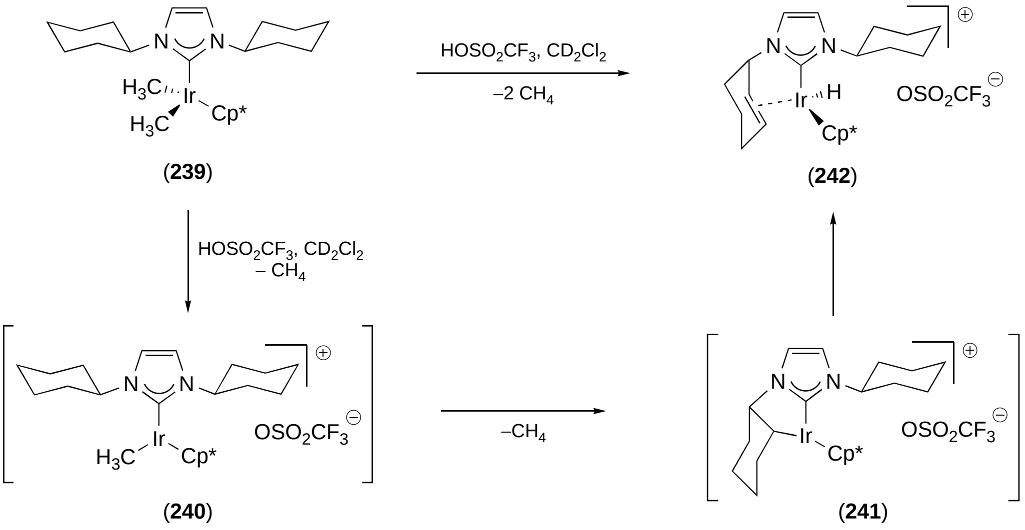
Nolan *et al.* reported an early example of C–H activation of the methyl group, namely, cyclometallation, by a rhodium center.[192] The reaction of four equivalents of IMes with $[Rh(COE)_2Cl]_2$ in THF at room temperature rapidly gave an orange microcrystalline product, identified as (**236**) (Scheme 37). This biscarbene-containing rhodium complex results from C–H bond activation of an internal aryl methyl C–H bond of one of the IMes ligands, producing a five-coordinate Rh(III) alkyl hydride complex. The stability of complex (**236**) has been investigated. Under an atmosphere of H_2, the dihydride complex (**237**) was quickly formed in quantitative yield. Moreover, under CO atmosphere, (**236**) gave the product (**238**) binding a carbonyl group with the cleavage of the Rh–C bond. These experiments show that, like the orthometallation, the cyclometallation can be reversed.

Many examples of cyclometallation process have been reported involving iridium as the metallic center. As illustrated in Scheme 38, treatment of ICy-containing complex (**239**) with one equivalent of trifluoromethylsulfonic acid to replace one methyl group led instantly to the formation of the metal hydride (**242**) with methane evolution.[118] X-ray diffraction studies confirmed the π-coordination double bond of one of the *N*-substituents. To explain the formation of (**242**), the authors assumed that trifluoromethylsulfonic acid drove methane elimination and formation of the complex (**240**), with an equilibrium established between the coordinated and free triflate complexes. The 16-electron species (**240**) evolves by a C–H bond activation process of the cyclohexyl group to form (**241**) and subsequent β-hydrogen migration giving the final product. The overall reaction (cyclometallation/β-hydrogen migration) leads to the formation of a stereogenic center and a double bond.

Major achievements in cyclometallation processes involving NHC ligands have been achieved by Nolan and coworkers.[193,194] It was observed that the solvent could play a crucial role in the formation of rhodium- and iridium-based complexes. As shown in Scheme 39, the reaction performed in pentane between $[M(COE)_2Cl]_2$ (M = Rh or Ir) and four equivalents of I^tBu led only to COE substitution by the NHC ligand affording rhodium-based product (**243**) (the iridium complexing proving difficult to isolate). On the other hand, the same reaction carried out in hexanes gave, via C–H activation, the hydride complexes (**244**) and (**245**). Finally, in benzene, a unique double cyclometallation process occurred to yield the coordinatively unsaturated 16-electron



Scheme 37

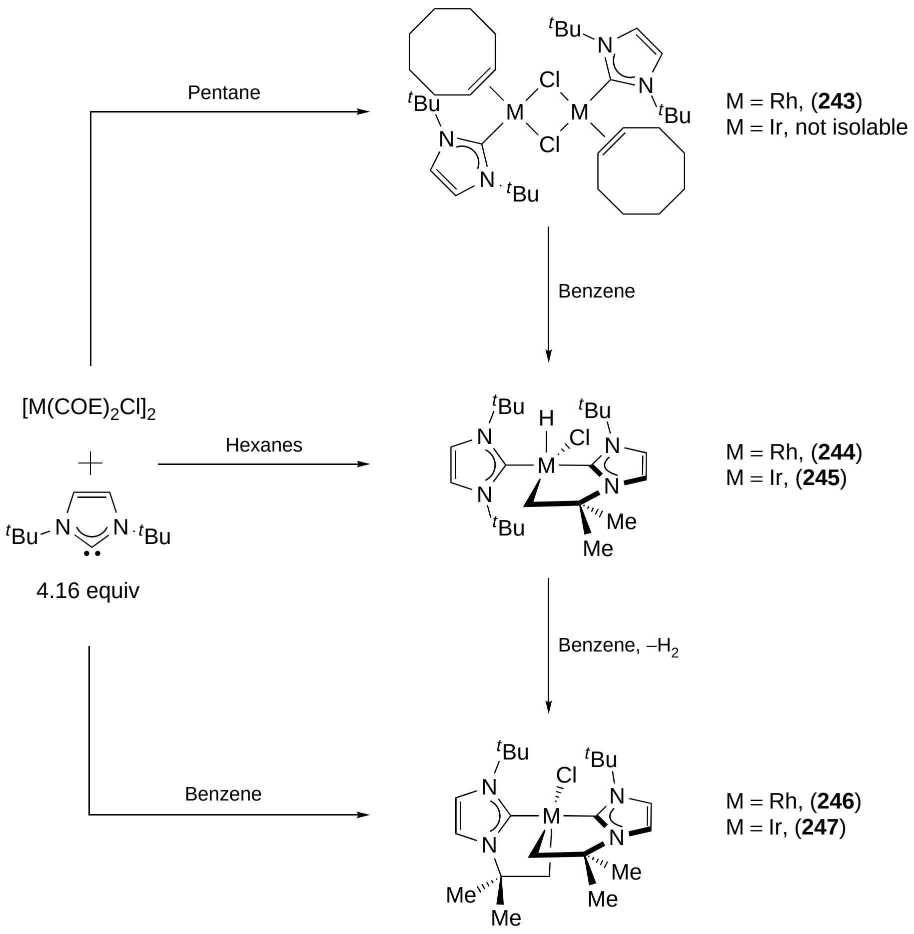


Scheme 38

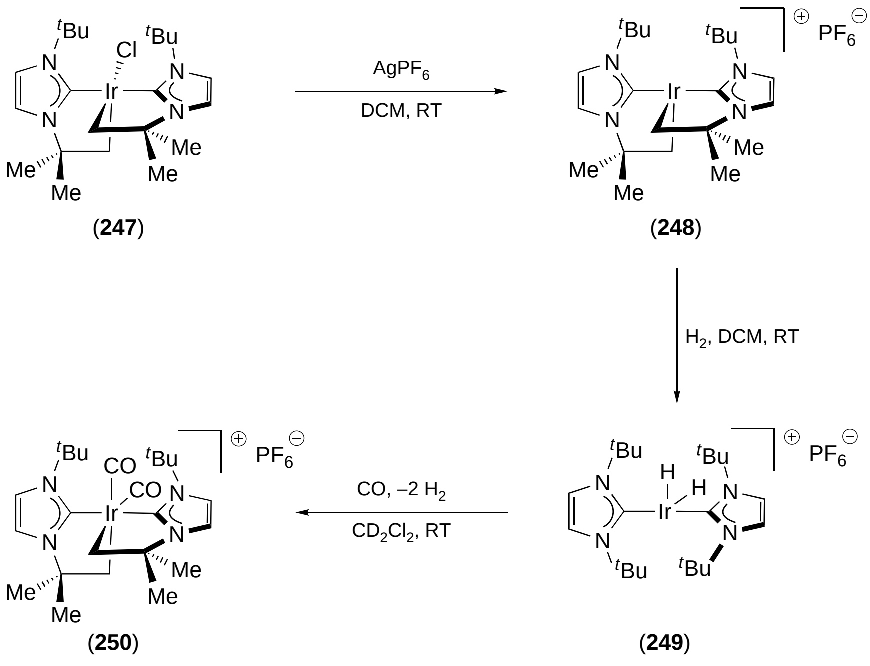
complexes (**246**) and (**247**), which are stabilized by agostic interactions. The solvent-dependent interaction, which is carried out in benzene, was also emphasized in the conversion of isolated complexes (**243**), (**244**) and (**245**) into (**244**), (**246**), and (**247**), respectively.

Abstraction of the chloride from complex (**247**) by a silver salt allowed for the preparation of the unprecedented *naked* cis-divacant four-coordinate 14-electron complex (**248**) (Scheme 40). Further examination of this coordinatively unsaturated cationic complex showed that, in presence of H_2 gas, the double cyclometallation process could be reversed to give a remarkable electron-deficient cationic dihydride complex (**249**).[195] The unsaturated nature of (**249**) allowed for its rapid reaction in the presence of carbon monoxide to form the dicarbonyl complex (**250**) by a double sequence C–H activation/hydrogen elimination.

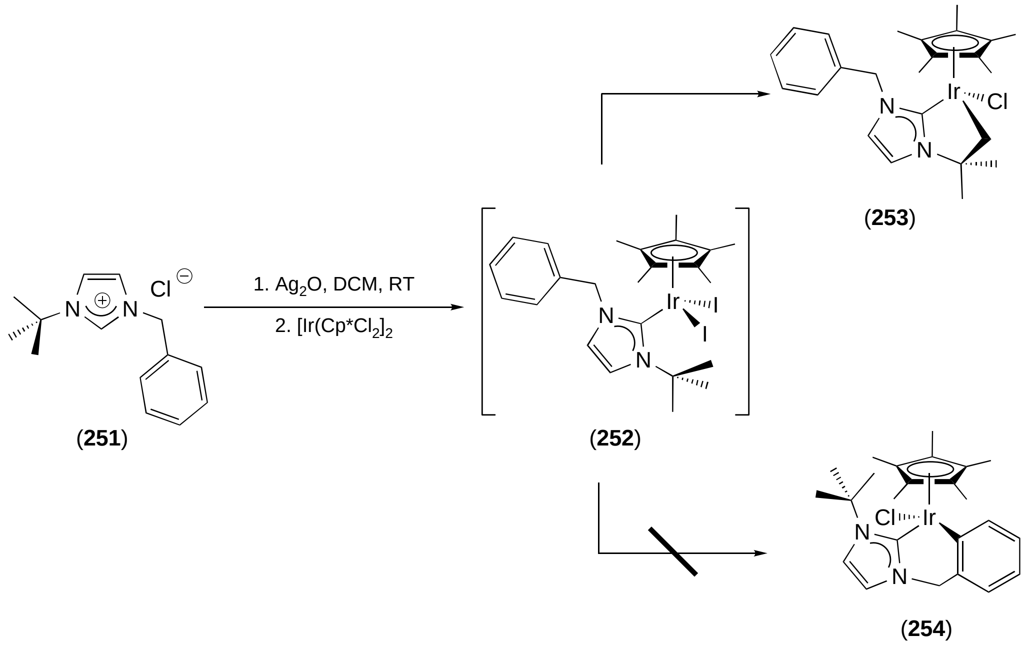
Following their work on orthometallation with iridium-based complexes, Peris *et al.* investigated the difference between aromatic and aliphatic C–H activation processes. They reported the preparation and reactivity of alkyl-functionalized imidazolylidene complexes of iridium (III) undergoing intramolecular cyclometallation.[196] As shown in



Scheme 39



Scheme 40



Scheme 41

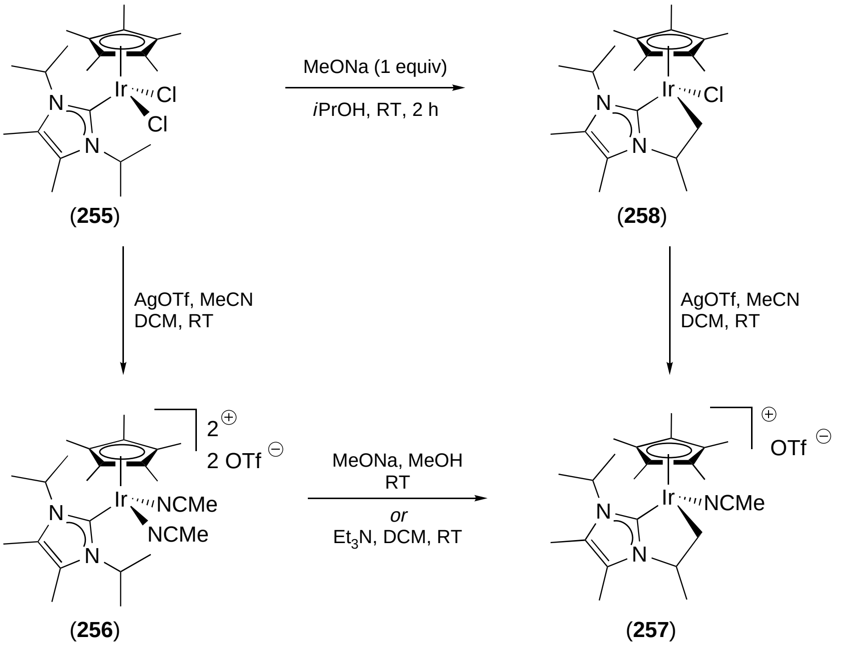
Scheme 41, starting from 1-benzyl-3-*tert*-butylimidazolium iodide (**251**), reaction with Ag_2O and further addition of $[Cp^*IrCl_2]_2$ provided the complex (**252**) that instantaneously gave alkyl C–H activated product (**253**). It is noteworthy that neither intermediate (**252**) nor orthometallated complexes (**254**) were detected. This suggests that the alkyl C–H activation is a readily accessible process. The unique formation of (**253**) suggests that the aliphatic C–H activation process is more favorable compared to the aromatic version, but this conclusion should be taken arrived at with caution. First, since the size of the metallacycle formed is not the same, ring size probably plays a major role. Moreover, using an imidazolium salt with an *iso*-propyl group instead of the *tert*-butyl requires the use of a base to achieve the C–H activation and only the orthometallated product was isolated.[196] To rationalize these results, the authors proposed that steric factors are critical. In the case of the *tert*-butyl group, the steric pressure around the metal center may be triggering the aliphatic cyclometallation to reduce congestion.

Independent investigations on the ability of NHC ligands to be involved in cyclometallation processes have been carried out by Yamagushi using an iridium system.[197] As presented in Scheme 42, reaction of iridium complex (**255**) with MeONa yielded the cyclometallated product (**256**) quantitatively by C–H activation of the *iso*-propyl group. It may be noted that when (**255**) was treated with silver salt, dicationic iridium complex (**257**) was formed without any cyclometallation product, showing that the base plays a role other than one as a chlorine abstractor. Reaction of (**256**) with silver triflate or (**257**) with a base gave the unstable cyclometallated complex (**258**), demonstrating that the coordination of basic ligands to the dicationic metallic center precedes the cyclometallation process. These data suggest the following mechanism: dechlorination of (**255**) is promoted by the base, then the intermediate undergoes direct C–H activation, and finally undergoes hydride elimination.

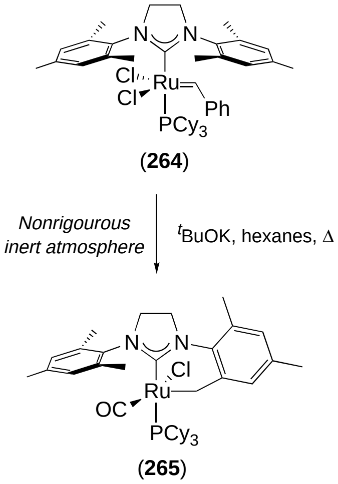
In this system, the cyclometallation may be favored by the presence of the methyl substituents on the NHC backbone, increasing the σ-donor character of the NHC ligand and enhancing the C–H activation process. These reactions have been successfully applied to introduce other ligands onto the metal center, such as alkoxy or amino groups that can be used as proton sponge.

Further studies demonstrated that changing the steric congestion of the NHC *N*-substituents allowed for tuning the reactivity of [Cp*Ir(NHC)Cl] complexes (Scheme 43).[198] Starting from (**259**), the use of one equivalent of *i*PrONa afforded the hydrido complex (**260**) contrasting with the previously presented reaction (Scheme 43); a second equivalent was necessary to form the stable cyclometallated product (**261**). Investigations of the stability of (**261**) showed that in chloroform a rapid chlorination occurred, leading to (**262**). While complex (**261**) was found stable in *iso*-propanol, in methanol it was slowly converted into dihydrido complex (**263**) with ring opening of the cyclometallated product.

Grubbs reported an unexpected reaction, which may be at play during the course of the synthesis of the second-generation olefin metathesis catalyst (**264**) (equation 46).[27] The product (**265**), air stable both in solution and in the solid state, results from the C–H activation of one *ortho* methyl of the mesityl group. Unfortunately, no explanation was proposed for the mechanistic pathway leading to (**265**).



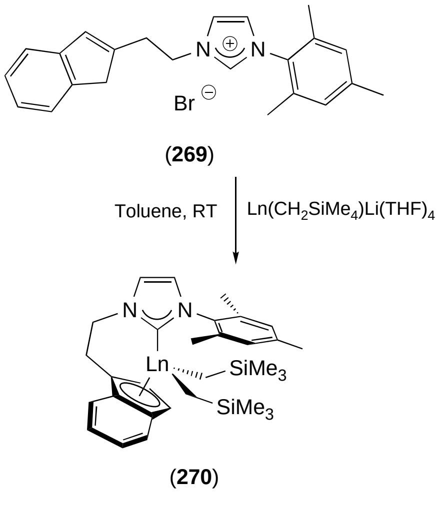
Scheme 42



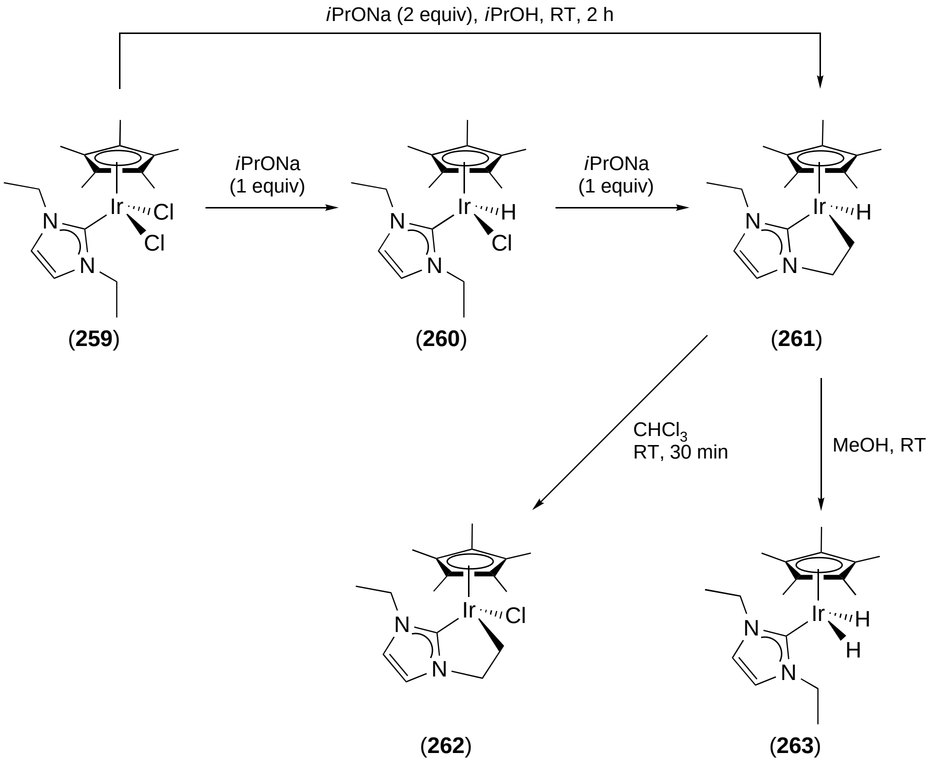
(46)

In the course of decomposition examinations of ruthenium olefin metathesis catalysts,[199] Grubbs and coworkers described a double C–H activation of the NHC ligand.[200] The heating of complex (**266**), bearing a benzimidazol-2-ylidene NHC, in benzene at 60 °C under inert conditions led to the formation of a decomposition product (**267**) in moderate yield (Scheme 44). Traces of a by-product (**268**) were observed. Interestingly, changing the solvent to dichloromethane-d_2 at 40 °C, led to (**268**) becoming the major decomposition product. X-ray crystallography analyses of these complexes showed that the benzylidene carbon atom of (**266**) had inserted into an *ortho* C–H bond of one of the *N*-substituents. Furthermore, η^6 binding of the ruthenium atom to the phenyl group of benzylidene pattern was noticed. Unlike (**267**), complex (**268**) showed an additional insertion of the ruthenium center into a second *ortho* C–H bond of the other *N*-phenyl group of the NHC ligand leading to the formation of a five-membered metallacycle. The authors have also shown that (**267**) can be converted quantitatively into (**268**) in the presence of tricyclohexylphosphine in dichloromethane-d_2.

An analogous example of C–H activation using rare earth metals has been recently described by Cui *et al.*[201] As shown in equation (47), starting from imidazolium salt (**269**) this one-step route involves a double-deprotonation process by the basic $Ln(CH_2SiMe_4)Li(THF)_4$ complex to give complexes (**270**) with Ln = yttrium, lutetium or scandium. The side substituents of the NHC ligand bind to Ln ion in η^5/k^1 constrained geometry configurations. Such solvent-free complexes of rare earth metal indicate the strong electron-donating nature of the NHC.

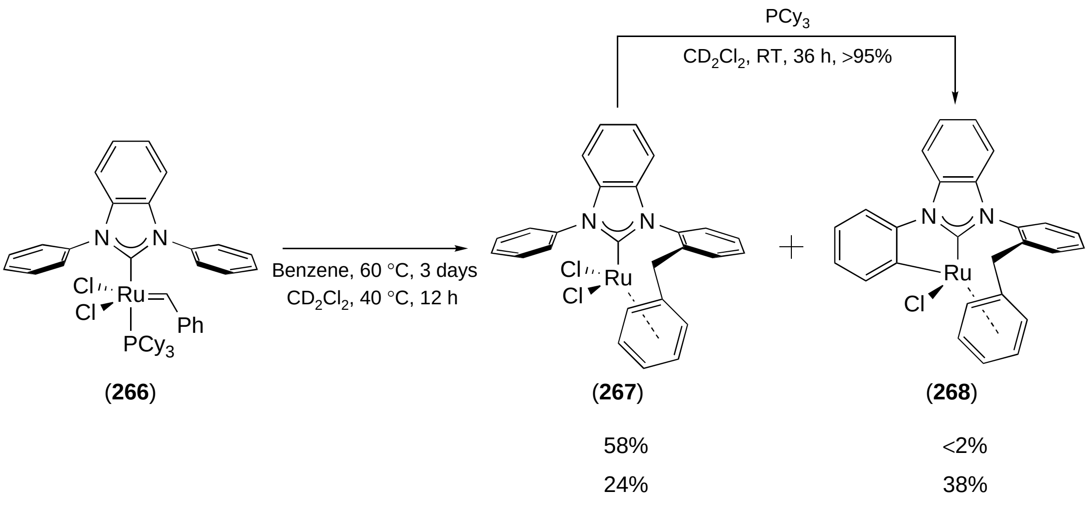


(47)

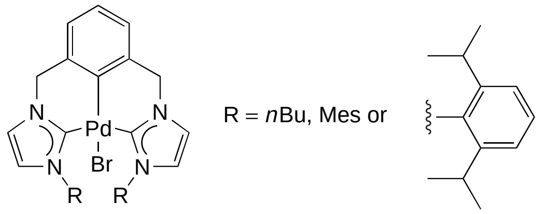


Scheme 43

Some other intermolecular C–H activations involving the NHC ligand have been observed during the synthesis of particular NHC-containing ''pincer''-type complexes also called CCC–NHC complexes.[202] In addition to zirconium- and rhodium-based complexes (**210**) and (**211**),[181] several examples involving palladium of general structure (**271**) have been synthesized. Whereas Faller and Crabtree have found that in presence of $Pd_2(dba)_3$ and K_2CO_3 the C–H activation of the bisimidazolium salt was unsuccessful (C–Br bond activation was used),[203] Danopoulos reported that heating $Pd(OAc)_2$ and the carbene precursor with NaOAc to 160 °C allowed for the efficient C–H activation yielding the orthometallated product (**271**).[204]



Scheme 44



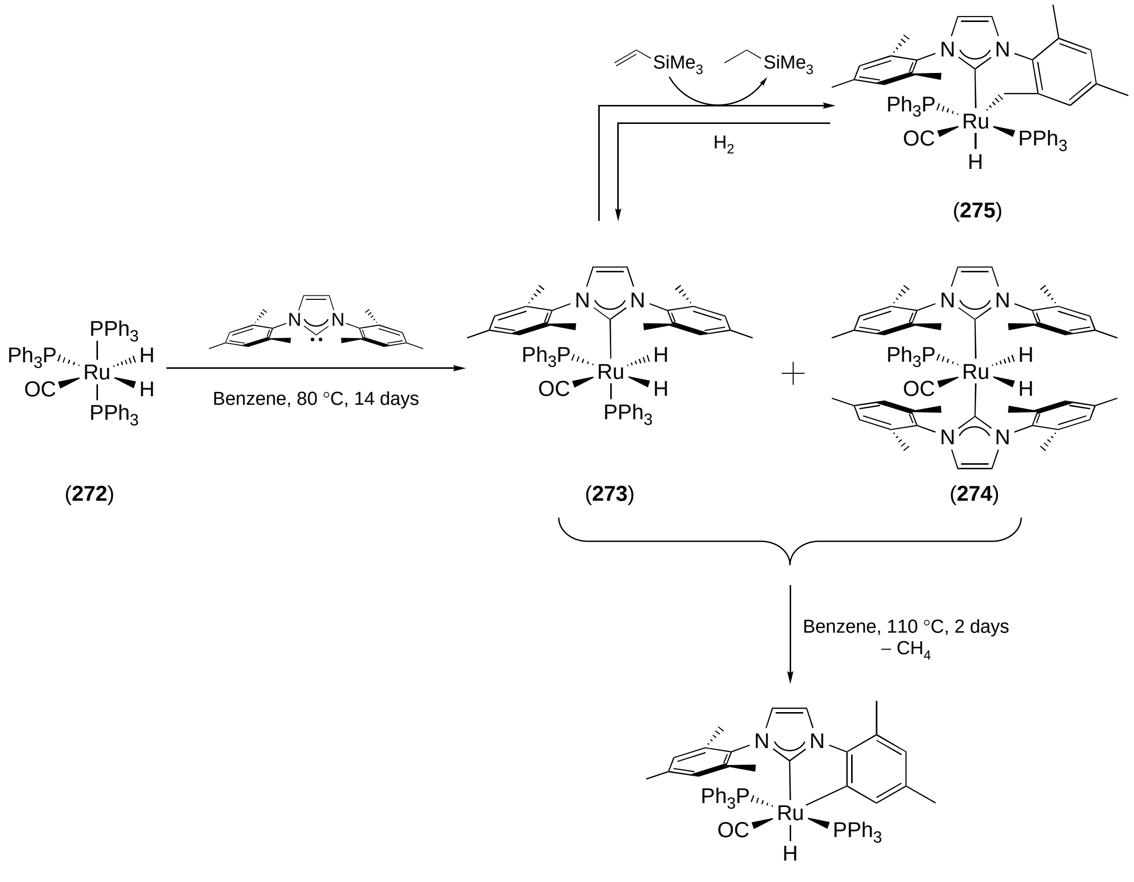
(**271**)

3.3 C–C Activation

While C–H activation reactions have been observed for many NHC–TM complexes, to the best of our knowledge, only one example of C–C bond activation has been reported to date.[60] As shown in Scheme 45, complex (**273**) reported by Whittlesey and Macgregor was found capable of either C–C or C–H bond activation as a function of reaction conditions. Reaction of three equivalents of free IMes with $[Ru(PPh_3)_2(CO)(H)_2]$ (**272**), at 80 °C, led to the formation of a mixture of monocarbene (**273**) and biscarbene complex (**274**). When more forcing conditions were used, product (**276**) was obtained in excellent yield resulting from the cleavage of methyl–mesityl bond. On the other hand, upon addition of vinyltrimethylsilane at room temperature, (**273**) reacted to produce a C–H activated species (**275**). It is to be noted that the same type of cyclometallation has been observed with ethyl groups as *N*-substituents.[205] Interestingly, direct insertion of ruthenium into an unstrained C–C bond of IMes is thermodynamically more favorable than the insertion into a C–H bond. Such an example is remarkable, since C–C single bonds are among the most unreactive bonds.

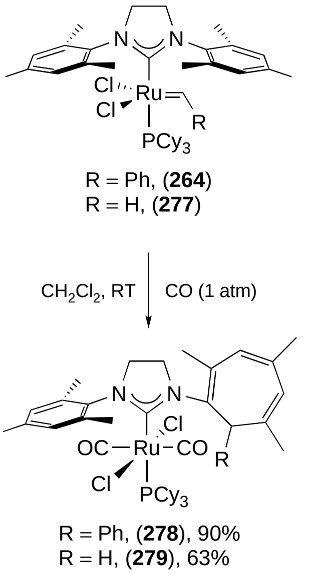
3.4 Insertion Reaction into the NHC Ligand

As previously presented, the ortho substituents on the aromatic rings of the NHC ligands can be involved in different activation processes. Keister, Diver, and coworkers reported an unprecedented carbene insertion into the mesityl group of the NHC.[206] In the presence of carbon monoxide, ruthenium carbenes such as second-generation Grubbs catalyst (**264**) gave a net insertion/ring expansion, namely, Buchner reaction, into one of the aromatic rings of the NHC ligand as illustrated in equation (48). Complexes (**278**) and (**279**) have been isolated in good to excellent yield with complete



Scheme 45

regioselectivity and their structures have been confirmed by X-ray crystallography. Alkylidene ruthenium catalysts are well known to efficiently promote alkene metathesis and only in special cases has cyclopropanation been observed.[9] The ability of the catalyst to perform cyclopropanation depends on both carbene electrophilicity and metal coordination environment. Metathesis catalysts usually dissociate a ligand (phosphine), however in presence of carbon monoxide saturated ruthenium carbene complexes were obtained and showed a different reactivity. The NHC ligand that is both robust and typically inert to reactions does act as a spectator. This unique reaction is completely regioselective.



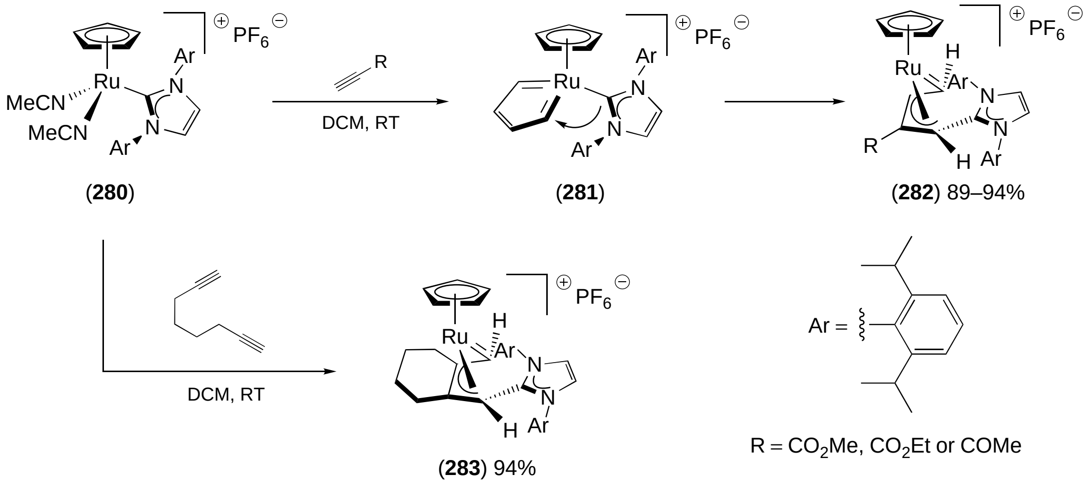
(48)

3.5 NHC Migration and Insertion

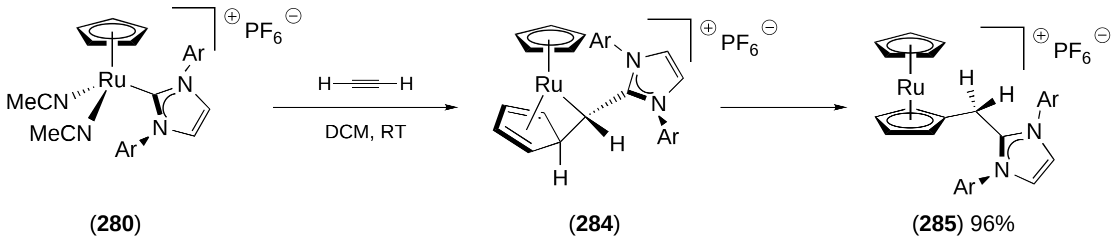
Recently, Kirchner reported a migratory insertion of an NHC into a ruthenium−carbon double bond,[207] in contrast to the well-established *innocent* character of this ligand type. Similar to tertiary phosphines,[208] NHCs can easily migrate from a formally Ru(IV) center of the highly electrophilic biscarbene intermediate (**281**), resulting from the reaction of (**280**) with terminal alkynes, onto the carbene carbon atom to quantitatively yield the allyl carbene complex (**282**) (Scheme 46). Treatment of (**280**) with one equivalent of 1,7-octadiene results in the rapid formation of complex (**283**).[209] These reactions occur via an electrophilic metallacyclopentatriene followed by migration of IPr onto the unsubstituted carbon atom of the intermediate with concomitant cleavage of the NHC−ruthenium bond.

When this reaction is performed in the presence of acetylene instead of substituted alkynes, air- and moisture-stable product (**285**) containing a substituted cyclopentenyl moiety was isolated in excellent yield (Scheme 47).[210] This outstanding reaction proceeds by cleavage of the Ru–NHC bond followed by migration of the NHC ligand to give the formal $[2 + 2 + 1]$ cyclotrimerization. According to calculations, the key step of this reaction involving the conversion of three C–C triple bonds into two C–C double bonds and one C–C triple bond is the facile insertion of an acetylene molecule into the Ru–NHC bond. The final transformation of (**284**) into imidazolium salt (**285**) occurs by a spontaneous 1,2-H shift. Interestingly, similar reactions have been carried out with phosphines,[211] without observation of the 1,2-H shift product, highlighting the singular behavior of NHC–TM complexes.

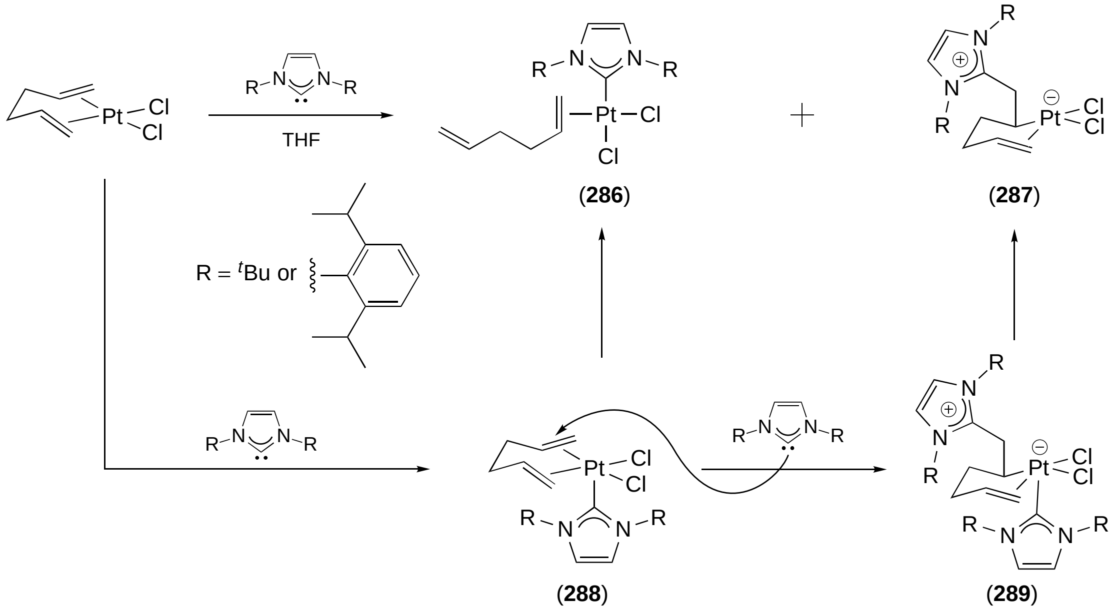
Another unusual behavior of NHC–TM complex was recently reported by Nolan *et al.* and involves the insertion of an NHC into a platinum−olefin bond.[212] In the course of preparation of new NHC-containing platinum complexes by reaction of equimolar amounts of [(1,5-hexadiene)$PtCl_2$] and free NHC, the substitution product (**286**) in which one coordinated double bond was substituted by an NHC was isolated in good yield (Scheme 48). A by-product was also



Scheme 46



Scheme 47



Scheme 48

observed, isolated in low yield, and unequivocally identified by X-ray crystallography as the NHC insertion product onto the olefin (**287**). The use of an excess of free NHC afforded (**287**) in moderate yield. To gain some insight into the reaction mechanism and explain the formation of (**287**), DFT calculations were performed. The proposed mechanistic pathway assumes, as the first step, the coordination of NHC on the metal center to give (**288**), which can either yield (**286**) or undergo intermolecular attack of a second free NHC to (**289**) and subsequently lead to the more stable product (**287**). It may be noted that the formation of (**288**) to (**287**) by intramolecular migration of the NHC was found not to be energetically favorable.

4 CONCLUSION AND OUTLOOK

The access of well-defined, isolable NHC ligands has permitted significant advances in numerous fields of organometallic and homogeneous catalysis. Moreover, it is now clear that NHCs, initially considered as *innocent* ligands able to provide stable TM complexes, are far from being innocent. Dissociation from metal coordination sphere and C–H activation of *N*-substituent are limited examples of the reactivity of coordinated NHCs. Despite this, the present review is not to be taken as an endpoint, but rather as a ‘‘snapshot’’ of this rapidly growing field. The present state of the art is only in its infancy. The ever-growing number of structurally different NHC ligands constitutes opportunities in yet undiscovered reactivity. Numerous catalytic transformations are still waiting for their ad hoc catalyst, and therefore we believe that rational design of well-defined and stable catalysts is essential. Hence, easy-to-carry-out synthetic routes together with a thorough understanding of reactivity are of fundamental importance. Tremendous progress has been made in the last few years, but there is room for improvement in the area of NHCs as ligands for TM complexes and catalysts. We are convinced that the NHCs have not ceased to surprise and amaze.
